$$(\mathbf{S}_{\mathscr{A}_{Y'_d}})^{d/c} = \tau_*^{(m-d)/c} \circ \left[\frac{d \cdot (\dim X + 1) - m}{c} \right], \tag{6.4}$$

where τ is the involution of the double covering.

Applying this result to a 4-fold Y of degree 10 one constructs a semiorthogonal decomposition $\mathbf{D}^b(\mathsf{coh}(Y)) = \langle \mathscr{A}_Y, \mathcal{O}_Y, \mathcal{U}_Y^\vee, \mathcal{O}_Y(1), \mathcal{U}_Y^\vee(1)\rangle$ with $\mathcal{U}_Y$ being the restriction of the tautological bundle from the Grassmannian $\mathsf{Gr}(2,5)$ and $\mathscr{A}_Y$ a Calabi–Yau category of dimension 2. Again, for some special Y one can check that $\mathscr{A}_Y$ is equivalent to the derived category of a K3 surface and so altogether we get another family of noncommutative K3 categories. Moreover, in this case one can also construct a hyperkähler fourfold from Y. One of the ways is to consider the Fano scheme of conics on Y. It was proved in [16] that it comes with a morphism to $\mathbb{P}^5$ with the image being a singular sextic hypersurface, and the Stein factorization of this map gives a genus zero fibration over the double covering of the sextic, known as a double EPW sextic. This is a hyperkähler variety, deformation equivalent to the second Hilbert square of a K3 surface.

Finally, there is yet another interesting example. Consider a hyperplane section Y of a 5-fold X, which is the zero locus of a global section of the vector bundle $\Lambda^2\mathcal{U}_3^\vee \oplus \Lambda^3(W/\mathcal{U}_3)$ on $\mathsf{Gr}(3,W)$ with W of dimension 7. This variety Y was found by O. Küchle in [22] (variety $c5$ in his table), and its Hodge diamond is as follows

$$\begin{array}{ccccccccc}
 & & & & 1 & & & & \\
 & & & 0 & & 0 & & & \\
 & & 0 & & 1 & & 0 & & \\
 & 0 & & 0 & & 0 & & 0 & \\
0 & & 1 & & 24 & & 1 & & 0 \\
 & 0 & & 0 & & 0 & & 0 & \\
 & & 0 & & 1 & & 0 & & \\
 & & & 0 & & 0 & & & \\
 & & & & 1 & & & &
\end{array}$$

Conjecture 6.5. *The 5-dimensional variety $X \subset \mathsf{Gr}(3,W)$ has a rectangular Lefschetz decomposition $\mathbf{D}^b(\mathsf{coh}(X)) = \langle \mathscr{B}, \mathscr{B}(1)\rangle$ with the category $\mathscr{B}$ generated by 6 exceptional objects. Consequently, its hyperplane section Y has a semiorthogonal decomposition $\mathbf{D}^b(\mathsf{coh}(Y)) = \langle \mathscr{A}_Y, \mathscr{B}\rangle$ with $\mathscr{A}_Y$ being a K3 type category.*

It would be very interesting to understand the geometry of this variety and to find out, whether there is a hyperkähler variety associated to it, analogous to the Fano scheme of lines on a cubic fourfold and the double EPW sextic associated to the 4-fold of degree 10. A natural candidate is the moduli space of twisted cubic curves.

Acknowledgements. In my work I was partially supported by RFFI grant NSh-2998.2014.1, the grant of the Simons foundation, and by AG Laboratory SU-HSE, RF government grant, ag.11.G34.31.0023. I am very grateful to A. Bondal and D. Orlov for their constant help and support. I would like to thank R. Abuaf, T. Bridgeland, T. Pantev and P. Sosna for comments on the preliminary version of this paper.

K3 surfaces in positive characteristic

Davesh Maulik

Abstract. We describe recent progress in the study of K3 surfaces in characteristic p, focusing on the Tate conjecture and moduli theory. We also discuss some geometric applications and open questions.

Mathematics Subject Classification (2010). Primary 14J28; Secondary 11G25.

Keywords. K3 surfaces, Tate conjecture, moduli spaces.

1. Introduction

K3 surfaces have long been a subject of active study in algebraic geometry, involving a combination of algebraic, arithmetic and complex-geometric perspectives. In the case of K3 surfaces over fields of characteristic $p > 0$, there has been a great deal of progress over the past few years in understanding certain basic questions. In this article, I survey some of these recent advances. In particular, I discuss various proofs of the Tate conjecture over finite fields in odd characteristic and global properties of the moduli space of polarized K3 surfaces, trying to give a sense of the different techniques at our disposal. In the last section, I discuss some geometric applications of this circle of ideas and some open questions.

2. Tate conjecture over finite fields

In this section, we discuss the Tate conjecture for K3 surfaces over finite fields. First, we recall the general statement for divisors on an arbitrary smooth projective variety. Given such a variety X, defined over a finite field $k = \mathbb{F}_q$ of characteristic p, and a prime $\ell \neq p$, the first Chern class in ℓ-adic cohomology defines a map

$$c_1^{\text{ét}} : \mathrm{Pic}(X) \otimes \mathbb{Q}_\ell \to H^2_{\text{ét}}(X, \mathbb{Q}_\ell(1))^{\mathrm{Gal}(\overline{k}/k)},$$

where $\mathrm{Pic}(X)$ denotes the Picard group of X, parametrizing line bundles, and the right-hand side denotes the Galois-invariant part of the (Tate-twisted) second étale cohomology group. The Tate conjecture for X predicts that this map is surjective. It can be viewed as a more difficult analog of the Lefschetz $(1,1)$ theorem for complex varieties, in that it gives a way of understanding the subspace of cohomology generated by divisor classes via linear-algebraic data. It remains completely open for most varieties; in the case of K3 surfaces, however, we have the following:

Proceedings of the International Congress of Mathematicians, Seoul, 2014

Theorem 2.1. *The Tate conjecture holds for K3 surfaces in odd characteristic.*

After a series of earlier results [4, 11, 31, 36, 43], the most general statement given here is due to Madapusi Pera [28], whose proof we discuss in the next section; his result applies not just for finite fields but all finitely generated fields in characteristic p. In this section, we will review a somewhat weaker approach, via work of Nygaard-Ogus [36] in the case of finite height and, in the remaining cases, via work of myself [31] (for primes larger than the polarization degree plus 4) and Charles [11] (for primes at least 5). We then close with some questions regarding the behavior of Picard groups in families of surfaces.

2.1. Earlier results. Before discussing more recent arguments, we mention two significant earlier results (among others)

In the case where the K3 surface admits the structure of an elliptic fibration, the Tate conjecture is equivalent to the statement that the Brauer group $H^2_{\text{ét}}(X, \mathbb{G}_m)$ is finite. In this form, the conjecture was proven in 1974 by Artin and Swinnerton-Dyer [4]. If the group is infinite, they produce twists of the elliptic fibration, trivialized by multisections of increasing degree; a beautiful intersection theory argument shows that eventually these twists must become isomorphic as abstract surfaces which leads to a contradiction. Since K3 surfaces whose Picard groups have rank at least 5 are automatically elliptically fibered, the Tate conjecture follows already in these cases.

A more general breakthrough came via Nygaard [35] and Nygaard-Ogus [36], who handle the case of finite height K3 surfaces. In order to explain this result, we first explain the definition of the height of a K3 surface. Given a K3 surface X, its formal Brauer group $\widehat{\mathrm{Br}}(X)$ of X, defined by Artin and Mazur [3], is a one-dimensional formal group scheme representing the functor

$$T \mapsto [\mathrm{Ker}(\mathrm{Br}(X \times T) \to \mathrm{Br}(X))]\,,$$

on local Artin k-algebras, where $\mathrm{Br}(X \times T)$ is the Brauer group of $X \times T$. The *height* of the K3 surface is simply the height of its formal Brauer group. When finite, it can take values between 1 and 10; otherwise, when $\widehat{\mathrm{Br}} = \widehat{\mathbb{G}_a}$, we say the K3 surface has infinite height or, equivalently, that the K3 surface is *supersingular*.

In [35] and [36], Nygaard and Ogus prove the Tate conjecture for finite height K3 surfaces in characteristic $p \geq 5$; these comprise an open, dense subset in the moduli space of K3 surfaces. Their argument uses the notion of canonical and quasi-canonical lifts of X over the ring of Witt vectors $W(k)$. These are distinguished lifts for which certain properties of X are preserved; in particular, both the cohomological Frobenius action as well as the entire Picard group of X extend to quasi-canonical lifts. Once this is shown, the authors use the Lefschetz $(1,1)$ theorem to construct the expected line bundles in characteristic zero and specialize them back to k.

2.2. Supersingular K3 surfaces. It remains to handle the case supersingular K3 surfaces.

In general, supersingular K3 surfaces exhibit behavior that cannot occur in characteristic zero. For instance, the Tate conjecture is equivalent to a conjecture of Artin which states that, after passage to $\overline{k}$, the geometric Picard rank of X is as large as possible, i.e. $\mathrm{rk}\,\mathrm{Pic}(X_{\overline{k}}) = 22 = b_2(X)$. As an example, if we take $p \equiv 3 \mod 4$, Tate [44] showed that the Fermat quartic

$$\{x^4 + y^4 + z^4 + w^4 = 0\} \subset \mathbb{P}^3_k$$

has geometric Picard rank 22. This phenomenon is quite striking when compared to characteristic zero, where Hodge theory tells us that $\mathrm{rk}\,\mathrm{Pic}(X) \leq 20$.

As another example, it was conjectured by several people that supersingular K3 surfaces are unirational, and can be seen explicitly in the above example. Again, this phenomenon is ruled out in characteristic zero, since the pullback of a non-vanishing two-form to a rational variety would remain non-vanishing while in characteristic p the map can (and must) be inseparable. Quite recently, Liedtke [26] has announced a proof of this conjecture.

Unfortunately, due to this unusual behavior, the strategy of quasi-canonical lifts does not apply for supersingular surfaces, since the Picard group cannot be lifted to characteristic zero. Instead, the approach of [11, 31] is to exploit another instance of strange supersingular behavior, first observed by Artin [2]: in a connected family of supersingular K3 surfaces, although the Picard group can jump under specialization, the rank of the Picard group must remain constant. This observation is significant because, over $\mathbb{C}$, such phenomena never occur. Indeed, by a result of Green ([47, 4.2]) and Oguiso [37], given a non-isotrivial family of K3 surfaces over a complex base B, the set of points on B where the Picard group jumps in rank is *dense* in the complex-analytic topology. The approach to showing the Tate conjecture in the supersingular case is to exploit the tension between these two behaviors to force the existence of extra cycles in supersingular families.

2.3. Automorphic forms. In order to to do this, we apply work of Borcherds [9, 10] on automorphic forms to find an arithmetic approach to the Green-Oguiso result. Let $\mathsf{M}_{2d,k}$ denote the moduli space of primitively polarized K3 surfaces over k of degree $2d$. Given a rank 2 lattice Λ with a distinguished basis vector v of self-intersection $2d$, the Noether-Lefschetz divisor D_Λ is the locus of polarized surfaces (X, L) with an inclusion of pairs $(\Lambda, v) \subset (\mathrm{Pic}(X), L)$ (this locus is non-empty for suitable lattices). Given such a lattice Λ, we can associate discrete invariants $(\mathrm{disc}(\Lambda), \delta)$ as follows. If we extend v to a basis $\langle v, w\rangle$, the congruence class $\delta \in H_d = \mathbb{Z}/2d$ of the pairing $\langle v, w\rangle$ is well-defined up to a sign.

Using an explicit construction of automorphic forms, Borcherds shows that the generating function (with coefficients in $\mathrm{Pic}(\mathsf{M}_{2d}) \otimes \mathbb{Z}[H_d]$)

$$\phi(q) = -[\lambda]q^0 \otimes e_0 + \sum_{\Lambda} [D_\Lambda] q^{-\mathrm{disc}(\Lambda)/2d} \otimes e_\delta \in \mathrm{Pic}(\mathsf{M}_{2d})[[q]] \otimes \mathbb{Z}[H_d]$$

is a holomorphic modular form of weight $21/2$. Here, the constant term is the Hodge bundle $\lambda = c_1(\pi_*(\Omega^2_\pi))$ associated to the universal family of K3 surfaces $\pi : \mathcal{X} \to \mathsf{M}_{2d,k}$. This result has already found many applications in the enumerative geometry of K3 surfaces over the complex numbers (see [19, 32]).

Although Borcherds' work is in characteristic zero, we can still apply it to characteristic p by spreading out and intersecting these divisors with a proper curve in the locus of supersingular surfaces. In order to find proper curves in the supersingular locus, we can either study degenerations of K3 surfaces (which leads to the constraint on the prime in [31]) or instead use degenerations of abelian varieties, as in [11]. The result is a modular form whose coefficients encode the Noether-Lefschetz degrees of our family. One also needs to ensure this modular form isn't zero; by looking at the constant term, this follows from positivity properties of the Hodge bundle (see Corollary 3.3 in the next section). Once the constant term is nonzero, an elementary estimate shows that the modular coefficients grow very fast and we can deduce that Noether-Lefschetz degrees for sufficiently large discriminant are non-vanishing. This shows the following:

Proposition 2.2. *Let B be a proper curve and let $\mathcal{X} \to B$ denote a non-isotrivial family of K3 surfaces of degree $2d$ not divisible by p. For any suitable lattice Λ with $-\mathrm{disc}(\Lambda) \gg 0$, there exists $b \in B$ with $\mathrm{Pic}(\mathcal{X}_b) \supseteq \Lambda$.*

With this proposition in hand (and assuming we have proper curves to work with), the Tate conjecture follows easily. Indeed, if we consider lattices $\Lambda_k = \begin{pmatrix} 2d & k \\ k & 0 \end{pmatrix}$, these have arbitrarily large discriminant and correspond to elliptic fibrations. Therefore, the Tate conjecture holds for at least one fiber on any proper family by the result of Artin-Swinnerton-Dyer. As the Picard rank is constant in families, it must hold for every fiber in the family by Artin's observation.

One can push these techniques further. Using a more intricate analysis, Charles is able to prove the Tate conjecture for codimension two cycles on cubic fourfolds as well as divisors on certain reductions of higher-dimensional holomorphic symplectic varieties.

2.4. Noether-Lefschetz behavior. Over the complex numbers, the theorem of Green and Oguiso gives us more detailed information about how Picard ranks vary in a family of K3 surfaces; it says that these ranks jump when compared to the generic geometric rank on a dense set of points in the Euclidean topology (although note that by [33] p-adic density statements no longer hold). If we have a family over a more general one-dimensional base, we can at least ask for a Zariski dense (i.e. infinite) set of points in the jumping locus.

In what follows, let B denote either a smooth irreducible curve over an algebraically closed field k or let $B = \mathrm{Spec}\, \mathcal{O}_K[1/N]$ for a number field K; in either case, let $\overline{\eta}$ denote a geometric point lying over the generic point of B.

Question 2.3. *Let $\pi : \mathcal{X} \to B$ be a smooth non-isotrivial family of polarized K3 surfaces over B. Are there infinitely many closed points $b \in B$ such that $\mathrm{rk}\,\mathrm{Pic}(\mathcal{X}_b) > \mathrm{rk}\,\mathrm{Pic}(\mathcal{X}_{\overline{\eta}})$?*

As already stated, the answer is yes in equicharacteristic zero. Furthermore, since we have families of supersingular K3 surfaces (which have constant Picard rank 22), we know the answer is no in equicharacteristic p. Supersingular families are not the only counterexample; another example is the family of Kummer surfaces associated to the product of a fixed supersingular elliptic curve and a varying family of elliptic curves.

However, it seems reasonable to expect that this question has a positive answer if we put some further constraints on the family, e.g. that the generic fiber is ordinary or that the family does not meet the supersingular locus at all (even after passing to a partial compactification of B). In the mixed characteristic setting, it is expected that the answer is always yes; at least for certain Kummer surfaces, there is unpublished work of Charles along these lines.

Motivated by the last section, a more careful analysis of the modularity of Noether-Lefschetz degrees should help here. As before, the rapid growth of the coefficients of modular forms will typically produce infinitely many intersection points (although not always). Indeed, in the equicharacteristic p setting, one can often prove the answer to this question is yes for certain families using precisely this argument. In the arithmetic setting, there are conjectures of Kudla and collaborators (see [20] for an overview) predicting modular behavior for arithmetic Noether-Lefschetz degrees, in the sense of Arakelov theory; if provable, it seems natural to apply these modularity conjectures for Question 2.3.

3. Moduli of K3 surfaces

In this section, we discuss moduli spaces of polarized K3 surfaces in mixed and finite characteristic, following the work of Madapusi Pera [27, 28]. We discuss extensions of the period map, defined using the classical Kuga-Satake construction, and its structure in odd characteristic. From this, we can deduce many useful geometric corollaries.

3.1. Constructions in characteristic zero. Given an even positive integer $2d$, let M_{2d} denote the moduli space of K3 surfaces over $\mathbb{Z}[1/2]$, equipped with a primitive polarization of degree $2d$. It is a Deligne-Mumford stack, smooth over $\mathbb{Z}[1/2d]$ [13] (and has mild singularities at other odd primes).

Over $\mathbb{C}$, many global properties of the moduli space can be deduced via Hodge theory and the global Torelli theorem [40]. We recall briefly how this goes. Let U be the two-dimensional hyperbolic lattice, and let

$$M = U^{\oplus 3} \oplus E_8(-1)^{\oplus 2}$$

denote the abstract K3 lattice. If we write (e, f) for the standard basis of the first copy of U, then we set

$$L_{2d} = \langle e + df \rangle^{\perp} \subset M,$$

i.e. we take the orthogonal complement of a fixed primitive vector of degree $2d$.

Let $G = \mathrm{SO}(L_{2d})$ and $G' = \mathrm{CSpin}(L_{2d})$ denote the orthogonal and spin groups associated to L_{2d} and consider the period domain

$$\Omega_{2d} = \{\omega \in \mathbb{P}(L_{2d,\mathbb{C}}) | \langle \omega, \omega \rangle = 0, \langle \omega, \overline{\omega} \rangle > 0\} = \mathrm{SO}(2, 19)/\mathrm{SO}(2) \times \mathrm{SO}(19).$$

Let $\Gamma_{2d} \subset G(\mathbb{Z})$ be the subgroup which acts trivially on the discriminant group $L_{2d}^{\vee}/L_{2d}$. The analytic quotient $[\Omega_{2d}/\Gamma_{2d}]$ is algebraic via [5] and can be identified with the Shimura variety of orthogonal type $\mathrm{Sh}_{2d,\mathbb{C}} := \mathrm{Sh}(G_{\mathbb{Q}}, \Omega)_{\mathbb{C}}$.

Given a polarized complex K3 surface (X, L) and an isomorphism of its primitive cohomology with L_{2d}, the line $H^{2,0}(X)$ defines a point in Ω_{2d}. This map behaves well in families; after forgetting the marking, we obtain the period map

$$\mathsf{P}_{\mathbb{C}} : \widetilde{\mathsf{M}}_{2d,\mathbb{C}} \to \mathrm{Sh}_{2d,\mathbb{C}},$$

where $\widetilde{\mathsf{M}}_{2d}$ is an étale double cover corresponding to a choice of spin structure. It follows from the Torelli theorem that the period map is an open immersion, although not surjective. However, we can enlarge our moduli space to include pairs (X, L) where L is a big and nef line bundle on X (so-called quasi-polarized K3 surfaces). The period map extends to this larger space $\mathsf{M}^{\mathrm{qp}}_{2d,\mathbb{C}}$, and becomes surjective and étale (although not quite an isomorphism since $\mathsf{M}^{\mathrm{qp}}_{2d}$ is non-separated).

It follows from [1, 42] that this morphism descends to $\mathbb{Q}$: $\mathsf{P}_{\mathbb{Q}} : \widetilde{\mathsf{M}}_{2d,\mathbb{Q}} \to \mathrm{Sh}_{2d,\mathbb{Q}}$. After passing to a further finite étale cover, the analogous story holds with the Shimura variety of spin type $\mathrm{Sh}'_{2d} := \mathrm{Sh}(G'_{\mathbb{Q}}, \Omega)$.

The second classical idea I want to mention is the Kuga-Satake construction [21] which associates an abelian variety to a polarized K3 surface. Its definition is purely transcendental: given any polarized integral weight two Hodge structure V of K3 type, the Kuga-Satake construction defines a polarized weight one Hodge structure on the Clifford algebra $W =$

$\mathrm{Cl}(V)$. When V is the primitive cohomology of a polarized K3 surface (X, L), the abelian variety corresponding to W is its Kuga-Satake variety $\mathsf{KS}(X, L)$. As a consequence of its definition, we have an embedding of weight 0 Hodge structures

$$P^2(X, \mathbb{Z})(1) \hookrightarrow \mathrm{End}(H^1(\mathsf{KS}(X, L), \mathbb{Z})) \tag{*}$$

where P^2 is the primitive cohomology, which can be used to recover information about (X, L) from $\mathsf{KS}(X, L)$.

This construction can be rephrased via the Shimura variety Sh'_{2d} as follows. The spin representation defines a homomorphism from G' to the symplectic group $\mathrm{CSp}(\mathrm{Cl}(L_{2d}))$ associated to the Kuga-Satake variety. This map induces a morphism of Shimura varieties, and the Kuga-Satake construction comes from the composition

$$\widetilde{\mathsf{M}}_{2d,\mathbb{C}} \to \mathrm{Sh}'_{2d,\mathbb{C}} \to \mathcal{A}_{g,\mathbb{C}},$$

where the last space is the moduli space of principally polarized abelian varieties. One remarkable feature of this Shimura-theoretic approach is that the transcendental Kuga-Satake construction descends to $\mathbb{Q}$.

3.2. Extension to mixed characteristic. As far as I know, it was Deligne [12] who first applied a pointwise extension of the Kuga-Satake construction to characteristic p in his proof of the Weil conjectures for K3 surfaces.

In [17] and [27], Kisin and Madapusi Pera prove the following

Theorem 3.1. *There exists a regular integral canonical model* Sh_{2d} *over* $\mathbb{Z}[1/2]$ *for the Shimura varieties* $\mathrm{Sh}_{2d,\mathbb{Q}}$. *A similar result holds for* $\mathrm{Sh}'_{2d,\mathbb{Q}}$.

We briefly explain this terminology, referring the reader to the references for a precise statement. These integral canonical models are defined by an extension property analogous to Néron models for abelian schemes. For each prime p (after passage to infinite level) we require them to satisfy an extension property from certain regular test schemes over $\mathbb{Z}_p$. When p doesn't divide $2d$, Kisin constructs the integral model for Sh'_{2d} via taking the normalization of the closure inside a moduli space of abelian varieties with level structure, defined over $\mathrm{Spec}\,\mathbb{Z}[1/2d]$. To weaken the constraint on the prime, Madapusi Pera embeds Sh_{2d} inside a larger orthogonal type Shimura variety where Kisin's approach applies. The difficulty in both cases is proving regularity; this requires delicate deformation theory arguments.

Using the extension property, one can show that the period map defined on $\widetilde{\mathsf{M}}_{2d,\mathbb{Q}}$ can be extended over all primes, so we have the mixed-characteristic period map:

$$\mathsf{P} : \widetilde{\mathsf{M}}_{2d} \to \mathsf{Sh}_{2d}.$$

Since our integral models are defined via $\mathcal{A}_g$, we can think of the period map as being defined via its compatibility with the Kuga-Satake construction (and in particular this gives a definition of Kuga-Satake varieties in mixed characteristic). This approach to the extension of the period map and Kuga-Satake constructions was first pursued by Vasiu [46] and Rizov [42] with stronger constraints on the prime.

The key result is the following ([28], Theorem 4.2). For primes not dividing $2d$, the result was shown in [31].

Theorem 3.2. *The period map* P *is étale.*

For primes not dividing $2d$, this result was shown in [31] and [42] as well. The key step in all approaches is to extend the inclusion (*) to de Rham cohomology in characteristic p. Indeed, since deformations of K3 surfaces are detected by the Kodaira-Spencer map, this controls the differential of the period map. Since the period map is defined by extending from characteristic zero, this requires an *integral* comparison theorem between cohomology in characteristic p and characteristic 0 (Fontaine-Messing [14] in [31], Bloch-Kato [6] in [28]).

3.3. Geometric consequences. Theorem 3.2 has immediate geometric consequences:

Corollary 3.3.

(i) *For every $p > 2$, the moduli space $\mathsf{M}_{2d,\mathbb{F}_p}$ is a quasi-projective Deligne-Mumford stack over $\mathbb{F}_p$.*

(ii) *The Hodge bundle $\pi_*(\Omega^2_\pi)$ is an ample line bundle.*

(iii) *If p^2 does not divide d then $\mathsf{M}_{2d,\mathbb{F}_p}$ is geometrically irreducible.*

The last statement uses the existence of toroidal compactifications [29] in mixed characteristic, mimicking the Deligne-Mumford argument for the moduli space of curves. Madapusi Pera has further recent work which should weaken the constraint on the prime. I find the ampleness of the Hodge bundle especially interesting, since I know of no geometric approach to this question. Recent work of Patakfalvi [38] has provided semi-positivity statements in greater generality and it would be interesting to see if they apply here.

Lastly, one can ask for surjectivity of the period morphism, as in characteristic zero. Here, the results are currently limited. If the degree of the polarization is sufficiently small, we have the following results, from [30, 31].

Assuming $p > 18d+4$, in [31], I show that any one-parameter degeneration of polarized K3 surfaces can be replaced with a K-trivial central fiber with at worst normal-crossings and rational singularities, following a combinatorial classification due to Kulikov, Pinkham, and Persson [22, 39] over $\mathbb{C}$. In [30], Matsumoto uses this classification to prove a criterion for good reduction, analogous to the Néron-Ogg-Shafarevich condition for abelian schemes. The combination yields the following:

Corollary 3.4. *Assume $p > 18d + 4$. After extending to quasipolarized K3 surfaces, the period map*

$$\mathsf{P} : \widetilde{\mathsf{M}}^{\mathrm{qp}}_{2d,\overline{\mathbb{F}}_p} \to \mathsf{Sh}_{2d,\overline{\mathbb{F}}_p}$$

is surjective.

The condition on the prime is used to find semistable models for degenerations, so that we can run the semistable minimal model program using work of Kawamata [16]. Better results on semistable reduction for surfaces in characteristic p would allow us to remove this bound.

3.4. Application to Tate. Finally, we sketch briefly how the mixed-characteristic period map helps approach the Tate conjecture, independent of the arguments of the last section. Given a polarized K3 surface (X, L), the extended period map and its composition to $\mathcal{A}_g$ again gives us an abelian variety $A = \mathsf{KS}(X, L)$. The arguments above (in particular the proof of the étale property) show that we have ℓ-adic and crystalline versions of (*). Let $L_\ell(A) \subset \mathrm{End}(H^1(A, \mathbb{Q}_\ell)$ denote the image of the ℓ-adic version of (*) and $L_{\mathrm{cris}}(A)$ the

analogous crystalline subspace. We can define a subspace $\mathrm{LEnd}(A)$ of special endomorphisms of A to be those whose cycle classes (for all realizations) lie in $L_\ell(A)$ and $L_{\mathrm{cris}}(A)$. The Tate conjecture can then be rephrased as an isomorphism

$$\mathrm{LEnd}(A) \otimes \mathbb{Q}_\ell \to L_\ell(A)^{\mathrm{Gal}(\overline{k}/k)}.$$

After passing to a larger spin-type Shimura variety (leaving the world of K3 surfaces), one can assume the left-hand side is nonzero. Let $I \subset \mathrm{Aut}(A)_{\mathbb{Q}}$ be the largest algebraic subgroup whose realizations are contained in the image of CSpin. For a particular choice of ℓ, a result of Kisin [18] shows that this is a nonzero map between irreducible representations of I. Since the Tate conjecture is independent of ℓ, the result follows.

4. Applications

We close by explaining a pair of geometric applications.

4.1. Finiteness of K3 surfaces. We first explain a consequence of the Tate conjecture, shown in joint work with Lieblich and Snowden [25]:

Theorem 4.1. *Fix a finite field $k = \mathbb{F}_q$ of characteristic $p \geq 5$.*

(i) *The Tate conjecture holds for K3 surfaces over k implies that there are finitely many isomorphism classes of K3 surfaces defined over k that satisfy the Tate conjecture.*

(ii) *Conversely, the Tate conjecture for K3 surfaces over finite extensions of k is implied the finiteness of the set of isomorphism classes of K3 surfaces over extensions of k.*

As a consequence of the first implication and the Tate conjecture, we see that there are finitely many K3 surfaces over any finite field of characteristic ≥ 5. Even though the second direction is redundant now, I have stated it here, since the technique is quite different from the approach mentioned eariler.

For the first implication, notice that finiteness of the set of isomorphism classes does not follow from the existence of the moduli spaces of finite type, since we need to fix an auxiliary polarization and consider $\mathsf{M}_{2d,k}$ for all $d \geq 1$. A similar result for abelian varieties was shown by Zarhin (see [48]). The argument proceeds as follows. Using the Tate conjecture (in both the ℓ-adic and crystalline incarnations), for any K3 surface X defined over k, we can control $\mathrm{Pic}(X_{\overline{k}}) \otimes \mathbb{Z}_\ell$ and $\mathrm{Pic}(X_{\overline{k}}) \otimes \mathbb{Z}_p$ in terms of the action of geometric Frobenius on étale/crystalline cohomology. Since k is fixed, there are only finitely many possibilities for the eigenvalues of this action and thus we can control the discriminant of the Picard group. This allows us to find a polarization on X of degree bounded by a constant $C(k)$. One also needs to bound the number of non-isomorphic twists, but this follows from structure theory of $\mathrm{Aut}(X_{\overline{k}})$ due to Totaro [45].

In the other direction, the idea is to mimic the argument of Artin and Swinnerton-Dyer discussed earlier. Following [4], instead of considering twists of the elliptic structure, one can take Brauer classes and consider moduli spaces of twisted sheaves associated to these classes - for the right choice of discrete invariants, these will be twisted K3 surfaces. If the Brauer group were infinite, using period-index results of Lieblich [24] and the finiteness assumption, one can create an infinite sequence of (non-isomorphic) derived equivalent twisted

K3 surfaces over k. One can further lift this sequence (and the derived equivalences) to $\mathbb{C}$ which violates work of Huybrechts and Stellari [15].

While no longer strictly necessary, I think it is interesting to ask the following:

Question 4.2. *Is there an argument for finiteness without assuming the Tate conjecture?*

A positive answer to this question would be quite interesting; all the approaches to the Tate conjecture discussed above (including the work of Nygaard and Ogus) require crystalline techniques and global properties of the moduli space, while this approach is ℓ-adic in nature (although still technical in a different way).

4.2. Construction of rational curves. In this section, we mention briefly very interesting results of Bogomolov-Hassett-Tschinkel [7] and Li-Liedtke [23] on using the Tate conjecture to construct rational curves on K3 surfaces in characteristic zero.

The starting point is the following conjecture:

Conjecture 4.3. *Any K3 surface X over an algebraically closed field contains infinitely many integral rational curves.*

Over characteristic zero (and for non-supersingular surfaces in characteristic p), rational curves are necessarily isolated. The naive reason to expect this conjecture is a rough dimension count for any sufficiently ample linear system. One can make a stronger conjecture, asking for infinitely many rational curves contained in the linear systems $|nL|$ where $n \geq 1$ and L is a fixed polarization.

The first result along these lines is an old theorem of Bogomolov and Mumford [34] who prove the conjecture holds for a very general K3 surface, i.e. on the complement of a countable union of subvarieties of the moduli space. Their proof proceeds by writing reducible genus 0 curves C on Kummer surfaces X of increasing degree and proving the pair (X, C) can be deformed so that C is irreducible. By work of Bogomolov-Tschinkel [8], the conjecture also holds for elliptic K3 surfaces or surfaces with infinite automorphism group. Most recently, we have the following theorem [7, 23]:

Theorem 4.4. *In characteristic $\neq 2$, there are infinitely many integral rational curves on a K3 surface X with odd geometric Picard rank.*

We restrict to the characteristic zero case; the general case is similar. The strategy of the argument, first pursued in [7], is to execute a mixed-characteristic version of the Bogomolov-Mumford argument. That is, after reducing to the case of $\overline{\mathbb{Q}}$, one can spread X over the ring of integers R of a number field. Using the Tate conjecture (in fact, via a density argument, the finite height case suffices), it follows that the geometric Picard rank of specializations $X_{\overline{s}}$ is even and in particular larger than the generic Picard rank. This fact allows us to produce rational curves of increasing degree, contained in different specializations. In [23], the authors show that, after adding additional rational curve components, these curves can be lifted to characteristic zero. By taking appropriate irreducible components, they produce integral rational curves on X of ever-increasing degree.

The only situation not covered by this theorem and the Bogomolov-Tschinkel result are K3 surfaces with Picard lattices of rank 2 and 4. For example, the Picard lattice $\begin{pmatrix} -2 & 3 \\ 3 & -2 \end{pmatrix}$ is a simple example where we do not know how to produce enough rational curves in general. In all such cases, if we had a positive answer to Question 2.3, then the specialization strategy would apply here as well.

Acknowledgements. The author is partially supported by NSF Grant DMS-1159416. Most of the material in this note has been learned through conversation with François Charles, Brendan Hassett, Daniel Huybrechts, Max Lieblich, Christian Liedtke, Keerthi Madapusi Pera, and Andrew Snowden. I am grateful to all of them for these extremely useful discussions.

The dimension of jet schemes of singular varieties

Mircea Mustaţă

Abstract. Given a scheme X over k, a generalized jet scheme parametrizes maps $\operatorname{Spec} A \to X$, where A is a finite-dimensional, local algebra over k. We give an overview of known results concerning the dimensions of these schemes for $A = k[t]/(t^m)$, when they are related to invariants of singularities in birational geometry. We end with a discussion of more general jet schemes.

Mathematics Subject Classification (2010). Primary 14E18; Secondary 14B05.

Keywords. Jet scheme, log canonical threshold, minimal log discrepancy.

1. Introduction

Given a scheme X (say, of finite type over an algebraically closed field k), a tangent vector to X can be identified with a morphism $\operatorname{Spec} k[t]/(t^2) \to X$. The tangent vectors to X are the closed points of the first jet scheme $J_1(X)$ of X. More generally, for every $m \geq 1$ one can define a scheme of finite type $J_m(X)$ whose closed points parametrize all morphisms $\operatorname{Spec} k[t]/(t^{m+1}) \to X$. Explicitly, if X is defined in some affine space $\mathbf{A}^N$ by polynomials $f_1, \ldots, f_r$, then as a set $J_m(X)$ is identified to the set of solutions of $f_1, \ldots, f_r$ in $k[t]/(t^{m+1})$. Truncating induces natural maps $J_p(X) \to J_q(X)$ for every $p > q$. When X is a smooth, n-dimensional variety, then every such projection is locally trivial in the Zariski topology, with fiber $\mathbf{A}^{(p-q)n}$. In particular, $J_m(X)$ is a smooth variety of dimension $(m+1)n$. However, when X is singular, the jet schemes $J_m(X)$ have a more complicated behavior that reflects in a subtle way the singularities of X.

In fact, instead of the algebras $k[t]/(t^{m+1})$ we can consider an arbitrary local, finite k-algebra A. The morphisms $\operatorname{Spec}(A) \to X$ are parametrized by a generalized jet scheme that we denote $J_A(X)$. For example, if

$$A = k[t_1, \ldots, t_r]/(t_1^{m_1+1}, \ldots, t_r^{m_r+1}),$$

then $J_A(X)$ is isomorphic to the r-iterated jet scheme $J_{m_1}(J_{m_2}(\ldots J_{m_r}(X)))$. The construction and the formal properties of these more general jet schemes are very similar to those of the usual ones. We give an overview of the construction and of the basic properties of the generalized jet schemes in §2. By taking suitable projective limits, one can then define $J_A(X)$ when A is a local, complete k-algebra, with residue field k. We describe this construction in §3. The much-studied case is that of $A = k[\![t]\!]$, when $J_A(X)$ is known as the scheme of arcs of X.

Information on the schemes $J_m(X)$ is provided by the change of variable formula in motivic integration, see [8]. More precisely, if X is embedded in a smooth variety Y, then

Proceedings of the International Congress of Mathematicians, Seoul, 2014

one can use a log resolution of the pair (Y, X) to compute, for example, the dimensions of the schemes $J_m(X)$ in terms of the data of the resolution. In this way one can relate the behavior of these dimensions to some of the invariants of the pair (Y, X) that appear in birational geometry. We describe this story in §4.

One can ask questions with a similar flavor about the dimensions of the generalized jet schemes $J_A(X)$, but very little is known in this direction. We propose in §5 some invariants defined in terms of the asymptotic behavior of the dimensions of $J_A(X)$, when A varies over certain sequences of algebras of embedding dimension 2. We also discuss the irreducibility of iterated jet schemes for locally complete intersection varieties.

2. Generalized jet schemes

Let k be a field of arbitrary characteristic. All schemes we consider are schemes over k. Let LFA/k be the category whose objects are local finite k-algebras, with residue field k, with the maps being local homomorphisms of k-algebras. Given a scheme X and $A \in \mathrm{LFA}/k$, the scheme of A-jets of X is a scheme $J_A(X)$ that satisfies the following universal property: for every scheme Y, there is a functorial bijection

$$\mathrm{Hom}_{\mathrm{Sch}/k}(Y, J_A(X)) \simeq \mathrm{Hom}_{\mathrm{Sch}/k}(Y \times \mathrm{Spec}\, A, X). \tag{2.1}$$

Standard arguments imply that it is enough to have a functorial bijection as in (2.1) when Y is an affine scheme. In particular, by taking $Y = \mathrm{Spec}\, k$, we see that the set of k-valued points of $J_A(X)$ is in bijection with the set of A-*jets* of X, that is, A-valued points of X. Note that if $A = k$, then $J_A(X) = X$.

Before discussing existence, we make some general remarks. Suppose that $\phi\colon A \to B$ is a homomorphism in LFA/k and that $J_A(X)$ and $J_B(X)$ exist. We have a functorial transformation

$$\mathrm{Hom}_{\mathrm{Sch}/k}(Y \times \mathrm{Spec}\, A, X) \to \mathrm{Hom}_{\mathrm{Sch}/k}(Y \times \mathrm{Spec}\, B, X)$$

given by composition with $Y \times \mathrm{Spec}\, B \to Y \times \mathrm{Spec}\, A$. This is induced via the isomorphism (2.1) by a unique scheme morphism $\pi^X_{B/A}\colon J_A(X) \to J_B(X)$. In particular, if $A \in \mathrm{LFA}/k$, then the morphism to the residue field $A \to k$ induces $\pi^X_A = \pi^X_{A/k}\colon J_A(X) \to X$. Similarly, the structure morphism $k \to A$ induces a section $s^X_A\colon X \to J_A(X)$ of π^X_A. Given two morphisms $A \to B$ and $B \to C$ in LFA/k, if $J_A(X)$, $J_B(X)$, and $J_C(X)$ exist, then it is easy to see that $\pi^X_{C/B} \circ \pi^X_{B/A} = \pi^X_{C/A}$. When the scheme X is clear from the context, we simply write $\pi_{B/A}$, π_A, and s_A instead of $\pi^X_{B/A}$, π^X_A, and s^X_A.

When $A = k[t]/(t^{m+1})$, the A-jets are called m-jets and the corresponding scheme is denoted $J_m(X)$, the m^{th} *jet scheme* of X. It is not hard to deduce from the universal property that $J_1(X)$ is isomorphic as a scheme over X with the total tangent space $\mathcal{S}pec(\mathrm{Sym}(\Omega_{X/k}))$. We now sketch the proof of the existence of $J_A(X)$. The argument is the same as in the case of the usual jet schemes, hence we refer the reader to [12, Section 2] for details.

Consider first the case when $X = \mathrm{Spec}\, S$ is affine and consider a presentation

$$S \simeq k[x_1, \ldots, x_N]/(f_1, \ldots, f_r).$$

Let us fix a basis $(e_i)_{1\leq i\leq m}$ for A. We can thus write

$$e_i \cdot e_j = \sum_{\ell=1}^{m} c_{i,j,\ell} e_\ell. \tag{2.2}$$

We consider an affine scheme $Y = \operatorname{Spec} R$. Giving a morphism $Y \times \operatorname{Spec} A \to X$ is equivalent to giving a ring homomorphism

$$\phi\colon k[x_1, \ldots, x_N]/(f_1, \ldots, f_r) \to R \otimes_k A. \tag{2.3}$$

This is uniquely determined by $\phi(x_j)$, for $1 \leq j \leq N$, which can be written as

$$\phi(x_j) = \sum_{i=1}^{m} a_{i,j} \otimes e_i, \text{ with } a_{i,j} \in R \text{ for } 1 \leq i \leq m,\ 1 \leq j \leq N.$$

Furthermore, for any such choice of $\phi(x_j)$, we get a k-algebra homomorphism

$$\widetilde{\phi}\colon k[x_1, \ldots, x_N] \to R \otimes_k A$$

and this induces a k-algebra homomorphism (2.3) if and only if $\widetilde{\phi}(f_\alpha) = 0$ for $1 \leq \alpha \leq r$. On the other hand, the relations (2.2) imply that for every α, we can find polynomials $P_\alpha^{(i)}$ in $a_{j,\ell}$, with coefficients in k (these coefficients in turn are polynomials in the structure constants $c_{i,j,\ell}$) such that for $\widetilde{\phi}$ as above, we have

$$\widetilde{\phi}(f_\alpha) = \sum_{i=1}^{m} P_\alpha^{(i)}(a_{1,1}, \ldots, a_{m,N}) \otimes e_i.$$

This shows that $J_A(X)$ is cut out in $\mathbf{A}^{mN}$ by the equations $P_\alpha^{(i)}$ for $1 \leq \alpha \leq r$ and $1 \leq i \leq m$.

The above argument shows that $J_A(X)$ exists whenever X is affine. It is then easy to check that if X is any scheme such that $J_A(X)$ exists, then for every open subset U of X, the scheme $J_A(U)$ exists and it is isomorphic to $(\pi_A^X)^{-1}(U)$. Given now an arbitrary scheme X, consider an affine open cover $X = \cup_i U_i$. Note that $J_A(U_i)$ exists for every i. Moreover, for every i and j, the schemes $(\pi_A^{U_i})^{-1}(U_i \cap U_j)$ and $(\pi_A^{U_j})^{-1}(U_i \cap U_j)$ are canonically isomorphic, being isomorphic to $J_A(U_i \cap U_j)$. We can thus glue the schemes $J_A(U_i)$ along these open subsets and it is then straightforward to check that the resulting scheme satisfies the universal property of $J_A(X)$. We collect in the next proposition the conclusion of the above discussion.

Proposition 2.1. *For every $A \in \mathrm{LFA}/k$ and every scheme X, the scheme $J_A(X)$ of A-jets of X exists. Moreover, the following hold:*

i) *If X is of finite type over k, then $J_A(X)$ is of finite type over k.*

ii) *The canonical projection $\pi_A\colon J_A(X) \to X$ is affine.*

iii) *If X is an affine subscheme of $\mathbf{A}^N$ defined by r equations and $\dim_k(A) = m$, then $J_A(X)$ is defined in $J_A(\mathbf{A}^N) \simeq \mathbf{A}^{Nm}$ by rm equations. More generally, if $A \to A'$ is a surjective homomorphism in LFA/k, then*

$$J_A(X) \hookrightarrow (\pi_{A'/A}^{\mathbf{A}^N})^{-1}(J_{A'}(X))$$

is cut out by $r \cdot (\dim_k(A) - \dim_k(A'))$ equations.

In what follows we discuss some basic properties of generalized jet schemes. It is clear that if $f\colon X \to Z$ is a morphism and $A \in \mathrm{LFA}/k$, we have a unique morphism $J_A(f)\colon J_A(X) \to J_A(Z)$ such that the bijection (2.1) is functorial also in X. Therefore taking X to $J_A(X)$ gives a functor, such that if $A \to B$ is a morphism of finite k-algebras, then $\pi_{B/A}$ is a natural transformation.

Example 2.2. Iterated jet schemes can be described as schemes of A-jets. Indeed, given $m_1, \ldots, m_r \in \mathbf{Z}_{\geq 0}$, if we take $A = k[t_1, \ldots, t_r]/(t_1^{m_1+1}, \ldots, t_r^{m_r+1})$, then it follows from the universal property that for every scheme X, we have a canonical isomorphism of schemes over X

$$J_A(X) \simeq J_{m_1}(J_{m_2}(\ldots J_{m_r}(X))).$$

Remark 2.3. It follows from the explicit description of the scheme of A-jets of an affine scheme X that if $\iota\colon Z \hookrightarrow X$ is a closed immersion, then for every $A \in \mathrm{LFA}/k$, the induced morphism $J_A(\iota)$ is a closed immersion.

Remark 2.4. If X is any scheme over k and K/k is a field extension, for every $A \in \mathrm{LFA}/k$ we have $A \otimes_k K \in \mathrm{LFA}/K$ and there is a canonical isomorphism

$$J_{A\otimes_k K}(X \times_{\operatorname{Spec} k} \operatorname{Spec} K) \simeq J_A(X) \times_{\operatorname{Spec} k} \operatorname{Spec} K.$$

The assertion follows easily from the isomorphism (2.1).

The following proposition describing the behavior of generalized jet schemes with respect to étale morphisms is an immediate consequence of (2.1) and of the fact that étale morphisms are formally étale.

Proposition 2.5. *If $f\colon X \to Y$ is an étale morphism of schemes of finite type over k, then for every $A \in \mathrm{LFA}/k$ we have a Cartezian diagram*

$$\begin{array}{ccc} J_A(X) & \xrightarrow{J_A(f)} & J_A(Y) \\ {\scriptstyle \pi_A^X}\downarrow & & \downarrow{\scriptstyle \pi_A^Y} \\ X & \xrightarrow{f} & Y. \end{array}$$

Using Proposition 2.5 and the description of the scheme of A-jets for an affine space, we obtain the following

Corollary 2.6. *If X is a smooth n-dimensional variety*[1] *over k, then for every surjective morphism $A \to B$ in LFA/k, the induced morphism $J_A(X) \to J_B(X)$ is locally trivial in the Zariski topology, with fiber $\mathbf{A}^{dn}$, where $d = \dim_k(A) - \dim_k(B)$. In particular, $J_A(X)$ is a smooth variety of dimension $n \cdot \dim_k(A)$.*

Corollary 2.7. *If X is a scheme of finite type over k, then for every $A \in \mathrm{LFA}/k$, we have*

$$\dim(X) \leq \frac{\dim(J_A(X))}{\dim_k(A)} \leq \max_{x\in X} \dim(T_x X).$$

[1] A *variety* is assumed to be reduced, irreducible, and of finite type over k.

Proof. The first inequality follows from Corollary 2.6 and the fact that there is a locally closed immersion $Y \hookrightarrow X$, with Y smooth and $\dim(Y) = \dim(X)$. The second inequality also follows from Corollary 2.6 since for every $x \in X$, if $n = \dim(T_x X)$, then there is an open neighborhood U of x in X and a closed immersion $U \hookrightarrow Z$, where Z is a smooth variety of dimension n. □

Example 2.8. If we consider arbitrary $A \in \mathrm{LFA}/k$, then we can get arbitrarily close to the upper-bound in Corollary 2.7. Indeed, if $x \in X$ is such that $n = \dim(T_x X)$ and $(A, \mathfrak{m}) \in \mathrm{LFA}/k$ is such that $\mathfrak{m}^2 = 0$ and $\dim_k(A) = r$, then

$$(\pi_A)^{-1}(x) \simeq \mathbf{A}^{(r-1)n} \text{ hence } \frac{\dim(J_A(X))}{\dim_k(A)} \geq n - \frac{n}{r}.$$

Remark 2.9. If G is a group scheme over k, then it is easy to see that $J_A(G)$ is a group scheme over k for every $A \in \mathrm{LFA}/k$. Moreover, if G acts on a scheme X, then $J_A(G)$ acts on $J_A(X)$.

Remark 2.10. Suppose that $A \in \mathrm{LFA}/k$ is a graded[2] k-algebra. The grading of A induces a morphism $\phi\colon \mathbf{A}^1 \times \mathrm{Spec}(A) \to \mathrm{Spec}(A)$ that corresponds to the k-algebra homomorphism $A \to A[t]$ that takes a homogeneous element $a \in A$ of degree m to at^m. If X is any scheme, then we obtain an induced morphism $\Phi_A^X\colon \mathbf{A}^1 \times J_A(X) \to J_A(X)$ that takes any morphism $(u, v)\colon Y \to \mathbf{A}^1 \times J_A(X)$, with

$$v \in \mathrm{Hom}(Y, J_A(X)) \simeq \mathrm{Hom}(Y \times \mathrm{Spec}(A), X)$$

to the composition

$$Y \times \mathrm{Spec}(A) \xrightarrow{(\mathrm{id}, u \circ \mathrm{pr}_1)} Y \times \mathrm{Spec}(A) \times \mathbf{A}^1 \xrightarrow{(\mathrm{id}_Y, \phi)} Y \times \mathrm{Spec}(A) \xrightarrow{\quad v \quad} X.$$

It is easy to see that the restriction of Φ_A^X to $J_A(X) \simeq \{0\} \times J_A(X)$ is equal to $s_A^X \circ \pi_A^X$. In particular, for such A we see that if Z is an irreducible component of $J_A(X)$, then Φ_A^X induces a morphism $\mathbf{A}^1 \times Z \to Z$, hence $s_A^X \circ \pi_A^X(Z) \subseteq Z$.

3. Generalized arc schemes

We now generalize the construction in the previous section to complete local algebras. More precisely, let LCA/k be the category of complete local Noetherian k-algebras, with residue field k (the maps being local morphisms of k-algebras). Note that LFA/k is a full subcategory of LCA/k.

Given $(A, \mathfrak{m}) \in \mathrm{LCA}/k$ and a scheme X over k, we define a scheme $J_A(X)$

$$J_A(X) := \varprojlim_{A \to B} J_B(X), \tag{3.1}$$

where the projective limit is over all surjective maps $A \to B$ in LCA/k, with B lying in LFA/k. Note that a map from $\phi\colon A \to B$ to $\psi\colon A \to C$ is a map $f\colon B \to C$ such that $f \circ \phi = \psi$ and such a map induces a morphism $\pi_{C/B}^X\colon J_B(X) \to J_C(X)$. Since all $J_B(X)$

[2] All graded algebras we consider are graded by $\mathbf{Z}_{\geq 0}$.

are affine schemes over X, it follows that the projective limit (3.1) exists. In fact, if $U \subseteq X$ is an affine open subset, then

$$\Gamma(J_A(U), \mathcal{O}_{J_A(U)}) \simeq \varinjlim_{A \to B} \Gamma(J_B(U), \mathcal{O}_{J_B(U)}).$$

Note that if $A \in \mathrm{LFA}/k$, then we recover the previous definition. It is clear that if $h\colon X \to Y$ is a morphism of schemes, we obtain an induced morphism $J_A(h)\colon J_A(X) \to J_A(Y)$ and in this way we get a functor from the category of schemes over k to itself. If $g\colon A_1 \to A_2$ is a morphism in LCA/k, we obtain a functorial transformation

$$\pi^X_{A_2/A_1}\colon J_{A_1}(X) \to J_{A_2}(X).$$

Indeed, if $\phi\colon A_2 \to B_2$ is a surjective map in LCA/k, with B_2 finite over k, then $\phi \circ g$ factors through a quotient B_1 of A_1 by a power of the maximal ideal, hence we have a map $J_{A_1}(X) \to J_{B_1}(X) \to J_{B_2}(X)$, where the first map is given by the definition of projective limit and the second map is $\pi^X_{B_2/B_1}$. Note that this definition has the following two properties:

i) If $\phi\colon A \to B$ is a surjective map in LCA/k, with B finite over k, then the map $J_A(X) \to J_B(X)$ given by the projective limit definition is the same as $\pi^X_{B/A}$.

ii) If $A \to B \to C$ are maps in LCA/k, then $\pi^X_{C/B} \circ \pi^X_{B/A} = \pi^X_{C/A}$.

Remark 3.1. Suppose that X is a scheme and $A \in \mathrm{LCA}/k$. For every k-algebra R, consider the completion $R\widehat{\otimes}_k A$ of $R \otimes_k A$ with respect to the topology induced by A (more precisely, if $\mathfrak{m}_A$ is the maximal ideal in A, then the topology on $R \otimes_k A$ is the $\mathfrak{m}_A \cdot (R \otimes_k A)$-adic topology). In this case we have a canonical functorial map

$$\mathrm{Hom}(\mathrm{Spec}\, R\widehat{\otimes}_k A, X) \to \mathrm{Hom}(\mathrm{Spec}\, R, J_A(X)). \tag{3.2}$$

It is easy to see that this is a bijection if $R = k$ or if X is affine.

As we see in the next example, even when X is a finite type, the scheme $J_A(X)$ is not, in general, of finite type.

Example 3.2. If $A = k[\![t]\!]$, the scheme $J_A(X) = \varprojlim_m J_m(X)$ is the *scheme of arcs* of X, denoted by $J_\infty(X)$. For example, if $X = \mathbf{A}^n$, with $n \geq 1$, then $J_\infty(X)$ is an infinite-dimensional affine space, that is, $J_\infty(X) \simeq \mathrm{Spec}\, k[x_1, x_2, \ldots]$.

If $A = k[\![t_1, t_2]\!]$, then $J_A(X)$ is known as the *space of wedges* of X. It is easy to deduce from Remark 3.1 that this is canonically isomorphic to $J_\infty(J_\infty(X))$. More generally, if we put $A_n = k[\![x_1, \ldots, x_n]\!]$, then we have a canonical isomorphism $J_\infty(J_{A_n}(X)) \simeq J_{A_{n+1}}(X)$ for every $n \geq 1$.

Remark 3.3. It would be interesting to have explicit examples of schemes $J_A(X)$, when X is singular. Very few such examples are known and all of these only deal with $J_m(X)$ or $J_\infty(X)$. Moreover, in almost all cases one can only describe the reduced structure on these spaces. An easy example is that of schemes defined by monomial ideals in a polynomial ring (see [23, Proposition 4.10]). A more interesting example is that of $J_\infty(X)$, when X is a toric variety. In this case, if T is the torus acting on X, one can completely describe the orbits of the $J_\infty(T)$-action on $J_\infty(X)$, see [15]). It is much trickier to describe $J_m(X)$ for

a toric variety X; this is only understood in the 2-dimensional case, see [21]. One example in which both $J_m(X)$ and $J_\infty(X)$ are well understood is that of a generic determinantal variety X. In this case, X is a closed subscheme of a space of matrices $M = M_{m,n}(k)$ and the group $G = GL_m(k) \times GL_n(k)$ acts on M inducing an action on X. For a description of the orbits of $J_m(G)$ on $J_m(X)$ and of the orbits of $J_\infty(G)$ on $J_\infty(X)$, see [9].

4. Dimensions of jet schemes and invariants of singularities

Beyond the formal properties that we discussed, little is known about jet schemes in the generality that we considered in the previous two sections. We now restrict to the case of the "usual" jet schemes $J_m(X)$, for which a lot is known due to the connection to birational geometry that comes out of the theory of motivic integration.

In order to describe this connection, we first recall how one measures singularities in birational geometry. The idea is to use *all* divisorial valuations, suitably normalized by the order of vanishing along the relative Jacobian ideal. From now on we assume that the ground field k is algebraically closed, of characteristic 0, and we only consider the k-valued points of the schemes involved.

For simplicity, we assume that we work on an ambient smooth variety X. Let $\mathfrak{a}$ be a nonzero ideal on X (all ideals are assumed to be coherent). A *divisor over* X is a prime divisor on a normal variety Y that has a birational morphism to X (Y is a *birational model over* X). Each such divisor induces a valuation ord_E of the function field $K(Y) = K(X)$. We identify two such divisors if they give the same valuation. In particular, if $Z \to Y$ is a birational morphism, with Z normal, then we identify E with its strict transform on Z. Therefore we may always assume that Y is smooth (using a resolution of singularities of Y) and that Y is proper over X (using Nagata's compactification theorem). Given a divisor E over X, its center on X denoted $c_X(E)$ is the closure of the image of E in X (it is easy to see that this is independent of the chosen model).

Let E be a divisor over X. To a nonzero ideal $\mathfrak{a}$ on X, we can attach a nonnegative integer $\mathrm{ord}_E(\mathfrak{a})$, defined as follows. We may assume that E is a divisor on a smooth variety Y over X, such that the structural morphism $f\colon Y \to X$ factors through the blow-up along $\mathfrak{a}$. Therefore we may write $\mathfrak{a}\cdot\mathcal{O}_Y = \mathcal{O}_Y(-D)$ for an effective divisor D on Y and $\mathrm{ord}_E(\mathfrak{a}) = \mathrm{ord}_E(D)$ is the coefficient of E in D. For example, if $x \in X$ and E is the exceptional divisor on the blow-up of X at x, then $\mathrm{ord}_E(\mathfrak{a})$ is the *order of* $\mathfrak{a}$ at x, denoted by $\mathrm{ord}_x(\mathfrak{a})$. This is characterized by

$$\mathrm{ord}_x(\mathfrak{a}) := \max\{r \mid \mathfrak{a} \subseteq \mathfrak{m}_x^r\},$$

where $\mathfrak{m}_x$ is the ideal defining x.

The idea is to measure the singularities of $\mathfrak{a}$ using all invariants $\mathrm{ord}_E(\mathfrak{a})$, where E varies over the divisors over X. Very roughly, one thinks of the singularities of $\mathfrak{a}$ being "worse" if $\mathrm{ord}_E(\mathfrak{a})$ is larger. On the other hand, when we vary E, the numbers $\mathrm{ord}_E(\mathfrak{a})$ are unbounded, hence we need a normalizing factor. It turns out that the right factor to use is provided by the *log discrepancy*, which is defined as follows. If $f\colon Y \to X$ is a proper, birational morphism, with Y a smooth variety and E is a prime divisor on Y, then the *relative canonical class* $K_{Y/X}$ is the degeneracy locus of the morphism of vector bundles of the same rank $f^*(\Omega_X) \to \Omega_Y$. In other words, $K_{Y/X}$ is locally defined by the determinant of the Jacobian matrix of f. The log discrepancy of ord_E is $A(\mathrm{ord}_E) := \mathrm{ord}_E(K_{Y/X}) + 1$. It is easy to check that the definition does not depend on the model Y we have chosen.

There are various related invariants of singularities that one considers in birational geometry. In what follows, we focus on two such invariants, the *log canonical threshold* and the *minimal log discrepancy*. We begin by introducing the former invariant. If X is smooth and $\mathfrak{a}$ is a nonzero ideal on X, then the log canonical threshold of $\mathfrak{a}$ is

$$\mathrm{lct}(\mathfrak{a}) := \inf_E \frac{A(\mathrm{ord}_E)}{\mathrm{ord}_E(\mathfrak{a})},$$

where the infimum is over all divisors E over X. Note that this is finite whenever $\mathfrak{a} \neq \mathcal{O}_X$ and by convention we put $\mathrm{lct}(\mathcal{O}_X) = \infty$ and $\mathrm{lct}(0) = 0$. If W is the closed subscheme defined by $\mathfrak{a}$, we sometimes write $\mathrm{lct}(X, W)$ for $\mathrm{lct}(\mathfrak{a})$. Note that in the definition of $\mathrm{lct}(\mathfrak{a})$ we consider the reciprocals of the invariants $\mathrm{ord}_E(\mathfrak{a})$, hence "worse" singularities correspond to smaller log canonical thresholds.

While defined in terms of all divisors over X, it is a consequence of resolution of singularities that the log canonical threshold can be computed on suitable models. Recall that a log resolution of the pair $(X, \mathfrak{a})$ is a proper birational morphism $f\colon Y \to X$, with Y smooth, such that $\mathfrak{a} \cdot \mathcal{O}_Y = \mathcal{O}_Y(-D)$ for an effective divisor D on Y such that $D + K_{Y/X}$ has simple normal crossings[3]. The existence of such resolutions follows from Hironaka's fundamental results. A basic result about log canonical thresholds says that if $f\colon Y \to X$ is a log resolution of $(X, \mathfrak{a})$ as above, then $\mathrm{lct}(\mathfrak{a})$ is computed by the divisors on Y: if we write $D = \sum_{i=1}^r a_i E_i$ and $K_{Y/X} = \sum_{i=1}^r k_i E_i$, then

$$\mathrm{lct}(\mathfrak{a}) = \min_{i=1}^r \frac{k_i + 1}{a_i}.$$

A consequence of this formula is the fact, not apparent from the definition, that $\mathrm{lct}(\mathfrak{a})$ is a rational number.

The log canonical threshold is a fundamental invariant of singularities. It appeared implicitly already in Atiyah's paper [2] in connection with the meromorphic continuation of complex powers. The first properties of the log canonical threshold have been proved by Varchenko in connection with his work on asymptotic expansions of integrals and mixed Hodge structures on the vanishing cohomology, see [27], [28], and [29]. It was Shokurov who introduced the log canonical threshold in the context of birational geometry in [25]. From this point of view, $\mathrm{lct}(\mathfrak{a})$ is the largest rational number q such that the pair $(X, \mathfrak{a}^q)$ is *log canonical*. We mention that the notion of log canonical pairs is of central importance in the Minimal Model Program, since it gives the largest class of varieties for which one can hope to apply the program. In fact, in the context of birational geometry it is useful to not require that the ambient variety is smooth, but only that it has mild singularities, and it is in this more general setting that one can define the log canonical threshold. A remarkable feature of this invariant is that it is related to many points of view on singularities. We refer to [19] and [24] for an overview of some of these connections and for the basic properties of the log canonical threshold.

Example 4.1. In order to illustrate the behavior of the log canonical threshold, we list a few examples. When $\mathfrak{a}$ is generated by $f \in \mathcal{O}(X)$, we simply write $\mathrm{lct}(f)$ for the corresponding log canonical threshold.

[3] A divisor on a smooth variety has simple normal crossings if around every point we can find local algebraic coordinates $x_1, \ldots, x_n$ such that the divisor is defined by $x_1^{a_1} \cdots x_n^{a_n}$ for some nonnegative integers $a_1, \ldots, a_n$.

i) If the subscheme $V(\mathfrak{a})$ defined by $\mathfrak{a}$ has codimension r, then $\mathrm{lct}(\mathfrak{a}) \leq r$. This is an equality if $V(\mathfrak{a})$ is smooth.

ii) If $f = x_1^{a_1} \cdots x_n^{a_n} \in k[x_1, \ldots, x_n]$, then $\mathrm{lct}(f) = \min_i \frac{1}{a_i}$.

iii) If $f = x_1^{a_1} + \ldots + x_n^{a_n} \in k[x_1, \ldots, x_n]$, then $\mathrm{lct}(f) = \min\left\{1, \sum_i \frac{1}{a_i}\right\}$.

Remark 4.2. In terms of size, the log canonical threshold in a neighborhood of a point $x \in X$ is comparable to $\mathrm{ord}_x(\mathfrak{a})$. More precisely, given $x \in X$, there is an open neighborhood U of x such that the following inequalities hold:

$$\frac{1}{\mathrm{ord}_x(\mathfrak{a})} \leq \mathrm{lct}(\mathfrak{a}|_U) \leq \frac{\dim(X)}{\mathrm{ord}_x(\mathfrak{a})}.$$

It turns out that the log canonical threshold governs the growth of the dimensions of the jet schemes $J_m(W)$ of a scheme W. Note that by taking a finite affine open cover of W, we can reduce to the case when W can be embedded in a smooth variety (for example, in an affine space).

Theorem 4.3. *If X is a smooth n-dimensional variety and W is a proper, nonempty, closed subscheme of X, then*

$$\lim_{m\to\infty} \frac{\dim(J_m(W))}{m+1} = \max_m \frac{\dim(J_m(W))}{m+1} = n - \mathrm{lct}(X, W).$$

Moreover, the maximum above is achieved for all m such that $(m+1)$ is divisible enough.

This result was proved in [23] by making use of the change of variable formula in motivic integration (in fact, the formula had appeared implicitly earlier in [7]). We explain below, following [10], how this theorem follows from a more general result relating the approach to singularities via divisors over X and that using certain subsets in the space of arcs $J_\infty(X)$. Before doing this, we discuss another invariant of singularities, whose definition is similar to that of the log canonical threshold, but whose behavior turns out to be more difficult to study.

Suppose, as above, that X is a smooth variety, $\mathfrak{a}$ is a nonzero ideal on X, and q is a positive rational number. In order to avoid some pathologies of a trivial nature, we assume $\dim(X) \geq 2$. If Z is a proper, irreducible closed subset of X, then the *minimal log discrepancy* $\mathrm{mld}_Z(X, \mathfrak{a}^q)$ is defined as

$$\mathrm{mld}_Z(X, \mathfrak{a}^q) := \inf\{A(\mathrm{ord}_E) - q \cdot \mathrm{ord}_E(\mathfrak{a}) \mid c_X(E) \subseteq Z\}. \tag{4.1}$$

Note that "better" singularities correspond to larger minimal log discrepancies. It is a basic fact that the minimal log discrepancy is either $-\infty$ or it is nonnegative. We have $\mathrm{mld}_Z(X, \mathfrak{a}^q) \geq 0$ if and only if the pair $(X, \mathfrak{a}^q)$ is log canonical around Z, that is, there is an open neighborhood U of Z such that $\mathrm{lct}(\mathfrak{a}|_U) \geq q$. Like the log canonical threshold, the minimal log discrepancy can be computed on suitable models. More precisely, if I_Z is the ideal defining Z and $f\colon Y \to X$ is a log resolution of $(X, I_Z \cdot \mathfrak{a})$, then there is a prime divisor E on Y that achieves the infimum in (4.1), assuming that this infimum is not $-\infty$ (moreover, finitenes also can be tested just on the divisors on Y). For an introduction to minimal log discrepancies, we refer to [1]. The following result gives an interpretation of minimal log discrepancies in terms of jet schemes.

Theorem 4.4. *Let X be a smooth variety of dimension ≥ 2, $\mathfrak{a}$ a nonzero ideal on X defining the subscheme W, and q a positive rational number. For every proper, irreducible closed subset Z of X, we have*

$$\mathrm{mld}_Z(X, \mathfrak{a}^q) = \inf\{(m+1)(\dim(X) - q) - \dim(J_m(W) \cap (\pi_m^W)^{-1}(Z))\}.$$

Moreover, if the infimum is not $-\infty$, then it is a minimum.

The theorem was proved in [13] using the change of variable formula in motivic integration. In this special form in which X is assumed to be smooth, it can also be deduced from the main result in [10] that we discuss below.

We note that part of the interest in invariants of singularities like the log canonical threshold and the minimal log discrepancy comes from the fact that their behavior is related to one of the outstanding open problems in birational geometry, namely Termination of Flips (see [3] for the connection of this conjecture to log canonical thresholds and [26] for the connection to minimal log discrepancies). In this respect, there are two points to keep in mind:

- For all applications to birational geometry, it is important to work with ambient varieties that have mild (log canonical) singularities, and not just smooth, as above. In this context, one can still describe minimal log discrepancies in terms of properties of (certain subsets in) jet schemes, see [13]. However, this description is less effective in general. It was used to prove some open questions about minimal log discrepancies, such as Inversion of Adjunction and Semicontinuity in the case when the ambient variety is locally complete intersection, see [11] and [13]. However, this method has not been successful so far in dealing with more general ambient varieties.
- While properties of log canonical thresholds are better understood (see below for the ACC property), it is in fact the (conjectural) properties of minimal log discrepancies that would give a positive answer to the Termination of Flips Conjecture. More precisely, Shokurov has shown that two conjectures on minimal log discrepancies, the Semicontinuity Conjecture and the ACC Conjecture imply Termination of Flips; see [26] for the precise statements.

In order to give the flavor of ACC statements regarding invariants of singularities, we state the following result concerning log canonical thresholds.

Theorem 4.5. *For every $n \geq 1$, the set of rational numbers*

$$\{\mathrm{lct}(\mathfrak{a}) \mid \mathfrak{a} \subsetneq \mathcal{O}_X,\ X \text{ smooth},\ \dim(X) \leq n\}$$

satisfies ACC, that is, it contains no infinite strictly increasing sequences.

This result was conjectured by Shokurov and proved in [6]. A general version, in which the ambient variety is not assumed to be smooth (which, as we have already mentioned, is much more useful for birational geometry) has been recently proved in [14]. It is worth mentioning that a corresponding conjecture for minimal log discrepancies is widely open even in the case of smooth ambient varieties. For recent progress motivated by this question, see [17] and [18].

Besides the ACC Conjecture for minimal log discrepancies, the other important open problem about these invariants concerns their semicontinuity (this was conjectured by Ambro [1]). As we have already mentioned, when the ambient variety is smooth, this can be deduced from Theorem 4.4 using general properties of the dimension of algebraic varieties in families.

Corollary 4.6. *If X is a smooth variety, $\mathfrak{a}$ is a nonzero ideal on X, and q is a positive rational number, then the map*

$$X \ni x \to \mathrm{mld}_x(X, \mathfrak{a}^q)$$

is lower semicontinuous.

Our next goal is to describe more generally, following [10], a dictionary between the approach to singularities using divisorial valuations and that using certain subsets in the space of arcs. We fix a smooth variety X of dimension n. We will be concerned with certain subsets in the space of arcs $J_\infty(X)$. In what follows we restrict to the k-valued points of $J_\infty(X)$, considered as a topological space with the Zariski topology. Recall that we have canonical projections $\pi_m \colon J_\infty(X) \to J_m(X)$. A *cylinder* in $J_\infty(X)$ is a subset of the form $C = \pi_m^{-1}(S)$, where S is a constructible subset in $J_m(X)$. We say that C is closed, locally closed, or irreducible, if S has this property. Moreover, we put

$$\mathrm{codim}(C) := \mathrm{codim}(S, J_m(X)) = (m+1)n - \dim(S).$$

It is easy to see that all these notions do not depend on m, since the natural projections $J_{m+1}(X) \to J_m(X)$ are locally trivial with fiber $\mathbf{A}^n$.

The main examples arise as follows. Suppose that $\mathfrak{a}$ is a nonzero ideal on X, defining the subscheme W. Associated to W we have a function $\mathrm{ord}_W \colon J_\infty(X) \to \mathbf{Z}_{\geq 0} \cup \{\infty\}$ such that for $\gamma \colon \mathrm{Spec}\, k[\![t]\!] \to X$, we have

$$\mathrm{ord}_W(\gamma) = \mathrm{ord}_t(\gamma^{-1}(\mathfrak{a}))$$

(with the convention that this is ∞ if the ideal $\gamma^{-1}(\mathfrak{a})$ is 0). With this notation, the *contact locus*

$$\mathrm{Cont}^{\geq m}(W) := \mathrm{ord}_W^{-1}(\geq m)$$

is a closed cylinder, hence

$$\mathrm{Cont}^{m}(W) := \mathrm{ord}_W^{-1}(m) = \mathrm{Cont}^{\geq m}(W) \smallsetminus \mathrm{Cont}^{\geq (m+1)}(W)$$

is a locally closed cylinder. In fact, we have

$$\mathrm{Cont}^{\geq (m+1)}(W) = \pi_m^{-1}(J_m(W)).$$

In particular, we have

$$\mathrm{codim}(\mathrm{Cont}^{\geq (m+1)}(W)) = (m+1)n - \dim(J_m(W)).$$

The main point of the correspondence we are going to describe is that divisorial valuations correspond to cylinders in such a way that the log discrepancy function translates to the codimension of the cylinder. In order to simplify the exposition, let us assume that $X = \mathrm{Spec}(R)$ is affine. Note first that if C is an irreducible closed cylinder in $J_\infty(X)$, then we may define a map

$$\mathrm{ord}_C \colon R \to \mathbf{Z}_{\geq 0} \cup \{\infty\},\ \mathrm{ord}_C(f) := \min\{\mathrm{ord}_{V(f)}(\gamma) \mid \gamma \in C\}.$$

This satisfies

$$\mathrm{ord}_C(f+g) \geq \min\{\mathrm{ord}_C(f), \mathrm{ord}_C(g)\} \text{ and } \mathrm{ord}_C(fg) = \mathrm{ord}_C(f) + \mathrm{ord}_C(g).$$

Moreover, if C does not dominate X, then $\mathrm{ord}_C(f) < \infty$ for every nonzero f, hence ord_C extends to a valuation of the function field of X. The following is the main result from [10] concerning the description of divisorial valuations in terms of cylinders in the space or arcs. For an extension to singular varieties, see [4].

Theorem 4.7. *Let X be a smooth variety.*

i) *If C is an irreducible closed cylinder in $J_\infty(X)$ that does not dominate X, then there is a divisor E over X and a positive integer q such that* $\mathrm{ord}_C = q \cdot \mathrm{ord}_E$.

ii) *For every divisor E over X and every positive integer q, there is a closed irreducible cylinder C in $J_\infty(X)$ such that* $\mathrm{ord}_C = q \cdot \mathrm{ord}_E$. *Moreover, there is a unique maximal such cylinder $C = C_q(E)$, with respect to inclusion, and*

$$\mathrm{codim}(C_q(E)) = q \cdot A(\mathrm{ord}_E).$$

It is easy to see that this result implies both Theorems 4.3 and 4.4. The key step in the proof of Theorem 4.7 consists in analyzing the valuations corresponding to the irreducible components of $\mathrm{Cont}^{\geq m}(W)$, for a closed subscheme W. This is done by considering a log resolution $f\colon Y \to X$ of $(X, \mathfrak{a})$, where $\mathfrak{a}$ is the ideal defining W. In this case, we have an induced map $g = J_\infty(f)\colon J_\infty(Y) \to J_\infty(X)$. If f is an isomorphism over $X \smallsetminus A$, where A is a proper closed subset of X, then the valuative criterion for properness implies that g is a bijection over $J_\infty(Y) \smallsetminus J_\infty(A)$. While $J_\infty(A)$ is "small" in $J_\infty(X)$ (for example, if the ground field is uncountable, then no cylinder is contained in $J_\infty(A)$), the map g is far from being a homeomorphism over $J_\infty(Y) \smallsetminus J_\infty(A)$. In fact, it is a fundamental result that if C is a cylinder contained in $\mathrm{Cont}^e(K_{Y/X})$, then $g(C)$ is again a cylinder and

$$\mathrm{codim}(g(C)) = \mathrm{codim}(C) + e.$$

This is a consequence of the geometric statement behind the change of variable formula in motivic integration, due to Kontsevich [20]. For the relevant statement and its proof, as well as for an important generalization to the case when X is not smooth, we refer to [8]. Since $\mathrm{Cont}^{\geq m}(f^{-1}(W)) = g^{-1}(\mathrm{Cont}^{\geq m}(W))$, one can deduce the following formula for the codimension of $\mathrm{Cont}^{\geq m}(W)$, see [10] for details.

Theorem 4.8. *Let X be a smooth variety and W a proper closed subscheme of X, defined by the ideal $\mathfrak{a}$. If $f\colon Y \to X$ is a log resolution of the pair $(X, \mathfrak{a})$ and we write*

$$f^{-1}(W) = \sum_{i=1}^r a_i E_i \text{ and } K_{Y/X} = \sum_{i=1}^r k_i E_i,$$

then $\mathrm{codim}(\mathrm{Cont}^{\geq m}(W))$ *is equal to*

$$\min\left\{\sum_{i=1}^r (k_i+1)\nu_i \mid \nu = (\nu_1, \ldots, \nu_r) \in \mathbf{Z}^r_{\geq 0}, \bigcap_{\nu_i > 0} E_i \neq \emptyset, \sum_{i=1}^r a_i\nu_i \geq m\right\}.$$

Moreover, it is easy to see that in the setting of this theorem, every irreducible component C of $\mathrm{Cont}^{\geq m}(W)$ is the closure of the image of a multi-contact locus of the form $\cap_{i=1}^r \mathrm{Cont}^{\geq \nu_i}(E_i)$. Using this, one deduces that ord_C is equal to $q \cdot \mathrm{ord}_E$, where E is the

exceptional divisor on a suitable weighted blow-up of Y with respect to the simple normal crossing divisor $\sum_i E_i$. We note that since both log canonical thresholds and minimal log discrepancies can be computed using log resolutions, the statement of Theorem 4.8 is enough to imply Theorems 4.3 and 4.4. On the other hand, one can give a proof for Theorem 4.7 without using log resolutions, see [30]. An advantage of that approach is that one obtains the same result in positive characteristic.

Remark 4.9. It is an immediate consequence of Theorem 4.8 that if W is any scheme, then

$$\frac{\dim(J_{m-1}(W))}{m} \leq \frac{\dim(J_{mp-1}(W))}{mp}$$

for every positive integers m and p. It would be interesting to give a direct proof of this inequality without relying on log resolutions. Such an argument could then hopefully be extended to cover other jet schemes $J_A(X)$, for suitable A.

Remark 4.10. It was shown in [23] that one can use the description of the log canonical threshold in Theorem 4.3 to reprove some of the basic properties of this invariant. For example, one can use this approach to prove the following special case of Inversion of Adjunction: if X is a smooth variety and H is a smooth hypersurface in X, then for every ideal $\mathfrak{a}$ on X such that $\mathfrak{a} \cdot \mathcal{O}_H \neq 0$, there is an open neighborhood U of H such that

$$\mathrm{lct}(\mathfrak{a}|_U) \geq \mathrm{lct}(\mathfrak{a} \cdot \mathcal{O}_H). \tag{4.2}$$

The usual proof of this inequality makes use of vanishing theorems (see for example [19]). Since Theorem 4.8 also holds in positive characteristic, one deduces that the inequality (4.2) holds in this setting as well, see [30], in spite of the fact that vanishing theorems can fail.

Remark 4.11. It would be interesting to find a jet-theoretic proof of the following result of Varchenko. Suppose that T is a connected scheme and $\mathcal{W} \hookrightarrow \mathbf{A}^n \times T$ is an effective Cartier divisor, flat over T, such that for every (closed) point $t \in T$, the induced divisor $\mathcal{W}_t \hookrightarrow \mathbf{A}^n$ has an isolated singularity at 0. By using the connection between the log canonical threshold and Steenbrink's spectrum of a hypersurface singularity, Varchenko showed in [27] that if the Milnor number at 0 for each $\mathcal{W}_t$ is constant for $t \in T$, then $\mathrm{lct}_0(\mathbf{A}^n, \mathcal{W}_t)$ is independent of t (here $\mathrm{lct}_0(\mathbf{A}^n, \mathcal{W}_t) = \mathrm{lct}(U, \mathcal{W}_t \cap U)$, where U is a small neighborhood of 0). It would be interesting to deduce this fact from the behavior of jet schemes. It is easy to see that the jet schemes $J_m(\mathcal{W}_t)$ are the fibers of a relative jet scheme $J_m(\mathcal{W}/T)$ over T and a natural question is whether the constancy of Milnor numbers implies that this family is flat over T (in a neighborhood of the fiber over 0 via the natural map $J_m(\mathcal{W}/T) \to \mathbf{A}^n$).

Remark 4.12. Suppose, for simplicity, that $X = \mathrm{Spec}(R)$ is a smooth affine variety. Recall that if $\mathfrak{a}$ is an ideal in R, then its integral closure $\overline{\mathfrak{a}}$ consists of all $\phi \in R$ such that $\mathrm{ord}_E(\phi) \geq \mathrm{ord}_E(\mathfrak{a})$ for all divisors E over X. It follows from Theorem 4.7 that if $\mathfrak{b}$ is another ideal in R, then $\mathfrak{b} \subseteq \overline{\mathfrak{a}}$ if and only if $\mathrm{Cont}^{\geq m}(\mathfrak{a}) \subseteq \mathrm{Cont}^{\geq m}(\mathfrak{b})$ for all m. In particular, the integral closure $\overline{\mathfrak{a}}$ is determined by the contact loci $(\mathrm{Cont}^{\geq m}(\mathfrak{a}))_{m \geq 1}$. Given other invariants of an ideal that only depend on the integral closure, it would be interesting to find a direct description of these invariants in terms of the contact loci of that ideal. For example, if $\mathfrak{a}$ is supported at a point $x \in X$, it would be interesting to find a description of the Samuel multiplicity $e(\mathfrak{a} \cdot \mathcal{O}_{X,x}, \mathcal{O}_{X,x})$ in terms of the contact loci of $\mathfrak{a}$.

We now turn to a related connection between singularities and jet schemes. It turns out that in the case of locally complete intersection varieties, one can characterize various classes of singularities in terms of the behavior of the jet schemes. The following is the main result in this direction.

Theorem 4.13. *Let W be a locally complete intersection variety.*

i) *If W is normal, then W has log canonical singularities if and only if $J_m(W)$ has pure dimension for every $m \geq 0$. Moreover, in this case we have $\dim(J_m(W)) = (m+1) \cdot \dim(X)$ and $J_m(W)$ is a locally complete intersection.*

ii) *The variety W has rational (equivalently, canonical) singularities if and only if $J_m(W)$ is irreducible for every $m \geq 0$.*

iii) *The variety W has terminal singularities if and only if $J_m(W)$ is normal for every $m \geq 0$.*

The assertion in ii) was proved in [22] using motivic integration. It was then noticed in [10] that the main ingredient in the proof can also be deduced from Theorem 4.7. The result had been conjectured by David Eisenbud and Edward Frenkel. They use it in the appendix to [22] to give an analogue of a result of Kostant to the setting of loop Lie algebras. The assertions in i) and iii) follow using similar ideas once some basic Inversion of Adjunction statements are proved, see [11] and [13].

We end with an interpretation for the condition of having pure-dimensional or irreducible jet schemes under the assumptions of Theorem 4.13. It turns out that these considerations can be made in the context of generalized jet schemes and we will make use of this in the next section.

Proposition 4.14. *Let W be an n-dimensional locally complete intersection variety and let A be a local, finite k-algebra, with $\dim_k(A) = \ell$.*

i) *$J_A(W)$ is pure-dimensional if and only if all irreducible components of $J_A(W)$ have dimension ℓn. If this is the case, then $J_A(W)$ is locally a complete intersection.*

ii) *$J_A(W)$ is irreducible if and only if the inverse image in $J_A(W)$ of the singular locus of W has dimension $< \ell n$. If this is the case, then $J_A(W)$ is also reduced.*

iii) *Suppose that $A \to A'$ is a surjective k-algebra homomorphism, where A and A' are finite, local k-algebras, with A' being positively graded. If $J_A(W)$ is pure-dimensional or irreducible, then $J_{A'}(W)$ has the same property.*

Proof. If we write $W = U_1 \cup \ldots \cup U_m$, with each U_i open in X, then $J_A(W) = J_A(U_1) \cup \ldots \cup J_A(U_m)$. Using this, it is easy to see that if the assertions in the proposition hold for each U_i, then they hold for X. Therefore we may assume W is a closed subvariety of $X = \mathbf{A}^d$, whose ideal is generated by $r = d - n$ elements.

We have seen in Proposition 2.1 that $J_A(W)$ is cut out in $J_A(X) \simeq \mathbf{A}^{\ell d}$ by ℓr equations. Therefore each irreducible component of $J_A(X)$ has dimension $\geq \ell n$. On the other hand, it follows from Corollary 2.6 that $J_A(X_{\mathrm{sm}})$ is an open subset of $J_A(X)$ of dimension ℓn. We thus conclude that $J_A(X)$ is pure-dimensional if and only if all irreducible components of $J_A(X)$ have dimension ℓn. We also see that if this is the case, then $J_A(X)$ is itself a locally complete intersection. This proves i).

Note also that $J_A(W)$ is irreducible if and only if the inverse image of the singular locus W_{sing} in $J_A(W)$ has dimension $< \ell n$. If this is the case, then $J_A(W)$ is generically reduced

and being Cohen-Macaulay (recall that $J_A(W)$ has to be a locally complete intersection), it is reduced. This gives ii).

In order to prove iii), let $\ell' = \dim_k(A')$. It is enough to show that if Z is any closed subset of W, then

$$\dim\,(\pi^W_{A'})^{-1}(Z) \leq \dim\,(\pi^W_A)^{-1}(Z) - (\ell - \ell')n. \tag{4.3}$$

It follows from Proposition 2.1 that

$$J_A(W) \hookrightarrow (\pi^{\mathbf{A}^d}_{A'/A})^{-1}(J_{A'}(W)) \tag{4.4}$$

is cut out by $r(\ell - \ell')$ equations and the same holds if we restrict to the inverse images of Z. By putting these together, we obtain the inequality (4.3) if we can show that for every irreducible component R of $(\pi^W_{A'})^{-1}(Z)$, its inverse image $(\pi^{\mathbf{A}^d}_{A'/A})^{-1}(R)$ intersects $(\pi^W_A)^{-1}(Z)$. This is a consequence of the fact that if $x \in Z$, then $s^X_A(x)$ lies in this intersection by Remark 2.10. □

5. Some questions on generalized jet schemes

In this section we collect some questions and remarks concerning the behavior of the schemes $J_A(X)$, when $\mathrm{embdim}(A) \geq 2$. Very little is known in this context, partly due to a lack of examples. In what follows we work over an algebraically closed field k of characteristic zero.

Motivated by Theorem 4.3, we begin by proposing several invariants that measure the rate of growth of the dimensions of certain schemes $J_A(X)$. In order to simplify the notation, we restrict to the first unknown case, that when $\mathrm{embdim}(A) = 2$. We introduce three invariants, depending on the choice of algebras A.

We first consider the algebras $A_{p,q} = k[s,t]/(s^p, t^q)$, with $p, q \geq 1$. Note that $\dim_k(A) = pq$. Given a scheme X, let

$$\alpha_{p,q}(X) := \dim J_{A_{p,q}}(X)$$

and

$$\alpha(X) := \sup_{p,q\geq 1} \frac{\alpha_{p,q}(X)}{pq}.$$

Note that $\alpha(X) \leq \max_{x\in X} \dim(T_x X)$ by Corollary 2.7. Since $J_{A_{p,q}}(X) \simeq J_{p-1}(J_{q-1}(X))$, it follows from Remark 4.9 that for every positive integer m, we have

$$\frac{\alpha_{p,q}(X)}{pq} \leq \frac{\alpha_{mp,q}(X)}{mpq} \text{ and } \frac{\alpha_{p,q}(X)}{pq} \leq \frac{\alpha_{p,mq}(X)}{mpq}. \tag{5.1}$$

This clearly implies

$$\alpha(X) = \sup_{p\geq 1} \frac{\alpha_{p,p}(X)}{p^2} = \limsup_{p\to\infty} \frac{\alpha_{p,p}(X)}{p^2}. \tag{5.2}$$

On the other hand, it follows from Theorem 4.3 that if X is a closed subscheme of the smooth variety Y, then for every $q \geq 1$, we have

$$\lim_{p\to\infty} \frac{\alpha_{p,q}(X)}{pq} = \sup_{p\geq 1} \frac{\alpha_{p,q}(X)}{pq} = \dim(Y) - \frac{\mathrm{lct}(J_{q-1}(Y), J_{q-1}(X))}{q}. \tag{5.3}$$

It is easy to deduce from (5.1) and (5.3) the following proposition.

Proposition 5.1. *If X is a closed subscheme of the smooth variety Y, then*

$$\alpha(X) = \dim(Y) - \inf_{q \geq 1} \frac{\mathrm{lct}(J_{q-1}(Y), J_{q-1}(X))}{q}$$
$$= \dim(Y) - \liminf_{q \to \infty} \frac{\mathrm{lct}(J_{q-1}(Y), J_{q-1}(X))}{q}.$$

We now turn to another invariant, corresponding to a different sequence of algebras. For every $m \geq 1$, let $A_m = k[s,t]/(s,t)^m$. Note that $\dim_k(A_m) = \frac{m(m+1)}{2}$. For a scheme X over k, we put $\beta_m := \dim(J_{A_m}(X))$ and

$$\beta(X) := \sup_{m \geq 1} \frac{\beta_m(X)}{m(m+1)/2}. \tag{5.4}$$

It follows from Corollary 2.7 that $\beta(X) \leq \max_{x \in X} \dim(T_x X)$.

Question 5.2. Is the supremum in (5.4) also the limsup of the corresponding sequence? Is there any relation between $\alpha(X)$ and $\beta(X)$?

Example 5.3. The invariant $\beta(X)$ is slightly easier to compute than $\alpha(X)$. For example, suppose that X is defined in $\mathbf{A}^n = \operatorname{Spec} k[x_1, \ldots, x_n]$ by $x_1^{a_1} \ldots x_n^{a_n}$, for nonnegative integers $a_1, \ldots, a_n$, not all of them equal to 0. An element of $J_{A_m}(X)$ corresponds to a k-algebra homomorphism $\phi\colon k[x_1, \ldots, x_n] \to k[s,t]/(s,t)^m$, which is determined by $\phi(x_1), \ldots, \phi(x_n)$, such that $\prod_i \phi(x_i)^{a_i} = 0$. If we denote by ν_i the smallest power of (s,t) that contains $\phi(x_i)$, we see that we get a disjoint decomposition of $J_{A_m}(X)$ into locally closed subsets $J_{A_m}(X)_\nu$, parametrized by $\nu = (\nu_1, \ldots, \nu_n) \in \{0, 1, \ldots, m\}^n$ such that $\sum_{i=1}^n a_i \nu_i \geq m$. It is straightforward to see that

$$\dim(J_{A_m}(X)_\nu) = \frac{nm(m+1)}{2} - \sum_{i=1}^n \frac{\nu_i(\nu_i+1)}{2}$$

and an easy computation shows that since $\sum_{i=1}^n a_i \nu_i \geq m$, we have

$$\sum_{i=1}^n \nu_i(\nu_i+1) - \frac{m(m+1)}{\sum_{i=1}^n a_i^2} \geq 0. \tag{5.5}$$

Moreover, if we take $\nu_i = a_i \ell$ for some $\ell \geq 1$ and $m = \ell \cdot \sum_i a_i^2$, then the left-hand side of (5.5) is equal to $\ell\,(\sum_{i=1}^n a_i - 1)$. This implies that

$$\beta(X) = \limsup_{m \to \infty} \frac{\beta_m(X)}{m(m+1)/2} = n - \frac{1}{\sum_{i=1}^n a_i^2}.$$

Yet another invariant of a similar flavor is the following. If X is a scheme over k, then let

$$\gamma(X) := \sup_A \frac{\dim(J_A(X))}{\dim_k(A)},$$

where the supremum is over all algebras $A \in \mathrm{LFA}/k$ which are graded[4] and such that $\mathrm{embdim}(A) \leq 2$. It is clear from definition that $\alpha(X), \beta(X) \leq \gamma(X)$, while Corollary 2.7 implies that $\gamma(X) \leq \max_{x \in X} \dim(T_x X)$.

We now turn to a different question, motivated by Theorem 4.13 and inspired by [16]. Suppose that X is a locally complete intersection variety and r is a positive integer. We say that X has irreducible (resp. pure-dimensional) r-iterated jet schemes if the jet scheme $J_{m_1}(J_{m_2}(\ldots J_{m_r}(X)))$ is irreducible (resp. pure-dimensional) for all nonnegative integers $m_1, \ldots, m_r$.

Proposition 5.4. *For a locally complete intersection variety X, the following are equivalent:*

i) *X has irreducible (resp. pure-dimensional) r-iterated jet schemes.*

ii) *$J_A(X)$ is irreducible (resp. pure-dimensional) for every $A \in \mathrm{LFA}/k$ which is graded and such that $\mathrm{embdim}(A) \leq r$.*

iii) *$J_{A_m}(X)$ is irreducible (resp. pure-dimensional) for every $m \geq 1$, where $A_m = k[x_1, \ldots, x_r]/(x_1, \ldots, x_r)^m$.*

Furthermore, X has irreducible r-iterated jet schemes if and only if all $(r-1)$-iterated jet schemes of X have rational singularities. If this is the case, then all r-iterated jet schemes of X are reduced locally complete intersections.

The equivalence of i)-iii) is an easy consequence of Proposition 4.14, which together with Theorem 4.13 also gives the last assertions in the proposition. When $r \geq 2$, it is not easy to give examples of singular varieties which have all r-iterated jet schemes pure-dimensional. We discuss below the case of cones over smooth projective hypersurfaces, which provides the only nontrivial class of examples for $r = 2$.

Remark 5.5. Note that if X is a locally complete intersection variety, then it follows from Proposition 5.4 that X has pure-dimensional 2-iterated jet schemes if and only if $\alpha(X) = \dim(X)$, which is also equivalent to saying that either $\beta(X) = \dim(X)$ or that $\gamma(X) = \dim(X)$.

Remark 5.6. We note that Example 2.8 implies that if $x \in X$ is a singular point such that

$$r > \frac{\dim(X)}{\dim(T_x X) - \dim(X)},$$

then X does not have pure-dimensional r-iterated jet schemes.

Suppose now that $X \subseteq \mathbf{A}^n$, with $n \geq 3$, is defined by a homogeneous polynomial f of degree $d > 0$. We assume that $X \smallsetminus \{0\}$ is smooth, which is the case for general f. It is well-known that X has rational (log canonical) singularities if and only if $d < n$ (resp., $d \leq n$). Using Theorem 4.13, we conclude that X has irreducible (pure-dimensional) 1-iterated jet schemes if and only if $d < n$ (resp., $d \leq n$). We give a direct argument for this, in the spirit of [5, §3].

Example 5.7. We show that if $X = V(f) \subset \mathbf{A}^n$, with f homogeneous of degree $d > 0$, such that X has an isolated singularity at 0, then $J_m(X)$ is irreducible (pure-dimensional)

[4]Of course, it might make sense to remove the condition that A is graded. We do not know whether this would give a different invariant.

for all $m \geq 1$ if and only if $d < n$ (resp., $d \leq n$). Let us denote by $\pi_m \colon J_m(X) \to X$ and $\pi'_m \colon J_m(\mathbf{A}^n) \to \mathbf{A}^n$ the canonical projections. It follows from Proposition 4.14 that we need to show the following: we have $\dim(\pi_m^{-1}(0)) < (m+1)(n-1)$ (resp., $\dim(\pi_m^{-1}(0)) \leq (m+1)(n-1)$) for all $m \geq 1$ if and only if $d < n$ (resp., $d \leq n$). We use the following two facts:

i) If $m \leq (d-1)$, then the closed embedding $J_m(X) \hookrightarrow J_m(\mathbf{A}^n)$ induces an isomorphism $\pi_m^{-1}(0) \simeq {\pi'_m}^{-1}(0) \simeq \mathbf{A}^{mn}$.

ii) If $m \geq d$, then we have an isomorphism $\pi_m^{-1}(0) \simeq J_{m-d}(X) \times \mathbf{A}^{n(d-1)}$.

Both assertions follow from the universal property defining $J_m(X)$, together with the following observations: if R is a k-algebra and $u_1, \ldots, u_n \in tR[t]/(t^{m+1})$, then $f(u_1, \ldots, u_n) = 0$ whenever $m \leq d-1$; for $m \geq d$, we have $f(u_1, \ldots, u_n) = 0$ if and only if when we write $u_i = tv_i$, we have $f(\overline{v_1}, \ldots, \overline{v_n}) = 0$ in $R[t]/(t^{m+1-d})$, where $\overline{v_i}$ is the class of v_i in $R[t]/(t^{m+1-d})$.

In particular, it follows from i) that $\dim(\pi_{d-1}^{-1}(0)) = (d-1)n$. If $\dim(\pi_{d-1}^{-1}(0)) < d(n-1)$, we deduce that $d < n$. Conversely, suppose that $d < n$. We prove by induction on m that $\dim(\pi_m^{-1}(0)) < (m+1)(n-1)$. If $0 \leq m \leq d-1$, this follows easily from i). On the other hand, if $m \geq d$, then the assertion follows from ii) and the inductive hypothesis. One similarly shows that $d \leq n$ if and only if $\dim(\pi_m^{-1}(0)) \leq (m+1)(n-1)$ for all m.

With the above notation, we are interested in when the r-iterated jet schemes of X are irreducible or pure-dimensional for $r \geq 2$. It is easy to give a necessary condition, arguing as in Example 5.7.

Proposition 5.8. *Let $X \subset \mathbf{A}^n$ be defined by a homogeneous polynomial f of degree $d > 0$. If $r \geq 2$ and the r-iterated jet schemes of X are pure-dimensional, then $d^r \leq n$.*

Proof. For every positive integer j, we consider $A_j = k[t_1, \ldots, t_r]/(t_1, \ldots, t_r)^{jd}$. Note that for every k-algebra R and every $u_1, \ldots, u_n \in (t_1, \ldots, t_r)^j/(t_1, \ldots, t_r)^{jd} \subset R \otimes_k A_j$, we have $f(u_1, \ldots, u_n) = 0$. This shows that $J_{A_j}(X)$ contains a closed subscheme Z_j, with

$$\dim(Z_j) = n \cdot \dim_k (t_1, \ldots, t_r)^j A_j = n \left(\binom{jd+r-1}{r} - \binom{j+r-1}{r} \right).$$

Using Proposition 4.14 and the fact that $\dim_k(A_j) = \binom{jd+r-1}{r}$, we deduce from our assumption that

$$n \left(\binom{jd+r-1}{r} - \binom{j+r-1}{r} \right) \leq (n-1) \cdot \binom{jd+r-1}{r}.$$

This gives

$$\binom{jd+r-1}{r} \leq n \cdot \binom{j+r-1}{r}, \tag{5.6}$$

which we can rewrite as

$$n \geq d \cdot \prod_{i=1}^{r-1} \frac{jd+i}{j+i}. \tag{5.7}$$

Since each function $\phi_i(x) = \frac{dx+i}{x+i}$, with $1 \leq i \leq r-1$, is increasing, with $\lim_{x \to \infty} \phi_i(x) = d$, we conclude from (5.7) by letting j go to infinity that $n \geq d^r$. □

Remark 5.9. If in the above proposition we assume instead that the r-iterated jet schemes of X are irreducible, then in (5.7) we get strict inequality. However, this does not imply that $n > d^r$.

Question 5.10. Does the converse to the assertion in Proposition 5.8 hold when X has an isolated singularity? More precisely, suppose that X is defined in $\mathbf{A}^n$ by a homogeneous polynomial f of degree d, such that $X \smallsetminus \{0\}$ is smooth. If $r \geq 2$ is such that $n \geq d^r$, are all r-iterated jet schemes of X pure-dimensional? Are they irreducible? Do these assertions hold if f is general?

Remark 5.11. The only evidence for a positive answer to Question 5.10 is provided by the result from [16], saying that if $f = \sum_u a_u x^u \in k[x_1, \ldots, x_n]$, where the sum is over all $u = (u_1, \ldots, u_n) \in \mathbf{Z}^n_{\geq 0}$ with $\sum_i u_i = d$, then if $d^2 \leq n$ and the coefficients $(a_u)_u$ are algebraically independent over $\mathbf{Q}$, then the 2-iterated jet schemes of $X = V(f)$ are irreducible. The proof shows that all $J_m(X)$ have rational singularities by reducing to positive characteristic and using the theory of F-singularities. In particular, this shows that if the ground field k is uncountable, then for a very general polynomial, the 2-iterated jet schemes of $V(f)$ are irreducible.

Remark 5.12. It is interesting that the bound in Question 5.10 is (almost) the same as the bound that shows up in Lang's C_r condition on fields. Recall that if $r \geq 0$, then a field K satisfies the condition C_r if every homogeneous polynomial $f \in K[x_1, \ldots, x_n]$ of degree d, with $d^r < n$, has a nontrivial zero in K^n. For example, if k is algebraically closed, then it is known that the field $K = k(x_1, \ldots, x_r)$ satisfies condition C_r. It would be interesting if there was a connection between C_r fields and Question 5.10.

Acknowledgments. The author was partially supported by NSF grants DMS-1068190 and DMS-1265256. I am indebted to David Eisenbud and Edward Frenkel who introduced me to jet schemes and shared with me their conjecture on the irreducibility of jet schemes of locally complete intersection varieties. I am also grateful to Lawrence Ein, from whom I learned a great deal over the years, during our collaboration. In particular, several of the results discussed in this article have been obtained in joint work with him.

Some aspects of explicit birational geometry inspired by complex dynamics

Keiji Oguiso

Abstract. Our aim is to illustrate how one can effectively apply the basic ideas and notions of topological entropy and dynamical degrees, together with recent progress of minimal model theory in higher dimension, for an explicit study of birational or biregular selfmaps of projective or compact Kähler manifolds, through concrete examples.

Mathematics Subject Classification (2010). 14E05, 14E09, 37F99.

Keywords. Entropy, dynamical degree, primitive automorphism, rational manifolds, Calabi-Yau manifolds.

1. Introduction

This is a survey of some aspects of recent progress on birational and biregular complex algebraic geometry inspired by complex dynamics in several variables. Our aim is to illustrate how one can apply the basic ideas and notions of topological entropy and dynamical degrees, together with recent progress of minimal model theory in higher dimension, for an explicit study of birational or biregular selfmaps of projective or compact Kähler manifolds. Especially, we focus on the following one of the most basic, natural problems:

Problem 1.1. Find many examples of projective or Kähler manifolds M admitting *interesting* birational automorphisms of *infinite order*, or more preferably, *primitive biregular* automorphisms of *positive entropy*.

There are so many interesting works in this area since the breakthrough results due to Serge Cantat [19] and Curtis T. McMullen [58], and this note is definitely far from being a complete panorama of this area. Also, needless to say, there is no universally acceptable mathematical definition of the term *interesting* and the choice of topics and materials owes much to my own flavour and ability, and probably not the one that everyone agrees with. For instance, the terms *of infinite order* ignore very beautiful aspects of finite group actions on manifolds.

Throughout this note, we work over the complex number field $\mathbf{C}$. We assume some familiarity with basics on complex geometry and algebraic geometry. Unless stated otherwise, the topology we use is the Euclidean topology (not Zariski topology), a point means a closed point, and manifolds and varieties are connected. By abuse of language, we call a (bi)meromorphic map also a (bi)rational map even under non-algebraic settings. We denote

Proceedings of the International Congress of Mathematicians, Seoul, 2014

by $I(f)$ the indeterminacy locus of a rational map $f : M \cdots \to N$, i.e., the complement of the maximal, necessarily Zariski open dense, subset $U \subset M$ such that $f|U$ is holomorphic. $I(f)$ is a Zariski closed subset of M of codimension ≥ 2 if M is normal. The set of birational selfmaps (resp. biregular selfmaps, resp. birational selfmaps being isomorphic in codimension one) of M form a group under the natural composition. We denote these groups by $\mathrm{Bir}\,(M)$ (resp. $\mathrm{Aut}\,(M)$, resp. $\mathrm{PsAut}\,(M)$). Here we call f isomorphic in codimension one if f neither contracts nor extracts any divisors, in other words, if there are Zariski open dense subsets U, U' of M such that $\mathrm{codim}\, M \setminus U \geq 2$, $\mathrm{codim}\, M \setminus U' \geq 2$ for which the restriction map $f|U : U \to U'$ is an isomorphism. We call an element of $\mathrm{Bir}\,(M)$ (resp. $\mathrm{PsAut}\,(M)$, resp. $\mathrm{Aut}\,(M)$) a birational automorphism (resp. a pseudo-automorphism, resp. an automorphism or a biregular automorphism) of M. We call a compact complex variety of class $\mathcal{C}$ if it is birational to a compact Kähler manifold. Unless stated otherwise, we denote the golden number $(\sqrt{5}+1)/2$ by η, the cyclic group of order n by $\mathbf{Z}_n$, the free product of groups G_1 and G_2 by $G_1 * G_2$.

2. What kind of manifolds we are interested in?

Let M be a compact Kähler manifold of $\dim M = l > 0$. We are interested in a *birational automorphism* f of M, in particular, *of infinite order*.

2.1. Primitive birational automorphisms after De-Qi Zhang. If $f_i \in \mathrm{Bir}\,(M_i)$ $(i = 1, 2)$, then $f_1 \times f_2 \in \mathrm{Bir}\,(M_1 \times M_2)$ and it is of infinite order if so is one of f_i. We are more interested in birational automorphisms *not coming from lower dimensional pieces*, more precisely, *primitive* ones in the sense of De-Qi Zhang [90]:

Definition 2.1. A birational automorphism f of M is *imprimitive* if there are a dominant rational map $\varphi : M \cdots \to B$ to a compact complex variety B with $0 < \dim B < \dim M = l$ and a rational map $g : B \cdots \to B$, necessarily a birational automorphism of B, such that $\varphi \circ f = g \circ \varphi$. A birational automorphism that is not imprimitive is *primitive*.

Here we may assume that B is smooth and $\varphi : M \to B$ is holomorphic whenever it is more convenient. Indeed, we may resolve B first and then resolve the indeternimacy of φ, by the fundamental result of Hironaka.

> *What kind of manifolds can have primitive birational automorphisms of infinite order?*

We can not answer this question completely, but if we *assume* that minimal model program [43, 49, 52] in higher dimensional projective manifolds work, then one has the following rough but quite nice picture at least in the projective case. This beautiful observation is due to De-Qi Zhang (see [90] and [65] for more precise results):

Theorem 2.2. *Let M be a projective manifold of dimension l. Assume that the minimal model conjecture (MMP) and the weak abundance (WA) in dimension l hold, in the sense that any l-dimensional projective manifold V is birational to either a minimal model with weak abundance or a Mori fiber space, i.e., there is a projective variety $V_{\min}$, birational to V, with only normal, $\mathbf{Q}$-factorial terminal singularities such that either one of the following two holds:*

(MMP-1) *in addition, $K_{V_{\min}}$ is nef (minimal model); or*

(MMP-2) *in addition, there exists an extremal contraction $\varphi : V_{\min} \to B$, with respect to $K_{V_{\min}}$ onto a normal projective variety such that $0 \leq \dim B < \dim V$ (Mori fiber space),*

and additionally,

(WA) *In the case* (MMP-1)*, $|mK_{V_{\min}}|$ is non-empty for some $m > 0$.*

Then any l-dimensional projective manifold M with a primitive birational automorphism f of infinite order is birational to either:

(RC) *a rationally connected manifold, in the sense that any two points can be connected by a finite chain of rational curves;*

(WCY) *a minimal Calabi-Yau variety, in the sense that it is a minimal variety with numerically trivial canonical divisor and of irregularity 0; or*

(T) *an abelian variety, i.e., a projective complex torus.*

Example 2.3.

(1) When $l = 1$, (RC) is $\mathbf{P}^1$, (T) is an elliptic curve and no (WCY).

(2) When $l = 2$, (RC) is a rational surface, (T) is an abelian surface, and (WCY) is a K3 surfaces or an Enriques surface (see eg. [2]).

Since the proof of Theorem 2.2 provides a good introduction on objects we are interested in, we give here a fairly complete proof, following [86, 90].

Proof. The most essential point is that any *canonically defined maps* are preserved by $\mathrm{Bir}(M)$.

Let $\kappa(M) \in \{-\infty, 0, 1, \cdots, l\}$ be the Kodaira dimension. $\kappa(M)$ is the maximal dimension of the images W_m under the pluri-canonical maps associated to the complete linear system $|mK_M|$ $(m = 1, 2, 3, \cdots)$:

$$\Phi_m := \Phi_{|mK_M|} : M \cdots \to W_m := \mathrm{Im}\, \Phi_{|mK_M|} \subset |mK_M|^* = \mathbf{P}^{\dim\, |mK_M|}\ ,$$

if $|mK_M| \neq \emptyset$ for some $m > 0$ and $\kappa(M) = -\infty$ otherwise. It is a birational invariant.

Consider first the case where $\kappa(M) \geq 0$. We may assume that Φ_m is regular. We can and do choose m so that $\dim W_m = \kappa(M)$ and Φ_m is of connected fibers. We write $W = W_m$. Note that any birational automorphism f preserves the set of global holomorphic pluri-canonical forms, as $\mathrm{codim}\, I(f) \geq 2$. Then the induced projective linear map $f_* \in \mathrm{PGL}(|mK_M|^*) = \mathrm{Aut}(|mK_M|^*)$ preserves W and is equivariant to f with respect to Φ_m. Hence f is imprimitive if $1 \leq \kappa(M) \leq l - 1$.

If $\kappa(M) = l$, then the same is true but M and W are birational. So

$$\mathrm{Bir}(M) = \mathrm{Aut}(W) \subset \mathrm{PGL}(|mK_M|^*).$$

It is Zariski closed in the affine noetherian group $\mathrm{PGL}(|mK_M|^*)$, as it is the stabilizer of the point $[W]$ of the action of $\mathrm{PGL}(|mK_M|^*)$ on $\mathrm{Hilb}(|mK_M|^*)$. Hence it is finite. Indeed, if otherwise, $\dim \mathrm{Aut}(W) \geq 1$ and we can choose a one dimensional algebraic subgroup, which is necessarily isomorphic to $\mathbf{C}$ or $\mathbf{C}^\times$. The Zariski closures of the orbits of general points of W under this 1-dimensional algebraic subgroup are necessarily rational, and cover W and M. Then again by the Hilbert scheme, we have a dominant holomorphic

maps $\pi : Y \to M$ from the fiber space $Y \to X$ whose general fibers Y_x are isomorphic to $\mathbf{P}^1$. Since we work over the field of characteristic 0, the map π is separable so that $|mK_Y| \neq \emptyset$ as well. Hence for general Y_x, we have $\deg mK_{Y_x} \geq 0$ by the adjunction formula, a contradiction to the fact that $Y_x \simeq \mathbf{P}^1$. Hence $\mathrm{Bir}\,(M)$ is finite and in particular, f is of finite order when $\kappa(M) = l$.

Hence $\kappa(M) = 0$ or $-\infty$. So far we did not use the assumption (MMP), (WA). Also, our assumption that f is of infinite order is used only to conclude $\kappa(M) \neq l$.

Assume that $\kappa(M) = 0$. Consider next the irregularity $q(M) := h^0(M, \Omega^1_M)$. If $q(M) > 0$, then we have the albanese morphism

$$\mathrm{alb}_M : M \to \mathrm{Alb}\,(M) = H^0(M, \Omega^1_M)^*/H_1(M, \mathbf{Z})\ .$$

It is classical that $\mathrm{Alb}\,(M)$ is an abelian variety. Since $\kappa(M) = 0$, a fundamental theorem due to Kawamata [46] (again free from (MMP), (WA)) says that alb_M is surjective with connected fibers, in particular $q(M) \leq l$. For the same reason as before, the action $\mathrm{Bir}\,(M)$ descends to the biregular action of $\mathrm{Alb}\,(M)$ equivariantly with respect to the albanese map. Hence either $q(M) = 0$ or $q(M) = l$. In the second case, M is birational to $\mathrm{Alb}\,(M)$. If $q(M) = 0$, then by our assumption (MMP), M is birational to a minimal Calabi-Yau variety. (Here, if one prefers, one also stops at the stage $\kappa(M) = 0$ and $q(M) = 0$. Then the conjectural (MMP) is not required here.)

It remains to treat the case $\kappa(M) = -\infty$. This is the most subtle case where we really use our assumptions (MMP) and (WA) (but we do not use our assumption that f is of infinite order anymore). (WA) is one way to conclude (MMP-1) and (MMP-2) are exclusive. Let us consider $W := M_{\min}$ in Theorem 2.2, whose existence needs (MMP). If K_W would be nef, then by (WA), $|mK_M| = |mK_W| \neq \emptyset$ for some $m > 0$, a contradiction to $\kappa(M) = -\infty$. Hence, the case (MMP-1) does not happen and therefore (MMP-2) happens by our assumptions (MMP). In (MMP-2), by the property of an extremal contraction, the fibers of the Mori fiber space are covered by rational curves. Now we consider the maximal rationally connected fibration, MRC fibration, for short [51]. The MRC fibration $r : M \cdots \to R$ is an almost holomorphic, rational dominant map such that for general $x \in M$, the fiber $M_p \ni x$ is the maximal rationally connected submanifold of M containing x, and birationally preserved by $\mathrm{Bir}\,(M)$, hence by f. Since $0 \leq \dim\, R \leq l - 1$ for our M, it follows that R is a point, i.e., M is rationally connected. □

(MMP) and (WA) hold in dimension ≤ 3, finally due to Mori [62] (MMP) and Kawamata [47] (WA) in the strongest form that nef $K_{V_{\min}}$ is actually semi-ample. So, Theorem 2.2 is unconditional in dimension ≤ 3. In higher dimension, both conjectures are expected to be true (cf. [13, 43, 64]). In dimension 2, Theorem 2.2 is essentially the same as the breakthough observation due to Cantat [19] (see also [22]), in terms of *topological entropy*.

2.2. Three classes of manifolds in Theorem 2.2. In this subsection, we discuss basic manifolds belonging to the three classes in Theorem 2.2, which are indeed the main objects in this note.

Rational manifolds. An excellent reference of rationally connected manifolds (RC manifolds) is [51]. Most basic examples of RC manifolds are rational manifolds, i.e., manifolds which are birational to $\mathbf{P}^l$. Note that $\mathrm{Aut}\,(\mathbf{P}^l) = \mathrm{PGL}(l+1, \mathbf{C})$. It is obvious that generic $g \in \mathrm{Aut}\,(\mathbf{P}^l)$ is of infinite order. On the other hand, any $g \in \mathrm{Aut}\,(\mathbf{P}^l)$ is imprimitive

if $l \geq 2$. Indeed, g has a fixed point $P \in \mathbf{P}^l$, corresponding to the eigenvector of a lift $\tilde{g} \in \mathrm{GL}(l+1, \mathbf{C})$. The family of lines through P is then stable under g. Let $\mathrm{Bl}_P \mathbf{P}^l$ be the blow up of $\mathbf{P}^l$ at P. The lines through P are the fibers of the natural morphism $\mathrm{Bl}_P \mathbf{P}^l \to \mathbf{P}^{l-1} = \mathbf{P}(T_{P,\mathbf{P}^l})$, and this fibration is stable under the natural (biregular) action of g.

So, *in our view*, $\mathrm{Aut}\,(\mathbf{P}^l) = \mathrm{PGL}\,(l+1, \mathbf{C})$ is not so interesting. However, the group $\mathrm{PGL}\,(l+1, \mathbf{C})$ has a very deep aspect in birational geometry, for instance, the following striking result due to Cantat [21]:

Theorem 2.4. *Let M be an l-dimensional projective manifold. If there is an injective group homomorphism $\mathrm{PGL}\,(n+1, \mathbf{C}) \to \mathrm{Bir}\,(M)$, as abstract groups, then $n \leq l$ and the equality $n = l$ holds if and only if M is rational. In particular, $\mathrm{Bir}\,(\mathbf{P}^l) \simeq \mathrm{Bir}\,(\mathbf{P}^{l'})$ as abstract groups if and only if $l = l'$.*

The *standard Cremona transformation*

$$\mathrm{cr}_l : \mathbf{P}^l \cdots \to \mathbf{P}^l \ , \ [x_0 : x_1 : \cdots : x_l] \mapsto \left[\frac{1}{x_0} : \frac{1}{x_1} : \cdots : \frac{1}{x_l}\right]$$

is the most basic birational non-biregular automorphism of $\mathbf{P}^l$ ($l \geq 2$). The indeterminacy locus of cr_l are $\cup_{i \neq j} L_{ij}$, where $L_{ij} := (x_i = x_j = 0)$. Let $\mathrm{SCr}_l := \langle \mathrm{PGL}(l+1, \mathbf{C}), \mathrm{cr}_l \rangle < \mathrm{Cr}_l := \mathrm{Bir}\,(\mathbf{P}^l)$. We have $\mathrm{SCr}_2 = \mathrm{Cr}_2$ (Noether's theorem, [35]). If $l \geq 3$, then SCr_l is much smaller than Cr_l but SCr_l is rich enough. One of unexpected applications of SCr_l is the following result due to Lesieutre [55]. In [55], the group SCr_3 and its complex dynamical aspect are effectively applied to prove the following derived categorical result:

Theorem 2.5. *There is a smooth rational threefold with infinitely many birational non-isomorphic Fourier-Mukai partners.*

Note that cr_l maps the coordinate hyperplane $H_i = (x_i = 0)$ to the standard coordinate point $e_i = [0 : \cdots : 0 : 1 : 0 : \cdots 0]$, where 1 is at the ith coordinate. So, $\mathrm{cr}_l \in \mathrm{Bir}\,(\mathbf{P}^l) \backslash \mathrm{PsAut}\,(\mathbf{P}^l)$. Actually $\mathrm{PsAut}\,(\mathbf{P}^l) = \mathrm{Aut}\,(\mathbf{P}^l)$ by $\mathrm{Pic}\,\mathbf{P}^l = \mathbf{Z}H$. However, if we blow-up $\mathbf{P}^l$ at the $(l+1)$ standard coordinate points e_i, then cr_l gives rise to a pseudo-automorphism $\tilde{\mathrm{cr}}_i$ of $\mathrm{Bl}_{\{e_i\}}\mathbf{P}^l$, and performing further blowing-ups, we can make it a biregular automorphism, of order 2. Let $S, T \in \mathrm{PGL}(l+1, \mathbf{C})$. Then $f = S \circ \mathrm{cr}_l \circ T^{-1} \in \mathrm{SCr}_l$ is of infinite order for almost all choices of S and T, and f lifts to a *pseudo-automorphism* of some blowing-ups of $\mathbf{P}^l$, under some periodicity condition for the indeterminacy loci $I(f^{\pm n})$ [6, 7, 9]. In this way, Bedford and Kim construct many interesting rational surface automorphisms as well as pseudo-automorphisms of rational threefolds very explicitly. However, when $l = 3$, none of them seems to be realized as a *biregular* automorphism (cf. Question 5.6).

A few properties of pseudo-automorphisms. Before entering two other classes, we recall a few basic properties of $\mathrm{PsAut}\,(M)$. The group $\mathrm{PsAut}\,(M)$ naturally acts on the Néron-Severi group $\mathrm{NS}\,(M) := \mathrm{Im}(c_1 : \mathrm{Pic}\,(M) \to H^2(M, \mathbf{Z}))$ as well as on $H^2(M, \mathbf{Z})$. This action is functorial, in the sense that $(f \circ g)^* = g^* \circ f^*$ on $H^2(M, \mathbf{Z})$ and preserves the Hodge decomposition of $H^2(M, \mathbf{Z})$ (but not the intersection (x^l) in general). For a minimal model in the sense (MMP-1), we have the following factorization. This fundamental result is due to Kawamata [48]:

Theorem 2.6. *Let M be a minimal model. Then* $\mathrm{Bir}\,(M) = \mathrm{PsAut}\,(M)$*, and any* $f \in \mathrm{Bir}\,(M)$ *is decomposed as* $f = \varphi \circ \iota_{m-1} \circ \cdots \circ \iota_0$*, where* $M_0 = M = M_m$ *and* $\iota_i : M_i \cdots \to M_{i+1}$ *(*$0 \leq i \leq m-1$*) are flops betweeen minimal models* M_i *and* M_{i+1} *and* $\varphi \in \mathrm{Aut}\,(M)$.

Complex tori, CY manifolds and HK manifolds. The case of complex tori is very much known (See [37, 78] for some dynamically interesting features in tori). Most basic examples of minimal Calabi-Yau varieties are CY manifolds and (projective) HK manifolds as defined below. CY manifolds, HK manifolds together with rational manifolds are the main objects in this note.

Definition 2.7. Let M be an l-dimensional simply-connected compact Kähler manifold.

(1) M is a Calabi-Yau manifold in the strict sense (*CY manifold*) if $l \geq 3$ and $H^0(M, \Omega^j_M) = 0$ for $0 < j \leq l-1$ and $H^0(M, \Omega^l_M) = \mathbf{C}\omega_M$, where ω_M is a nowhere vanishing holomorphic l-form.

(2) M is a compact hyperkähler manifold (*HK manifold*) if $H^0(M, \Omega^2_M) = \mathbf{C}\sigma_M$, where σ_M is an everywhere nondegenerate holomorphic 2-form.

Good references of CY manifolds and HK manifolds are [41, 56]. By definition, HK manifolds are of even dimension and K3 surfaces are nothing but HK manifolds of dimension 2. CY manifolds M are always projective by $h^0(\Omega^2_M) = 0$ (as $l \geq 3$). On the other hands, both projective HK manifolds and non-projective HK manifolds are dense both in the Kuranishi space and in the global moduli space of marked HK manifolds [38, 44]. Examples with interesting (birational) automorphisms in our view will be given in Sections 4, 5, 6.

The importance of CY manifolds and HK manifolds in complex algebraic geometry lies in the fact, called the Bogomolov decomposition theorem [4], that these two classes of manifolds together with complex tori form the building blocks of compact Kähler manifolds with trivial first Chern class.

We close this section by the following:

Remark 2.8. Let M be a CY manifold or a projective HK manifold and $G < \mathrm{Bir}\,(M) = \mathrm{PsAut}\,(M)$. Assume that there is an ample divisor H such that $f^*H = H$ in $\mathrm{Pic}\,(M) \simeq \mathrm{NS}\,(M)$ for all $f \in G$. Then $G < \mathrm{Aut}\,(M)$ and G is a finite group. In particular, if $\rho(M) := \mathrm{rank}\,\mathrm{NS}\,(M) = 1$, then $\mathrm{Bir}\,(M) = \mathrm{Aut}\,(M)$ and it is a finite group. *So, in our view, interesting cases are* $\rho(M) \geq 2$.

Indeed, the same argument as in Theorem 2.2, applied for the G-equivariant embedding $\Phi_{|mH|} : M \to |mH|^*$ for large $m > 0$, shows that $G < \mathrm{Aut}\,(M)$ and at the same time G is a Zariski closed algebraic subgroup of $\mathrm{PGL}\,(|mH|^*)$. Since $\dim G = 0$ by $H^0(M, TM) = 0$, the result follows.

3. Topological entropy and Dynamical degrees

3.1. Topological entropy. References of this subsection are [40, 45].
Let $X = (X, d)$ be a compact metric space and $f : X \to X$ be a continuous surjective selfmap of X. We denote by f^n the n-th iterate of f. The *topological entropy* of f is the fundamental invariant that measures *how fast two general points spread out under the*

action of the semi-group $\{f^n | n \in \mathbf{Z}_{\geq 0}\}$, hence, presents a kind of complexity of f. For the definition, we define the new distance $d_{f,n}$ on X by

$$d_{f,n}(x,y) = \max_{0 \leq j \leq n-1} d(f^j(x), f^j(y)) \text{ for } x, y \in X.$$

Under the identification $x \leftrightarrow \mathbf{x}^{(n)} := (x, f(x), \cdots, f^{n-1}(x))$, the new distance $d_{f,n}(x,y)$ is the distance of the graph

$$\Gamma_{f,n} := \{\mathbf{x}^{(n)} = (x, f(x), \cdots, f^{n-1}(x)) \,|\, x \in X\} \subset X^n$$

induced by the product distance on X^d. The first projection $\mathrm{pr}_1 : (\Gamma_{f,n}, d_{f,n}) \to (X, d_{f,n})$ is an isometry and $\mathrm{pr}_1 : (\Gamma_{f,n}, d_{f,n}) \to (X, d)$ is a homeomorphism.

Let $\epsilon > 0$ be a positive real number. We call two points $x, y \in X$ (n, ϵ)-*separated* if $d_{f,n}(y,x) \geq \epsilon$, and a subset $F \subset X$ (n, ϵ)-*separated* if any two distinct points of F are (n, ϵ)-separated. Let

$$N_d(f, n, \epsilon) := \mathrm{Max}\,\{|F| \mid F \subset X \text{ is } (n,\epsilon) - \text{separated } \}\ .$$

Note that $N_d(f, n, \epsilon)$ is a well-defined positive integer, because X is compact.

Remark 3.1. Please imagine that $\epsilon > 0$ is "very very small", so that we can *not* distinguish two points $x, y \in X$ with $d(x,y) < \epsilon$ by "our eyes" but can do if $d(x,y) \geq \epsilon$. Then, we can not distinguish x, y if they are not $(1, \epsilon)$-separated but we can distinguish them by performing f if they are $(2, \epsilon)$-separated. Similarly, we can distinguish x, y at some stage, say $f^j(x), f^j(y)$ $(0 \leq j \leq n-1)$, if they are (n, ϵ)-separated. In this sense, $N_d(f, 1, \epsilon)$ is the maximal number of points of X distinguished by eyes and $N_d(f, n, \epsilon)$ is the maximal number of points of X distinguished by eyes after performing f^j $(0 \leq j \leq n-1)$. So, roughly, the growth of the sequence $\{N_d(f, n, \epsilon)\}_{n \geq 1}$ measures how fast general points spread out under the iterations of f to be distinguishable by our eyes (if it will be).

Definition 3.2. The *topological entropy*, or *entropy* for short, of f is:

$$h_{\mathrm{top}}(f) := h_d(f) := \lim_{\epsilon \to +0} h_d(f, \epsilon)\ ,$$

where

$$h_d(f, \epsilon) := \limsup_{n \to \infty} \frac{\log N_d(f, n, \epsilon)}{n}\ .$$

Since $\log N_d(f, n, \epsilon) \geq 0$ is an increasing function of $\epsilon > 0$, the limit exists in $[0, \infty]$ (possibly ∞). More or less from the definition, we obtain:

Corollary 3.3.

(1) $h_{\mathrm{top}}(f)$ *is a topological invariant, in the sense that* $h_{d'}(f) = h_d(f)$ *for any distance* d' *of* X *such that* (X, d') *and* (X, d) *are homeomorphic.*

(2) *If* $h_{\mathrm{top}}(f) > 0$*, then* $f^m \neq id_X$ *for all* $m \geq 1$*, i.e.,* $\mathrm{ord}\,(f) = \infty$.

(3) *If* f *is an isometry, for instance a translation of a torus, then* $h_{\mathrm{top}}(f) = 0$*. In particular, the converse of (2) is not necessarily true.*

(4) $h_{\mathrm{top}}(f \times f') = h_{\mathrm{top}}(f) + h_{\mathrm{top}}(f')$ *where* f' *is a surjective selfmap of a compact metric space* $X' = (X', d')$.

Example 3.4. Let E be a 1-dimensional complex torus. Consider the abelian surface $A = E \times E$ and its surjective endomorphism $f_M(x) = Mx$ given by $M \in M(2, \mathbf{Z})$ with $\det M \neq 0$. Note that $f_M \in \mathrm{Aut}\,(A)$ if $\det M = \pm 1$. Let α, β be the eigenvalues of M such that $|\alpha| \leq |\beta|$. Then, according to the three cases (i) $|\alpha| \geq |\beta| \geq 1$, (ii) $|\alpha| \geq 1 \geq |\beta|$, (iii) $1 \geq |\alpha| \geq |\beta|$, the entropy $h_{\mathrm{top}}(f_M)$ is (i) $\log |\alpha\beta|^2$, (ii) $\log |\alpha|^2$, (iii) $\log 1 = 0$. In particular, $h_{\mathrm{top}}(f_M) = \log \eta^2 > 0$, the natural logarithm of (the square of) the golden number, for the Lie automorphism $f_M \in \mathrm{Aut}\,(A)$ given by

$$M = \begin{pmatrix} 2 & 1 \\ -1 & -1 \end{pmatrix} .$$

Very rough idea is as follows. For simplicity, we further assume that M is diagonalizable in $M(2, \mathbf{C})$. We fix the flat distance d on A from the universal cover $\mathbf{C}^2$. Let $\epsilon > 0$ be a very small number. Let us cover A by N mutually disjoint complex 2-dimensional ϵ-"parallelograms" (actual real dimension is 4) that are parallel to the complex eigenvectors of M. Then $N(f_M, 1, \epsilon)$ is about N. Next divide each of N ϵ-parallelograms into mutually disjoint ϵ-parallelograms with respect to the distance $d_{f_M,2}$. In case (i), each original parallelogram is devided into about $|\alpha\beta|^2$ new parallelograms, because $|\alpha| \geq 1$ and $|\beta| \geq 1$ (and real dimension is $2 + 2$). Therefore, $N(f_M, 2, \epsilon)$ is about $|\alpha\beta|^2 N$. In case (ii), each parallelogram is devided into $|\alpha|^2$ new parallelogram, because $|\alpha| \geq 1$ but $|\beta| \leq 1$. Therefore, $N(f_M, 2, \epsilon)$ is about $|\alpha|^2 N$. Similarly, in case (iii), $N(f_M, 2, \epsilon)$ remains N. Repeating this, we see that $N(f_M, n, \epsilon)$ is about $|\alpha\beta|^{2(n-1)} N$, $|\alpha|^{2(n-1)} N$, N according to the three cases (i), (ii), (iii). This implies the result.

Note that in each case, the entropy is the natural logarithm of the spectral radius of $f_M^* | H^*(A, \mathbf{Z})$. Actually, this is *not accidental* as we will explain in the next subsection.

3.2. Fundamental theorem of Gromov-Yomdin. References of this subsection are [33, 34, 39, 40, 89] (see also [22]).

Let M be a compact Kähler manifold of dimension l and η be any Kähler form on M. Then M is a compact metric space by the distance defined by η. Let $f : M \to M$ be a surjective holomorphic map. Then f^* naturally acts on the k-th cohomology group $H^k(M, \mathbf{Z})$ as well as each Hodge component $H^{p,q}(M)$. We define $r_p(f)$ to be the *spectral radius* of $f^* | H^{p,p}(M)$, that is, the maximum absolute value of eigenvalues of $f^* | H^{p,p}(M)$. Similarly, we denote by $r(f)$ (resp. $r^{\mathrm{even}}(f)$) the spectral radius of f^* on $\oplus_{k=0}^{2l} H^k(M, \mathbf{Z})$ (resp. $\oplus_{p=0}^{l} H^{2p}(M, \mathbf{Z})$).

We define the *p-th dynamical degree* $d_p(f)$ by

$$d_p(f) := \lim_{n \to \infty} (\delta_p(f^n))^{\frac{1}{n}} ,$$

where

$$\delta_p(f^n) := (\int_M (f^n)^*(\eta^p) \wedge \eta^{l-p}) = ([(f^n)^*(\eta^p)].[\eta^{l-p}])_M .$$

Here $(*, **)_M$ is the intersection number. The limit does not depend on the choice of η once the existence is guaranteed. Indeed, for two Kähler forms η and η', there are positive real number C and a Kähler form η" such that $C[\eta] = [\eta'] + [\eta"]$ in $H^{1,1}(M, \mathbf{R})$. The fact that the limit exists is non-trivial. There are many ways to see it. For instance, it is an immediate consequence of the following crucial observation by Dinh-Sibony, which holds also for *rational* dominant selfmaps [33, 34]:

Theorem 3.5. *There is a constant $C = C_{M,\eta}$ depending only on M and η (but not on f and g) such that*

$$\delta_p(f \circ g) \leq C\delta_p(f)\delta_p(g) \ ,$$

for any two dominant holomorphic selfmaps $f : M \to M$, $g : M \to M$.

The logarithmic volume $\mathrm{lov}\,(f)$, introduced by Gromov, is

$$\mathrm{lov}\,(f) := \mathrm{limsup}_{n\to\infty} \frac{\log \mathrm{Volume}(\Gamma_{f,n})}{n} \ ,$$

where

$$\mathrm{Volume}(\Gamma_{f,n}) := \frac{1}{l!}\int_{\Gamma_{f,n}} (\sum_{i=1}^{n} \mathrm{pr}_i^* \eta_M)^l \ .$$

The following fundamental theorem is due to Gromov-Yomdin:

Theorem 3.6. *Let M be a compact Kähler manifold of dimension l and $f : M \to M$ be a surjective holomorphic map. Then, $d_p(f) = r_p(f)$ and*

$$h_{\mathrm{top}}(f) = \mathrm{lov}\,(f) = \log \mathrm{max}_{0\leq p\leq l}\, d_p(f) = \log \mathrm{max}_{0\leq p\leq l}\, r_p(f) = \log r^{\mathrm{even}}(f) = \log r(f) \ .$$

Moreover, if M is projective, then $h_{\mathrm{top}}(f)$ is also equal to the natural logarithm of the spectral radius of $f^*|\oplus_p H^{p,p}(M, \mathbf{Z})$.

This theorem opens the door to compute the entropy of a biregular automorphism by algebro-geometric methods. For instance, Example 3.4 is immediate from this theorem; one may just compute $r_p(f)$ for $p = 0, 1, 2$. Moreover, $d_p(f)$ and $r_p(f)$ can be regarded as *finer* invariants of f than $h_{\mathrm{top}}(f)$, while geometric meanings become less apparent.

Corollary 3.7.

(1) $h_{\mathrm{top}}(f) = 0$ *if* $\dim\, M = 1$, *and also* $h_{\mathrm{top}}(f) = 0$ *for* $f \in \mathrm{Aut}^0(M)$ *(the identity component of* $\mathrm{Aut}\,(M)$*). For instance,* $h_{\mathrm{top}}(f) = 0$ *if* $f \in \mathrm{Aut}\,(\mathbf{P}^d)$ *or again if f is a translation automorphism of a complex torus.*

(2) *The topological entropy is the natural logarithm of an algebraic integer.*

Indeed, (1) is clear by Theorem 3.6. Since the eigenvalues of $f^*|H^*(M, \mathbf{Z})$ are algebraic integers, (2) follows from Theorem 3.6.

Corollary 3.8.

(1) $d_0(f) = 1$ *and* $d_l(f) = \deg f$, *the topological degree of f.*

(2) *The sequence* $\{d_p(f)\}_{0\leq p\leq l}$ *is log-concave, i.e.,* $d_{p-1}(f)d_{p+1}(f) \leq d_p(f)^2$.

(3) $d_p(f) \geq 1$ *for all p and,*

(4) $h_{\mathrm{top}}(f) > 0$ *if and only if* $d_1(f) > 1$.

(1) is clear by definition. We have $\delta_{p-1}(f)\delta_{p+1}(f) \leq \delta_p(f)^2$ by the Hodge index theorem (when M is projective and η is chosen to be a Hodge metric) and by the Tessier-Khovanski inequality in general case. Then (2) follows from (1), and (2) implies (3), (4).

Very brief outline of the proof of Theorem 3.6 is as follows [33, 40]. Note the *obvious* relation $(f^n)^* = (f^*)^n$ for $f \in \mathrm{Aut}\,(M)$. Then $d_p(f) = r_p(f)$ follows from linear algebra

plus the Perron-Frobenious theorem on the linear maps preserving a strict convex cone. So, $d_p(f) = r_p(f) \leq r^{\rm even}(f) \leq r(f)$. The deepest part is $h_{\rm top}(f) \geq \log r(f)$ for any compact oriented Riemannian C^∞-manifolds and surjective oriented C^∞-map $f : M \to M$. This is due to Yomdin [89] (see also [40]). Gromov [39] proved the reverse inequality $h_{\rm top}(f) \leq {\rm lov}\,(f) = \log \max_{0\leq p\leq k} d_p(f)$. The essential part of this inequality is that if $F \subset M$ is (n, ϵ)-separated, then the corresponding subset $\mathbf{F}^{(n)}$ in the graph $\Gamma_{f,n}$ is $(1, \epsilon)$-separated, and therefore the balls $\Gamma_{f,n} \cap B(\mathbf{x}^{(n)}, \epsilon/2)$ ($\mathbf{x}^{(n)} \in \mathbf{F}^{(n)}$) are mutually disjoint. This gives an obvious estimate of ${\rm Volume}\,(\Gamma_{f,n})$ from the below and leads the first inequality, via Lelong's theorem. ${\rm lov}\,(f) = \max_{0\leq p\leq d} d_p(f)$ is non-trivial but doable by fairly straightforward computations of the differential forms, *at least when f is holomorphic*.

See also [28] for derived categorical approach for the topological entropy.

3.3. Generalization for rational mappings after Dinh-Sibony. References of this subsection are [33, 34, 42] (see also [22]).

Let M be a compact Kähler manifold of dimension l, and $f : M \cdots \to M$ be a dominant rational selfmap. The topological entropy $h_{\rm top}(f)$ is defined in the same way as in the holomorphic case, just by considering the well-defined orbits, i.e., $\{f^k(x)\}_{k=0}^{n-1}$ with $f^k(x) \notin I(f)$ at each n-th step. The logarithmic volume ${\rm lov}\,(f)$ is defined again in the same way as above, just by taking the graph $\Gamma^0_{f,n}$ over $M \setminus \cup_{k=0}^{n-1} I(f^k)$ at each n-th step [33, 42].

The pullback operation $f^* : H^{p,p}(M) \to H^{p,p}(M)$ is well-defined if one uses *currents*. Let $\tilde{M}$ be a resolution of the indeterminacy of f and $p_i : \tilde{M} \to M$ $(i = 1, 2)$ be the natural projections. Then for any closed (p, p)-form α, we define $f^*(\alpha) = (p_1)_* p_2^*(\alpha)$, where p_2^* is the natural pullback as forms and $(p_1)_*$ is the natural pushforward as currents, i.e., $\langle (p_1)_*(p_2^*(\alpha)), \beta\rangle_M := \langle p_2^*(\alpha), p_1^*(\beta)\rangle_{\tilde{M}}$. The action f^*naturally descends to the linear action on $H^{p,p}(M)$. So, the definitions of $\delta_p(f)$ and the p-th dynamical degree $d_p(f)$ make sense without any change. $d_p(f)$ does not depend on the choice of η for the same reason as before, again once the existence of the limit is guaranteed. However, there is one crucial difference from the holomorphic case; $(f\circ g)^* \neq g^*\circ f^*$ *and* $(f^n)^* \neq (f^*)^n$ *in general.* This already happens for the standard Cremona transformation ${\rm cr}_l$ of $\mathbf{P}^l$ and makes outlined proof in the holomorphic case delicate at all the places where we freely use them. For instance, in general, there is no way to compare $d_p(f)$ and $r_p(f)$. Dinh and Sibony [33, 34] proved:

Theorem 3.9. *Let X be a compact Kähler manifold of dimension l and $f : M \cdots \to M$ be a dominant, rational map (= meromorphic map, by our convention). Then, Theorem 3.5 holds for rational dominat maps and*

$$h_{\rm top}(f) \leq {\rm lov}\,(f) = \log \max_{0\leq p\leq d} d_p(f)\ .$$

Moreover $d_p(f)$ are birational invariants in the sense that $d_p(f) = d_p(\varphi \circ f \circ \varphi^{-1})$ for any birational map $\varphi : M \cdots \to M'$ between compact Kähler manifolds.

On the other hand, $h_{\rm top}(f)$ is *not* a birational invariant by Guedj [42]:

Example 3.10. Let $f : \mathbf{C}^2 \to \mathbf{C}^2$ be a morphism defined by $(x, y) \to (x^2, y + 1)$. Then f naturally extends to a rational selfmap f_1 of $\mathbf{P}^2$ and a holomorphic selfmap f_2 of $\mathbf{P}^1 \times \mathbf{P}^1$. Then, $h_{\rm top}(f_1) = 0$ but $h_{\rm top}(f_2) = \log 2 > 0$.

Because of the birational invariance of dynamical degrees, one can define dynamical degrees for a dominant selfmap of a singular compact complex space of class $\mathcal{C}$ in an obvious

manner, but not the topological entropy in this way. For this reason, dynamical degrees fit well more with birational geometry than the entropy. They are also useful when we study *biregular* automorphisms in Problem 1.1, as we shall see in concrete cases in Section 5.

The essential part of the proof of Theorems 3.5, 3.9 and their variants later is a deep theory of semi-regularization of currents, very roughly, a method for approximating currents well by sequences of smooth forms. Once such semi-regularization results are well established, then the proof goes along the same line as in the holomorphic case *if one carefully replaces all necessary estimates for currents by those of semi-regularizing smooth forms*.

For a rational dominant selfmap f, Corollary 3.7 (2) *is expected to be true but unknown*. For instance, (2) is true for $d_1(f)$ if $f \in \mathrm{PsAut}\,(M)$. This is because then $(f^n)^* = (f^*)^n$ on $H^2(M, \mathbf{R})$, hence $d_1(f) = r_1(f)$ for the same reason as in the holomorphic case. Corollary 3.8 (1), (2), (3), being free from $h_{\mathrm{top}}(f)$, is clearly true, but (4) is *not true* as Example 3.10 shows.

3.4. Relative dynamical degrees after Dinh-Nguyên-Truong. References of this subsection are [30] and [31]. Corollary 3.3 (3) or dynamical degrees of the product map $f \times f' : X \times X' \to X \times X'$ suggests a good notion of relative dynamical degrees with nice properties. If exists, then it will provide a useful numerical criterion for the primitivity of a selfmap, as we shall test in some concrete cases in Section 5.

Setting I. *Let $f : M \cdots \to M$, $g : B \cdots \to B$ be dominant rational maps such that $\pi \circ f = g \circ \pi$. Here $\pi : M \to B$ is a surjective holomorphic map between compact Kähler manifolds M and B of dimensions l and b (necessarily $l \geq b$) with Kähler forms η_M and η_B.*

In Setting I, we define *the relative dynamical degrees* $d_p(f|\pi)$ by

$$d_p(f|\pi) := \lim_{n\to\infty} \left(\int_M (f^n)^*(\eta_M^p) \wedge \pi^*(\eta_B^b) \wedge \eta_M^{l-p-b} \right)^{1/n} , \ 0 \leq p \leq l-b \ .$$

This definition is due to Dinh and Nguyên [30]. If we take η_B so that η_B^b is the Poincaré dual of a point and *virtually identify* all the fibers M_b and regard then $f|M_b : M_b \cdots \to M_{g(b)}$ as the *virtual selfmap* of M_b, then $d_p(f|\pi)$ is the same form as the p-th dynamical degree of the *virtual* $f|M_b$. Note also that $\pi^*(\eta_B^b) \wedge \eta_M^{l-p-b}$ is a form as π is *holomorphic* and $(f^n)^*(\eta_M^p)$ is a current of proper bidegree. So the integration in the right hand side makes sense. This is the reason why we assume that π is holomorphic. The existence of the limit is again non-trivial, but settled by [30] and [31]. The following fundamental result is due to Dinh-Nguyên-Truong [30, 31]:

Theorem 3.11. *In Setting I, for all $0 \leq p \leq l$,*

$$d_p(f) = \max_j d_j(g) d_{p-j}(f|\pi) \ .$$

Here j runs through all the integers for which the integrations defining $d_j(g)$ and $d_{p-j}(f|\pi)$ are meaningful, i.e., j runs through $\max\{0, p-l+b\} \leq j \leq \min\{p, b\}$. Moreover, $\{d_p(f|\pi)\}_p$ satisfy $d_{p-1}(f|\pi) d_{p+1}(f|\pi) \leq d_p(f|\pi)^2$ (the log-concavity) and they are birational invariants in an obvious sense, within Setting I.

That π is holomorphic in Theorem 3.11 appears slightly restrictive, compared with usual situations, and the most natural setting is probably the following:

Setting II. *$\pi' : M' \cdots \to B'$ is a dominant rational map from an l-dimensional compact complex variety M' of class $\mathcal{C}$ to a compact complex variety B' of dimension b, equivariant with rational dominant selfmaps f' and g' of M' and B'.*

In Setting II, B' is of class $\mathcal{C}$ by the original definition of class $\mathcal{C}$, and therefore, there is a birational morphism $\varphi : B \to B'$ from a compact Kähler manifold B as well. Then resolving the indeterminacy of the rational map $\varphi^{-1} \circ \pi'$ from M' to B, we obtain a *holomorphic* surjective morphism between compact Kähler *manifolds* $\pi : M \to B$. Moreover, π is equivariant to the rational dominant selfmaps f and g of M and B, naturally induced from f' and g'. This is exactly Setting I in Theorem 3.11. By the birational invariance of dynamical degrees, we have $d_p(f) = d_p(f')$, $d_p(g) = d_p(g')$. Moreover, by the birational invariance of the relative dynamical degrees in Setting I in Theorem 3.11, we *can define* $d(f'|\pi') := d(f|\pi)$ which is independent of the choice of models $\pi : M \to B$. Then, the equation in Theorem 3.11 is nothing but the equation $d_p(f') = \max_j d_j(g')d_{p-j}(f'|\pi')$ in Setting II. Therefore:

Corollary 3.12. *Theorem 3.11 is true also in the* Setting II.

Note that $d_0(f'|\pi') = 1$ and $d_{l-b}(f'|\pi')$ is the topological degree of $f'|M_t : M_t \cdots \to M_{g'(t)}$ for a generic fiber M'_t ($t \in B$). The log-concavity then implies that $d_p(f'|\pi') \geq 1$ for any meaningful p as before.

Since only $d_0(f|\pi) = 1$ is the meaningful relative dynamical degree for a generically finite map, we obtain the following [30, 31] from Theorem 3.12:

Corollary 3.13.

(1) *The dynamical degrees are invariant under any equivariant generically finite dominant maps, i.e., if $\pi : M \cdots \to B$ is a generically finite dominant rational map equivariant to the rational dominant selfmaps f, g of M, B, then $d_p(f) = d_p(g)$ for every p.*

(2) *The topological entropy of dominant holomorphic selfmaps of compact Kähler manifolds are invariant under equivariant generically finite dominant rational maps. More precisely, in (1), if both M and B are compact Kähler manifolds and f and g are holomorphic, then $h_{\mathrm{top}}(f) = h_{\mathrm{top}}(g)$.*

(2) follows from (1) and Theorem 3.6.

Our primary interest in Theorem 3.11 is its applicability for primitivity of rational selfmaps. When $l = \dim M \leq 3$, we can deduce the following fairly useful *numerical* criterion for the primitivity of $f \in \mathrm{Bir}\, M$ from Theorem 3.11. (1) is known before Theorem 3.11 and (2) is due to Truong and myself [79]:

Corollary 3.14. *Let M be a compact Kähler manifold and $f \in \mathrm{Bir}\,(M)$.*

(1) *Assume that $\dim M = 2$. Then f is primitive if $d_1(f) > 1$. In particular, $f \in \mathrm{Aut}\,(M)$ is primitive if $h_{\mathrm{top}}(f) > 0$.*

(2) *Assume that $\dim M = 3$. Then f is primitive if $d_1(f) \neq d_2(f)$.*

Outline of (2) is as follows. Assume that f is imprimitive. Then there are a compact Kähler manifold B, dominant rational maps $\pi : M \cdots \to B$, $g : B \cdots \to B$ such that $\pi \circ f = g \circ \pi$. Here $0 < \dim B < 3 = \dim M$. We consider the case $\dim B = 2$ (the case $\dim B = 1$ is similar). Then by Corollary 3.12, we have

$$d_1(f) = \max\{d_1(g), d_1(f|\pi)\}\ ,\ d_2(f) = \max\{d_1(f|\pi)d_1(g), d_2(g)\}\ .$$

Since f and g are birational, $d_3(f) = d_2(g) = 1$. Thus, by Corollary 3.12, $1 = d_3(f) = d_2(g)d_1(f|\pi)$, hence, $d_1(f|\pi) = 1$. So, $d_1(f) = \max\{d_1(g), 1\} = d_2(f)$.

4. Surface automorphisms in the view of entropy

In this section, we take a closer look at surface automorphisms of positive entropy. They are primitive by Corollary 3.14(1). We assume some familiarity with classification of surfaces. A good reference is [2] with [35] for rational surfaces. Throughout this section, S is a smooth compact Kähler surface.

4.1. Surface automorphisms of positive entropy. We note that a birational automorphism $f \in \mathrm{Bir}\,(S)$ naturally induces a *biregular* automorphism of the minimal model $S_{\min}$ of the same dynamical degrees (Theorem 3.9) if $\kappa\,(S) \geq 0$. In this way, one can almost recover from Theorem 2.2 the following breakthrough observation due to Cantat [19]:

Theorem 4.1. *Assume that S admits an automorphism $f \in \mathrm{Aut}\,(S)$ of positive entropy, i.e., $d_1(f) > 1$. Then S is birational to either (i) $\mathbf{P}^2$, (ii) a K3 surface, (iii) a 2-dimensional complex torus, or (iv) an Enriques surface. In the case (i), S is a blow up of $\mathbf{P}^2$ at 10 or more points, possibly infinitely near [63].*

Recall that $d_1(f) = r_1(f) > 1$ is an algebraic integer (Corollary 3.7 (2)). It turns out to be a special algebraic integer of even degree, called a *Salem number*:

Definition 4.2. An irreducible monic polynomial $S(x) \in \mathbf{Z}[x]$ is called a *Salem polynomial* if the complex roots are of the following form (*possibly* $d = 1$):

$$a \in (1, \infty)\ ,\ 1/a \in (0,1)\ ,\ \alpha_i, \overline{\alpha_i} \in S^1 := \{z \in \mathbf{C}\,|\,|z| = 1\} \setminus \{\pm 1\} (1 \leq i \leq d-1)\ .$$

The unique root $a > 1$ is called a *Salem number* of degree $2d$ $(= \deg S(x))$.

The smallest *known* Salem number is the *Lehmer number* which is the unique root > 1 of the following Salem polynomial of degree 10:

$$x^{10} + x^9 - x^7 - x^6 - x^5 - x^4 - x^3 + x + 1\ .$$

It is approximately 1.17628 and conjectured to be the minimum among all Salem numbers. So far, this conjecture is neither proved nor disproved.

The following theorem is due to McMullen [57–59]:

Theorem 4.3. *Let $f \in \mathrm{Aut}\,(S)$ and assume that $d_1(f) > 1$. Then, $d_1(f)$ is a Salem number, and $d_1(f)$ is always greater than or equal to the Lehmer number.*

See also [60, 61, 73, 81, 85] for relevant results.

4.2. Examples of surface automorphisms of positive entropy. There is a huge number of works concerning automorphisms of surfaces. Here among many examples, I present four examples which are smoothly connected to the topics in the next sections.

Example 1 - Rational surface automorphisms. Recall that any birational automorphism of $\mathbf{P}^2$ is expressed by two rational functions of the affine coordinates $(x = x_2/x_1, y = x_3/x_1)$ of $\mathbf{P}^2_{[x_1:x_2:x_3]}$. Consider the birational automorphism of the following special form ([59], also compare with an earlier form in [6]):

$$f^*(x,y) := f^*_{(a,b)}(x,y) := (a+y, b+\frac{y}{x}) \ , \ a,b \in \mathbf{C} \ .$$

$I(f)$ is the set of coordinate points $\{e_1, e_2, e_3\}$ and $I(f^{-1})$ is $\{e_2, e_3, e_4\}$, where $e_4 := (a,b)$. Set $e_{k+4} := f^k(e_4)$. Choose (a,b) so that $e_k \notin e_1e_2 \cup e_2e_3 \cup e_3e_1$ for all $4 \leq k \leq n$ with $n \geq 10$ and $e_{n+1} = e_1$ (periodicity condition of indeterminacies). Then one can realize f as an automorphism of $S = S_n$, the blowing-ups of $\mathbf{P}^2$ at the n points e_k. This f also realizes the Coxeter element c_n of the Weyl group $W(E_n)$ in the sense that $f^* = c_n$ on $H^2(S, \mathbf{Z})$ under the natural identification $E_n = K_S^{\perp}$ and $W(E_n) < \mathrm{O}\,(H^2(S, \mathbf{Z}))$, hence of positive entropy. For instance, f with $n = 10$ and $(a,b) = (0.4995..., -0.0837...)$ realizes the Lehmer first dynamical degree and f with $n = 11$ and (a,b) approximately $(0.0444 - 0.4422i, 0.0444 + 0.4422i)$ has a Siegel domain (cf. Example 4). The actual construction in [59] is not merely the numerical one but is based on an explicit marked Torelli type result for log K3 surfaces (S, C) with C being a unique cuspidal rational curve in $|-K_S|$.

Example 2 - Birational automorphisms after Diller-Favre. Reference here is [27]. Let $c \in \mathbf{C}$ and consider the birational automorphism of $\mathbf{P}^1 \times \mathbf{P}^1$ defined by the following affine form:

$$f_c(x,y) := (y+1-c, x\frac{y-c}{y+1}) \ .$$

[27] computes the first dynamical degree of f_c and observes many interesting features, depending on $c \in \mathbf{C}$. For instance, if c is irrational, then $d_1(f_c) = \eta$, the golden number. Note that the golden number is *not* a Salem number, so that f_c with irrational c can *never* be realized as a biregular automorphism of any smooth birational models.

Example 3 - Cayley's K3 surface after Festi, Garbagnati, van Geemen and van Luijk. In the long history of automorphisms of K3 surfaces or more specifically those of smooth quartic surfaces, Cayley seems the first who suggested the existence of automorphisms of infinite order. Here we explain his beautiful, very explicit construction, following a modern elegant account [36]. This example will be also used to construct higher dimensional HK example in Section 6.

Let a_{ijk} $(1 \leq i,j,k \leq 4)$ be 4^3 generic complex numbers. Let us consider the following determinantal quartic surface in $\mathbf{P}^3$ with homogeneous coordinates $\mathbf{x} = [x_1 : x_2 : x_3 : x_4]$:

$$S_0 := (\det M_0(\mathbf{x}) = 0) \subset \mathbf{P}^3_{\mathbf{x}} \ ,$$

where $M_0 = M_0(\mathbf{x}) := (\sum_i a_{ijk}x_i)_{k,j}$ is the 4×4 matrix whose (k,j) entry is $\sum_i a_{ijk}x_i$. By our genericity assumption, $\mathrm{rank}\, M_0(\mathbf{x}) = 3$ for all $\mathbf{x} \in S_0$ and S_0 is a smooth quartic K3 surface. One can also construct two more smooth determinantal quartic K3 surfaces from a_{ijk}:

$$S_1 := (\det M_1(\mathbf{y}) = 0) \subset \mathbf{P}^3_{\mathbf{y}} \ , \ S_2 := (\det M_2(\mathbf{z}) = 0) \subset \mathbf{P}^3_{\mathbf{z}} \ .$$

Here $M_1 = M_1(\mathbf{y}) := (\sum_i a_{ijk}y_j)_{i,k}$, $M_2 = M_2(\mathbf{z}) := (\sum_i a_{ijk}z_k)_{j,i}$.

Let P_i be the cofactor matrix of M_i. Then,

$$P_iM_i = M_iP_i = \det(M_i)\cdot I_4 \text{ and } \mathbf{x}M_1(\mathbf{y}) = (\sum_{i,j} a_{ijk}x_iy_j)_k = \mathbf{y}M_0(\mathbf{x})^t \ .$$

Recall that $\mathrm{rank}\,(M_0(\mathbf{x})) \geq 3$ for each $\mathbf{x} \in \mathbf{P}^3$ and the same for $M_1(\mathbf{y})$, $M_2(\mathbf{z})$. Thus, the j-th column $(p_{ij}(\mathbf{x}))_i$ of $P_0 = P_0(\mathbf{x})$ gives a *Cremona transformation* $\varphi_0 : \mathbf{P}^3_{\mathbf{x}} \cdots \to \mathbf{P}^3_{\mathbf{y}}$ that maps S_0 to S_1, hence, an isomorphism $\varphi_0|S_0 : S_0 \to S_1$. In the same way, we have two more Cremona transformations $\varphi_1 : \mathbf{P}^3_{\mathbf{y}} \cdots \to \mathbf{P}^3_{\mathbf{z}}$, $\varphi_2 : \mathbf{P}^3_{\mathbf{z}} \cdots \to \mathbf{P}^3_{\mathbf{x}}$ and isomorphisms $\varphi_1|S_1 : S_1 \to S_2$, $\varphi_2|S_2 : S_2 \to S_0$. In this way, we obtain an *explicit* automorphism of S_0: $g := \varphi_2 \circ \varphi_1 \circ \varphi_0$. This is the automorphism that *Cayley first found around 1870 and said that "The process may be indefinitely repeated"* [25, 36].

As observed by [36], in modern terminologies, a characterization of linear determinantal varieties [5] with our genericity assumption says that S_0 is nothing but a K3 surface with

$$\mathrm{NS}\,(S_0) = (\mathbf{Z}h_1 \oplus \mathbf{Z}h_2, \begin{pmatrix} 4 & 6 \\ 6 & 4 \end{pmatrix}) = (\mathbf{Z}[\eta], 4\mathrm{Nm}(*)) \ , \ \mathrm{Nm}(a+b\eta) = a^2 + ab - b^2 \ .$$

Here η is the golden number and the lattice identification is given by $h_1 \leftrightarrow 1$ and $h_2 \leftrightarrow \eta^2$. Under this identification, the action of g on $\mathrm{NS}\,(S)$ is the multiplication by η^6 on $\mathbf{Z}[\eta]$. So, as predicted by Cayley, g is actually of infinite order and $h_{\mathrm{top}}(g) = \log \eta^6 > 0$. [36] further shows that $\mathrm{Aut}\,(S_0) = \langle g \rangle$. They also give the explicit *integers* $a_{ijk} \in \mathbf{Z}$ with desired properties. I re-discovered Cayley's automorphism in answering a question of Kawaguchi ([74], see also [12]):

Theorem 4.4. *Let W be a smooth compact Kähler surface with automorphism f such that f is of positive entropy and has no fixed point. Then W is birational to a projective K3 surface, and the pair of Cayley's K3 surface S_0 and its automorphism g is one of such examples.*

Example 4 - Non-projective K3 surface automorphism with Siegel domain after McMullen. Let f be an automorphism of a smooth surface S. We call a domain $U \subset S$ a *Siegel domain* of f if $f(U) = U$ and U is biholomorphic to the 2-dimensional unit disk Δ^2 with coordinates (z_1, z_2) such that the induced action of f on Δ^2 is of the form $f^*(z_1, z_2) = (\alpha_1 z_1, \alpha_2 z_2)$ for some multiplicatively independent complex numbers α_1 and α_2 on the unit circle S^1, i.e., $\alpha_1^{m_1}\alpha_2^{m_2} \neq 1$ for any integers $(m_1, m_2) \neq (0, 0)$ and $|\alpha_1| = |\alpha_2| = 1$.

If S is a K3 surface and f is an automorphism with Siegel domain as above, then $f^*\sigma_S = \alpha_1\alpha_2\sigma_S$. Here $\sigma_S \neq 0$ is a global holomorphic 2-form on S. Note that $\alpha_1\alpha_2$ is not root of unity. Thus S is necessarily non-projective, as the pluri-canonical representation of $\mathrm{Bir}\,(M)^*|H^0(M, \mathcal{O}_M(mK_M))$ is always finite if M is projective [86]. The next very surprising result due to McMullen [58] gave me a strong motivation to study birational automorphisms from the view of this note:

Theorem 4.5. *There is a K3 surface S of Picard number 0 with $\mathrm{Aut}\,(S) = \langle f \rangle$ such that f is of positive entropy and has a Siegel domain. In particular, the canonical representation $f^*|H^0(\mathcal{O}(K_S)) = f^*|H^0(\Omega^2_S)$ is of infinite order, and there is no point $Q \in S$ such that the orbit $\mathrm{Aut}\,(S)\cdot Q$ is topological dense (even though f is of positive entropy). Slightly more explicitly, one of such (S, f) is realizable so that the characteristic polynomial of $f^*|H^2(S, \mathbf{Z})$ is the following Salem polynomial of degree 22;*

$$S_{22}(X) := x^{22} + x^{21} - x^{19} - 2x^{18} - 3x^{17} - 3x^{16} - 2x^{15} + 2x^{13} + 4x^{12}$$

$$+5x^{11}+4x^{10}+2x^9-2x^7-3x^6-3x^5-2x^4-x^3+x+1\ .$$

In this case, $h_{\mathrm{top}}(f) = \log a$*, where* a *is the Salem number of* $S_{22}(x)$*, approximately,* 1.37289.

Unlike the examples above, construction is highly implicit, based on the surjectivity of the period map and golobal Torelli theorem for K3 surfaces, and the existence of Siegel domain is based on a deep transcendental number theoretical result [58], from which one can deduce the transcendency of π and e in one line. See also [73] for a slightly different example.

We close this section with a few remarks relevant to Theorem 4.5:

Remark 4.6. As mentioned, there are smooth rational surfaces with an automorphism with Siegel domain [7, 8, 59]. Rational surfaces are always projective, but this does not contradict the finiteness of pluri-canonical representation, because

$$\kappa(S) = -\infty,\ \text{i.e.}, H^0(S, \mathcal{O}_S(mK_S)) = 0 \quad \text{for all} \quad m > 0.$$

Remark 4.7. Let S, f be as in Theorem 4.5 and P be the center of the Siegel domain. Let M be the blowing-ups of $N := S \times S$, first at the intersection point (P, P) of $S \times \{P\}$, $\{P\} \times S$, the diagonal Δ, and the graph Γ_f, and next along the proper transforms of $S \times \{P\}$, $\{P\} \times S$, Δ, Γ_f. Then M is a simply-connected compact Kähler fourfold which can not be deformed into projective manifolds under any small proper deformation ([72], also compare with [88]).

Remark 4.8. Let S be a projective K3 surface. Then $1 \leq \rho(S) \leq 20$, and projective K3 surfaces with $\rho(S) \geq \rho$ form countable union of $(20-\rho)$-dimensional families. The automorphism group of S *tends* to be larger if $\rho(S)$ becomes larger (see [67] for the precise statement in terms of deformation). If $\rho(S) = 20$, for instance if S is the Fermat quartic surface, then $\mathrm{Aut}\,(S)$ contains the free subgroup $\mathbf{Z} * \mathbf{Z}$ with many elements of positive entropy, and the orbit $\mathrm{Aut}\,(S) \cdot P$ is topologically dense in S for generic $P \in S$ ([20, 69] see also [82]).

5. Rational and CY threefolds with primitive automorphisms of positive entropy

5.1. Biregular automorphisms vs. birational automorphisms. Some experiences show that in dimension ≥ 3, the biregular automorphisms tend to be drastically fewer than birational automorphisms. So, finding manifolds with "interesting" biregular automorphisms is more challenging in some sense. Here I present a few examples of this tendency.

Example 1 - CY manifolds in Fano manifolds. Cayley's K3 surfaces are smooth anti-canonical members of the Fano threefold $\mathbf{P}^3$. Smooth anti-canonical members of higher dimensional Fano manifolds are CY manifolds. However,

Theorem 5.1. *Let* $l \geq 3$ *and* M *be a smooth member of* $|-K_V|$ *of a smooth Fano manifold* V *of dimension* $l+1$*. Then* M *is a CY manifold of dimension* $l \geq 3$*, but* $|\mathrm{Aut}\,(X)|$ *is finite.*

Lefschetz hyperplane theorem shows that $\iota^* : H^2(V, \mathbf{Z}) \simeq H^2(M, \mathbf{Z})$ under the inclusion $\iota : M \to V$ for $l \geq 3$. Kollár [16] shows that $\overline{\mathrm{Amp}\,(M)} \simeq \overline{\mathrm{Amp}\,(V)}$ under

ι^*. Hence $\overline{\mathrm{Amp}\,(M)}$ is a finite rational polyhedral cone as so is $\overline{\mathrm{Amp}\,(V)}$. This implies $|\mathrm{Aut}\,(M)| < \infty$ by Remark 2.8.

Example 2 - CY manifolds of smaller Picard numbers. Recall that Cayley's K3 surfaces are of Picard number 2 and have automorphism of positive entropy. On the other hand, we have ([75]; see also [53, 54]):

Theorem 5.2. $|\mathrm{Aut}\,(M)| < \infty$ *for an odd dimensional CY manifold of* $\rho(M) = 2$.

Example 3. Let M be a general complete intersection in $\mathbf{P}^3 \times \mathbf{P}^3$ of 2 hypersurfaces of bidegree $(1,1)$ and a hypersurface of bidegree $(2,2)$. Then M is a CY threefold of Picard number 2 (hence an example of both Theorems 5.1, 5.2). Let ι_k be the covering involution of the k-th projection $\mathrm{pr}_k : M \cdots \to \mathbf{P}^3$ of degree 2. Set $f := \iota_2 \circ \iota_1 \in \mathrm{Bir}\,(M)$. Then, $d_1(f) = 17 + 12\sqrt{2} > 1$, $\langle f \rangle \simeq \mathbf{Z}$ and $[\mathrm{Bir}\,(M) : \langle f \rangle] < \infty$ even though $\mathrm{Aut}\,(M)$ is finite.

Recall that $\mathrm{Bir}\,(M) = \mathrm{PsAut}\,(M)$ for CY manifolds. Example 3 is an application of Theorem 2.6 with an explicit analysis of the movable cone [75].

The following theorem also shows a sharp contrast in dimension 2 and ≥ 3:

Theorem 5.3. *Let* $l \geq 2$ *and* $M = (2, \cdots, 2) \subset (\mathbf{P}^1)^{l+1} = \mathbf{P}^1_1 \times \mathbf{P}^1_2 \times \cdots \times \mathbf{P}^1_{l+1}$ *be a smooth generic hypersurface of multi-degree* $(2, \cdots, 2)$. *Then* M *is a K3 surface if* $l = 2$ *and a CY manifold of dimension* l *if* $l \geq 3$, *and:*

(1) *If* $l = 2$, *then* $\mathrm{Bir}\,(M) = \mathrm{Aut}\,(M) = \langle \iota_1, \iota_2, \iota_3 \rangle \simeq \mathbf{Z}_2 * \mathbf{Z}_2 * \mathbf{Z}_2$, *while*

(2) *If* $l \geq 3$, *then* $\mathrm{Aut}\,(M) = \{id_M\}$ *and* $\mathrm{Bir}\,(M) = \langle \iota_1, \cdots, \iota_{l+1} \rangle \simeq \mathbf{Z}_2 * \cdots * \mathbf{Z}_2$ *($(l+1)$-times free product).*

Here ι_k *is the covering involutions of the natural projection to the product* $(\mathbf{P}^1)^l$ *in which the* k*-th factor* $\mathbf{P}^1_k$ *of* $(\mathbf{P}^1)^{l+1}$ *removed. Moreover, there are (many) elements* f *with* $d_1(f) > 1$.

So, $\mathrm{Bir}\,(M)$ becomes larger and larger according to the dimension, but $\mathrm{Aut}\,(M)$ suddenly disappears in dimension ≥ 3. This is proved by Cantat and myself [23]. The essential algebro-geometric part of (2) is that in $l \geq 3$, the covering involutions ι_k are (no longer automorphism but) a birational involutions and at the same time all possible flops of M. We then apply Theorem 2.6.

Example 4 - CY manifold automorphisms of positive entropy. Only one "series" of examples with automorphisms of positive entropy that I know is:

Theorem 5.4. *Let* M *be the universal cover of the punctual Hilbert scheme* $\mathrm{Hilb}^l\,(S)$ *of length* $l \geq 2$ *of an Enriques surface* S. *Then* M *is a CY manifold of dimension* $2l$, *and* M *admits (many) biregular automorphisms of positive entropy if* S *is generic.*

See [77] and [23]. It is interesting to ask:

Question 5.5. *Does a CY manifold* M *in Theorem 5.4 admit a primitive automorphism of positive entropy?*

Higher dimensional rational manifold automorphisms of positive entropy. Finding "interesting" *biregular* automorphisms of rational manifolds seems much more difficult. Sur-

prisingly, the following most basic question, posed by Bedford, is still unsolved (See also [84] for many negative evidences):

Question 5.6. *Is there a biregular automorphism of positive entropy on a smooth rational threefold obtained by blowing-ups of* $\mathbf{P}^3$ *along smooth centers?*

On the other hand, in [9–11, 80], there are constructed many examples of rational manifolds with interesting pseudo-automorphisms, by generalizing constructions of rational surface automorphisms. Especially, the following result due to Bedford-Cantat-Kim [10] is quite remarkable and also strongly supports a negative answer for Question 5.6:

Theorem 5.7. *There is a smooth rational threefold* M*, obtained by blowing-ups of* $\mathbf{P}^3$ *at smooth centers, with* $f \in \mathrm{PsAut}\,(M)$ *such that* f *is primitive, of* $d_1(f) > 1$*, and* (M, f) *has no equivariant smooth birational model* (M', f') *with* $f' \in \mathrm{Aut}\,(M')$*.*

Their f does not preserve even any foliation. In their construction, $\pi : M \to \mathbf{P}^3$ is a partial resolution of indeterminacy of $\tau \circ \mathrm{cr}_3 \in \mathrm{Bir}\,(\mathbf{P}^3)$ and their iterates, for suitably chosen $\tau \in \mathrm{PGL}\,(4, \mathbf{C})$ with periodicity conditions of indeterminacy. Then the birational automorphism $f = \pi \circ (\tau \circ \mathrm{cr}_3) \circ \pi^{-1}$ becomes a pseudo-automorphism of M. In their construction, there is a rational surface $S \subset M$ preserved by f^4 in the sense that $f^4|S \in \mathrm{Bir}\,(S)$. Their crucial observation for the non-existence of (M', f') is that $d_1(f^4|S)$ is *neither* a Salem number *nor* 1. On the other hand, if f could be regularized, then so is $f^4|S$, possibly on other regularized models on which S survives. But, then $d_1(f^4|S)$ must be a Salem number or 1 by the birational invariance of the dynamical degrees (Theorem 3.9) and by Theorem 4.3.

5.2. First examples of rational and CY threefolds with primitive automorphisms of positive entropy. Main reference is [79]. The essential idea is the quotient construction from a manifold M with rich automorphisms: If $G < \mathrm{Aut}\,(M)$ is a "small" finite subgroup with "big" normalizer $N < \mathrm{Aut}\,(M)$, then the "big" group N/G acts biregularly on the quotient variety M/G and on its equivariant resolution as well.

Our actual construction is as follows. Let $E_\tau = \mathbf{C}/(\mathbf{Z} + \mathbf{Z}\tau)$ be the elliptic curve of period τ. There are exactly two elliptic curves with a Lie automorphism other than ± 1. They are $E_{\sqrt{-1}}$ and E_ω, where $\omega := (-1 + \sqrt{-3})/2$. Let X_4 (resp. X_6, resp. X_3) be the canonical resolutions of the quotient threefolds

$$E_{\sqrt{-1}} \times E_{\sqrt{-1}} \times E_{\sqrt{-1}}/\langle \sqrt{-1} I_3 \rangle \ , \ E_\omega \times E_\omega \times E_\omega/\langle -\omega I_3 \rangle \ , E_\omega \times E_\omega \times E_\omega/\langle \omega I_3 \rangle$$

i.e., the blow up at the maximal ideals of singular points. As is well known, X_3 is a CY threefold [3]. It is analytically rigid, but plays an important role in the classification of CY threefolds in the view of the second Chern class [66, 76]. Our X_3, X_6, X_4 provide the *first* examples of a Calabi-Yau threefold and smooth rational threefolds with *primitive biregular* automorphisms of *positive entropy*:

Theorem 5.8.

(1) *Both* X_6 *and* X_4 *are rational.*

(2) *Moreover,* X_3*,* X_6*,* X_4 *admit primitive biregular automorphisms of positive entropy.*

(1) is proved by Truong and myself for X_6 [79], and by Colliot-Thélène [26] for X_4 via [24] both answering a question of Ueno and Campana [17, 86]). (2) is proved by Truong and myself [79].

The most crucial parts are the rationality of X_6 and X_4 and finding primitive automorphisms. One of the key steps for the rationality is the following result ([79], [24]) shown via determination of the rational function fields:

Theorem 5.9. *Let (s,t,z,w) be the standard affine coordinates of $\mathbf{C}^4$. Then:*

(1) *X_4 is birational to the hypersurface H_4 in $\mathbf{C}^4$ defined by*

$$(t^2-z)(s^2-w^3)=(s^2-w)(t^2-z^3)\ .$$

(2) *X_6 is birational to the hypersurface H_6 in $\mathbf{C}^4$ defined by*

$$(w^3-1)(t^2-1)=(z^3-1)(s^2-1)\ .$$

The projection $p_{34}:(t,s,z,w)\mapsto(z,w)$ gives the conic bundle structures on H_4 and H_6; $p_{34}: H_4\to\mathbf{C}^2$, $p_{34}: H_6\to\mathbf{C}^2$. It is clear that $(t,s,z,w)=(1,1,z,w)$ is a section of $p_{34}: H_6\to\mathbf{C}^2$, and therefore H_6 is rational. $p_{34}: H_4\to\mathbf{C}^2$ does not admit a rational section. However, Colliot-Thélène [26] shows that the conic bundle $p_{34}: H_4\to\mathbf{C}^2$ is birational to the conic bundle $p_{34}: (H_4)'\to\mathbf{C}^2$ over the same base. Here $(H_4)'$ is the affine hypersurface defined by $t^2-zs^2-w=0$. This process is not explicit, but a consequence of the fact that these two conic bundles define the same element of the Brauer group $\mathrm{Br}\,(\mathbf{C}(z,w))$ of the base space $\mathbf{C}^2$ [26]. $(H_4)'$ is rational as $w=t^2-zs^2$, whence so is H_4.

Let us give an example of primitive biregular automorphisms of positive entropy of X_3, X_6, X_4. Let us consider the matrix

$$P=P_a=\begin{pmatrix}0 & 1 & 0\\ 0 & 0 & 1\\ -1 & 3a^2 & 0\end{pmatrix}\ ,$$

where a is an integer such that $a\geq 2$. Since $\det P=1$, P naturally defines Lie automorphisms $g_3=g_6$, g_4 of $(E_\omega)^3$ and $(E_{\sqrt{-1}})^3$. By the construction and by the universality of blowing-up, the automorphisms g_k descends to the *biregular* automorphisms, say f_k, of X_k. The eigenvalues of α, β, γ of P are real numbers with $|\alpha|>|\gamma|>1>|\beta|$. By using α, β, γ, one can compute that $d_1(g_k)=\alpha^2$ and $d_2(g_k)=\alpha^2\gamma^2$. Thus $d_2(g_k)>d_1(g_k)>1$. Then $d_2(f_k)>d_1(f_k)>1$ by Corollary 3.13. Hence f_k provide desired automorphisms by Corollary 3.14 (2).

Question 5.10. *It is interesting to connect X_6 and X_4 to $\mathbf{P}^3$ by explicit blowing-ups and blowing-downs along smooth centers. This is in principle possible by [1]. In the view of Question 5.6, it is quite interesting to see if one can obtain X_6 and/or X_4 only by blowing-ups of $\mathbf{P}^3$ along smooth centers or not.*

6. Birational automorphisms of HK manifolds

6.1. Some generalities. We assume some familiarity with basics on HK manifolds. Excellent references are [41], Part III before Verbitsky's Torelli theorem [87] and [56] after that. We only recall that any HK manifold admits a non-degenerate integral symmetric bilinear

form, called Beauville-Bogomolov form (BB-form, for short), $b_M(*,**) : H^2(M,\mathbf{Z}) \times H^2(M,\mathbf{Z}) \to \mathbf{Z}$ with signature $(3, b_2(M)-3)$, being compatible with Hodge decomposition and invariant under deformation and $\mathrm{Bir}\,(M)$. We denote by $S^{[n]} = \mathrm{Hilb}^n(S)$ the Hilbert scheme of the 0-dimensional closed subschemes of lengths $n \geq 2$ on a K3 surface S. $S^{[n]}$ is a HK manifold of dimension $2n$ and of $\rho(S^{[n]}) = \rho(S)+1$. Through the Hilbert-Chow morphism $S^{[n]} \to \mathrm{Sym}^n S$, we have a natural identification as $\mathbf{Z}$-modules, $H^2(S^{[n]},\mathbf{Z}) = H^2(S,\mathbf{Z}) \oplus \mathbf{Z}e$, where $e = [E]/2$, the half of the exceptional divisor E of the Hilbert-Chow morphism. Under the BB-form $b(*,**)$, the above isomorphism is also an isometry with $(e^2) = -2(n-1)$.

6.2. Rough structure theorem on birational automorphisms. Let M be a HK manifold of $\dim M = 2n$. We have the following Tits' alternatives:

Theorem 6.1. *Let $G < \mathrm{Bir}\,(M)$. Then:*

(1) *For each (M,G), either one of the following two holds:*

  (i) *G is an almost abelian group of rank r, i.e., G is isomorphic to $\mathbf{Z}^r$ ($r \geq 0$) up to finite kernel and cokernel, or*

  (ii) *G is essentially non-commutative, i.e., G contains a free subgroup $\mathbf{Z} * \mathbf{Z}$.*

(2) *(ii) happens only if M is projective and $\rho(M) \geq 3$. Moreover, in case (ii), there are (many) $f \in G$ such that $d_1(f) > 1$. In particular, if in addtion $G \subset \mathrm{Aut}\,(M)$, then there are (many) $f \in G$ with $h_{\mathrm{top}}(f) > 0$ in the case (ii).*

This is proved by [68–70]. The essential part is as follows. The natural representation $r : G \to \mathrm{GL}\,(H^2(M,\mathbf{Z}))$ has a finite kernel (Remark 2.8) for projective case and [44] for general case). Thus G is well approximated by the image $G^* := r(G)$. Then, the fundamental result of Tits (Theorem 6.2) reduces the problem to showing that if G^* is virtually solvable, then it is an almost abelian group of finite rank. This can be done by using the additional strong condition that G^* is a subgroup of $\mathrm{O}_{\mathrm{Hodge}}(H^2(M,\mathbf{Z}))$.

Theorem 6.2. *Any group $H < \mathrm{GL}\,(n,k)$ (k is a field of characteristic 0) satisfies either one of the following two:*

(1) *H has a solvable subgroup of finite index (virtually solvable), or*

(2) *H is essentially non-commutative, i.e., H contains $\mathbf{Z} * \mathbf{Z}$.*

Remark 6.3. Tits' alternative type result with the same form as in Theorem 6.1 does not hold in general. However, some meaningful different formulation is proposed and proved for the biregular automorphism group of any compact Kähler manifold ([50, 91], see also [29, 32]).

One can also compute the dynamical degrees and entropy [71]:

Theorem 6.4. *For any $f \in \mathrm{Aut}\,(M)$ of any HK manifold M, the dynamical degrees $d_k(f)$ are all Salem numbers or 1. More precisely, $d_{2n-k}(f) = d_k(f) = d_1(f)^k$ for all $0 \leq k \leq n = \dim M/2$. In particular, if $d_1(f) > 1$, then*

$$1 = d_0(f) < d_1(f) < \cdots < d_{n-1}(f) < d_n(f) > d_{n+1}(f) > \cdots > d_{2n}(f) = 1\ ,$$

and $h_{\mathrm{top}}(f) = n \log\, d_1(f) > 0$ (resp. 0) if $d_1(f) > 1$ (resp. $d_1(f) = 1$).

6.3. A few examples. By the definition of $S^{[n]}$, we have a natural inclusion $\mathrm{Aut}\,(S) \subset \mathrm{Aut}\,(S^{[n]})$. This shows that if $\mathrm{Aut}\,(S)$ is infinite, then so is $\mathrm{Aut}\,(S^{[n]})$. So, contrary to the case of CY manifolds and rational manifolds, there are many examples of HK manifold with many biregular automorphisms.

Example 1 - Non-projective primitive automorphism of positive entropy. Let (S, f) be as in Theorem 4.5. Set $M = S^{[n]}$ and denote by $f_M \in \mathrm{Aut}\,(M)$ the automorphism naturally induced by f. We have $d_1(f_M) = d_1(f) = a$, the Salem number, and therefore $h_{\mathrm{top}}(f_M) = n \log\, a > 0$. Since S has no non-constant global meromorphic function (as $\rho(S) = 0$), the same is true for M. Then M has no rational fibration [18]. Hence f_M is primitive as well. We also see that $\mathrm{Bir}\,(M) = \mathrm{Aut}\,(M) = \langle f_M \rangle \simeq \mathrm{Aut}\,(S) \simeq \mathbf{Z}$.

Example 2 - The case where Picard number 2. We have the following:

Theorem 6.5.

(1) *Let S be a projective K3 surface with $\rho(S) = 1$. Then, $\rho(S^{[n]}) = 2$ but $\mathrm{Bir}\,(S^{[n]})$ is a finite group.*

(2) *There is a projective HK fourfold M deformation equivalent to $S^{[2]}$ such that $\rho(M) = 2$, $\mathrm{Aut}\,(M) = \mathrm{Bir}\,(M)$ is almost abelian group of rank 1 with element of positive entropy. More specifically, M with $\mathrm{NS}\,(M) \simeq (\mathbf{Z}[\eta], 4\mathrm{Nm}(*))$, "the same Néron-Severi lattice as Cayley's K3 surface", gives such an example. In particular, 2 is the minimal Picard number of projective HK manfolds of dimension ≥ 4 with automorphism of positive entoropy (cf. Remark 2.8).*

(1) is observed by [75]. Unlike Cayley's K3 surfaces, our M in (2) is highly non-constructible. *However, it is likely true that M in (2) has a primitive automorphism of positive entropy (not yet settled).*

Example 3 - Projective HK manifold of Picard number 3. Let $S \subset \mathbf{P}^3$ be a smooth quartic surface. Then for two general points P, Q in S, the line PQ in $\mathbf{P}^3$ meets S in four points, say, P, Q, P', Q'. The correspondence $\{P, Q\} \mapsto \{P', Q'\}$ defines a birational automorphism ι_S of $S^{[2]}$ of order 2, called the *Beauville involution* [3]. If S has no line, then ι_S is biregular. Note that $\iota_S \in \mathrm{Bir}\,(S^{[2]}) \setminus \mathrm{Aut}\,(S)$ under $\mathrm{Aut}\,(S) \subset \mathrm{Aut}\,(S^{[2]})$.

Let S be a Cayley's K3 surface. Identifying $S = S_0 \subset \mathbf{P}^3$, our S has three different embeddings $\Phi_k : S \to S_k \subset \mathbf{P}^3$ ($k = 0, 1, 2$) under the notation in Example 3 in Subsection (4.2). Let ι_k be the Beauville involution with respect to the embedding Φ_k. We have the following theorem similar to Theorem 5.3:

Theorem 6.6. *Let S be a Cayley's K3 surface. Then,*

$$\mathrm{Bir}\,(S^{[2]}) = \mathrm{Aut}\,(S^{[2]}) = \langle \iota_0, \iota_1, \iota_2 \rangle \text{ and } g = \iota_0 \circ \iota_1 \circ \iota_2\ ,$$

under the natural inclusion $\langle g \rangle = \mathrm{Aut}\,(S) \subset \mathrm{Aut}\,(S^{[2]})$. Moreover, $\mathrm{Aut}\,(S^{[2]})$ has a subgroup isomorphic to the free product $\mathbf{Z} * \mathbf{Z}$, hence admits an automorphism of positive entoropy (Theorem 6.1). In particular, $[\mathrm{Aut}\,(S^{[2]}) : \mathrm{Aut}\,(S)] = \infty$ and 3 is the minimal Picard number of projective HK manfolds of dimension ≥ 4 with essentially non-commutative automorphism group.

One of interesting fact is that we have the second factorization $g = \iota_0 \circ \iota_1 \circ \iota_2$ in $S^{[2]}$, which looks similar to , but completely different from, the factorization that Cayley found

in $\mathbf{P}^3$ (Example 3 in Subsection (4.2)). Another interesting fact is that $\mathrm{Aut}\,(S^{[2]})$ becomes much bigger than $\mathrm{Aut}\,(S)$ in this example, which makes a sharp contrast to the following open question, called the naturality question, posed by Boissière and Sarti [14, 15]):

Question 6.7. *Is* $\mathrm{Aut}\,(S) = \mathrm{Aut}\,(S^{[m]})$ *under the natural inclusion for* $m \geq 3$*?*

Acknowledgements. First of all, I would like to express my sincere thanks to Professor Yujiro Kawamata for his continuous, warm encouragement, support and proper advices, both in mathematics and in life, since I was his graduate student on 1987. I would like to express my thanks to all my collaborators and teachers, especially Professors Tuyen Truong, De-Qi Zhang, Jun-Muk Hwang and Professors Fabrizio Catanese, Akira Fujiki, Heisuke Hironaka, JongHae Keum, Nessim Sibony, Tetsuji Shioda, Shing-Tung Yau, and Late Professors Eiji Horikawa, Eckart Viehweg, and to Professors Serge Cantat, Tien-Cuong Dinh for several valuable comments. *It is my great honor to dedicate this note to Professor Doctor Thomas Peternell on the occasion of his sixtieth birthday. He continues to inspire me through many interesting problems with his brilliant ideas since 1993*.

Local mirror symmetry in the tropics

Mark Gross and Bernd Siebert

Abstract. We discuss how the reconstruction theorem of [20] applies to local mirror symmetry [11]. This theorem associates to certain combinatorial data a degeneration of (log) Calabi-Yau varieties. While in this case most of the subtleties of the construction are absent, an important normalization condition already introduces rich geometry. This condition guarantees the parameters of the construction are canonical coordinates in the sense of mirror symmetry. The normalization condition is also related to a count of holomorphic disks and cylinders, as conjectured in [20] and partially proved in [7–9]. We sketch a possible alternative proof of these counts via logarithmic Gromov-Witten theory.

There is also a surprisingly simple interpretation via rooted trees marked by monomials, which points to an underlying rich algebraic structure both in the relevant period integrals and the counting of holomorphic disks.

Mathematics Subject Classification (2010). Primary 14J33; Secondary 14J32, 14T05.

Keywords. local mirror symmetry, tropical curves, Gross-Siebert program.

1. Introduction

In [18, 20], we proposed a mirror construction as follows. We begin with a polarized degenerating flat family $\mathcal{X} \to T = \operatorname{Spec} R$ of n-dimensional Calabi-Yau varieties where R is a complete local ring. We consider only degenerations of a special sort which we term *toric degenerations*, see [18], Def. 4.1. Roughly, these are degenerations for which the central fibre is a union of toric varieties glued along toric strata, and such that the map $\mathcal{X} \to T$ is locally given by a monomial near the zero-dimensional strata of the central fibre X_0. Associated to this degeneration we construct the *dual intersection complex* $(B, \mathscr{P}, \varphi)$, where

(a) B is an n-dimensional integral affine manifold with singularities (possibly with boundary). In other words, B is a topological manifold with an open subset B_0 with $\Delta := B \setminus B_0$ of codimension ≥ 2, such that B_0 has an atlas of coordinate charts whose transition maps lie in $\operatorname{Aff}(\mathbb{Z}^n)$, the group of integral affine transformations.

(b) $\mathscr{P}$ is a decomposition of B into convex lattice polyhedra (possibly unbounded). The singular locus Δ is typically the union of codimension two cells of the first barycentric subdivision of $\mathscr{P}$ not intersecting the interior of a maximal cell of $\mathscr{P}$ nor containing a vertex of $\mathscr{P}$. There is a one-to-one inclusion reversing correspondence between elements of $\mathscr{P}$ and toric strata of X_0. The local structure of $\mathscr{P}$ near a vertex is determined by the fan defining the corresponding irreducible component. The maximal cells of $\mathscr{P}$ are determined by the toric structure of the map $\mathcal{X} \to T$ near the corresponding zero-dimensional strata of X_0.

Proceedings of the International Congress of Mathematicians, Seoul, 2014

(c) φ is a *multi-valued piecewise affine function*. This is a collection $\{(U_i, \varphi_i)\}$ of $\mathbb{R}$-valued functions φ_i on an open cover $\{U_i\}$ of B, with each φ_i piecewise affine linear with respect to the polyhedral decomposition $\mathscr{P}$, and $\varphi_i - \varphi_j$ being affine linear on $U_i \cap U_j$. We assume the slopes of the φ_i on cells of $\mathscr{P}$ to be integral. In this case, φ is determined by the polarization on $\mathcal{X}$, with local representatives near vertices given by a piecewise linear function defined by restricting the polarization to the corresponding irreducible component.

Given this data, we obtain the mirror to the degeneration $\mathcal{X} \to T$ by reinterpreting $(B, \mathscr{P}, \varphi)$ as the *intersection complex* of another polarized toric degeneration $\mathcal{Y} \to \operatorname{Spec} \Bbbk[\![t]\!]$ (in the projective case). This time, there is a one-to-one inclusion preserving correspondence between cells of $\mathscr{P}$ and toric strata of X_0, the central fibre of this new degeneration. The cells of $\mathscr{P}$ are the Newton polytopes for the polarization restricted to the various strata of X_0, and φ is determined by the local toric structure of the map near zero-dimensional strata.

The prime difficulty in the program lies in reconstructing $\mathcal{Y} \to \operatorname{Spec} \Bbbk[\![t]\!]$ from the data $(B, \mathscr{P}, \varphi)$. The main result of [20] gives an algorithm for constructing a *structure* $\mathscr{S}$ of walls which tell us how to construct the degeneration.

More recently [15] has considered families constructed using the technology of [20] over higher dimensional base schemes. This represents a modification of the above procedure. In the typical example, instead of choosing a fixed polarization on $\mathcal{Y}$, one chooses a monoid P of polarizations. Let $Q = \operatorname{Hom}(P, \mathbb{N})$ be the dual monoid. Then this data determines a multi-valued piecewise linear function φ taking values in $Q^{\mathrm{gp}}_{\mathbb{R}} := Q^{\mathrm{gp}} \otimes_{\mathbb{Z}} \mathbb{R}$. If $\mathfrak{m}$ is the maximal monomial ideal of $\Bbbk[Q]$, and $\widehat{\Bbbk[Q]}$ denotes the completion of $\Bbbk[Q]$ with respect to this ideal, then the construction gives a family $\mathcal{Y} \to \operatorname{Spec} \widehat{\Bbbk[Q]}$.

The history of the problem of associating a geometric object (complex manifold, non-Archimedean space, toric degeneration...) to an integral affine manifold with singularities began with work of Fukaya [12]. Fukaya gave a heuristic suggesting that one should be able to construct the mirror to a K3 surface using objects that look like structures in two dimensions (in two dimensions, we can think of a structure as just consisting of a possibly infinite number of unbounded rays). Fukaya observed that holomorphic disks with boundary on fibres of an SYZ fibration ([27]) gave similar pictures of structures on the mirror side. In 2004, Kontsevich and Soibelman in [26] gave the first construction of a structure, showing how given a two-dimensional affine sphere with singularities one could construct a consistent structure and from this structure a non-Archimedean K3 surface. We combined the picture of toric degenerations we had been developing independently of the above-mentioned authors with some ideas from [26], allowing us to construct degenerations from structures in all dimensions in [20].

In the first two sections of this paper, we shall illustrate the program by carrying it out completely for toric Calabi-Yau manifolds, a case usually referred to as local mirror symmetry [11]. This particular case can be viewed as being complementary to the case that the ideas of [26] were able to handle. In the remaining sections, we shall analyze enumerative meaning and a tropical interpretation of this construction.

2. Degenerations of toric Calabi-Yau varieties

Our running example is the construction of the mirror of what is called "local $\mathbb{P}^2$", the total space X of the canonical bundle $K_{\mathbb{P}^2}$ over $\mathbb{P}^2$. Since X itself is a toric variety, its anti-

canonical divisor $-K_X$ is linearly equivalent to the sum of toric divisors. There are four toric divisors, the zero section $S \subset X$, which is the maximal compact subvariety of X, and the preimages F_0, F_1, F_2 of the three coordinate lines in $\mathbb{P}^2$ under the bundle projection $X \to \mathbb{P}^2$. Toric methods show that $S + F_0 + F_1 + F_2 \sim 0$ and hence X is a non-compact Calabi-Yau threefold. The normal bundle $N_{S|X} = \mathcal{O}_{\mathbb{P}^2}(-3)$ is determined by the adjunction formula from the Calabi-Yau condition and it is the dual of an ample line bundle. Hence, by a result of Grauert [13], any embedded $\mathbb{P}^2$ in a Calabi-Yau threefold has an analytic neighbourhood biholomorphic to an analytic neighbourhood of S in X.

For the general description, fix throughout $M = \mathbb{Z}^n$, $M_{\mathbb{R}} = M \otimes_{\mathbb{Z}} \mathbb{R}$, $N = \mathrm{Hom}_{\mathbb{Z}}(M, \mathbb{Z})$.[1] Let $\sigma \subseteq M_{\mathbb{R}}$ be a compact lattice polytope, and assume $0 \in \sigma$. Define

$$C(\sigma) = \{(rm, r) \,|\, m \in \sigma, r \in \mathbb{R}_{\geq 0}\} \subseteq M_{\mathbb{R}} \oplus \mathbb{R}.$$

The cone $C(\sigma)$ viewed as a fan defines an affine toric variety X_σ. A polyhedral decomposition $\overline{\mathscr{P}}$ of σ into standard simplices leads to a fan $\Sigma = \{C(\tau) \,|\, \tau \in \overline{\mathscr{P}}\}$ which is a refinement of $C(\sigma)$. This yields a toric resolution of singularities $X_\Sigma \to X_\sigma$. Assume also that the fan Σ supports at least one strictly convex piecewise linear function.

For the case of local $\mathbb{P}^2$ take $n = 2$ and $\sigma = \mathrm{Conv}\{(1,0),(0,1),(-1,-1)\}$, where $\mathrm{Conv}(S)$ denotes the convex hull of the set S. Then the dual cone $C(\sigma)^\vee$ is $C(\sigma^*)$, the cone over the polar polytope σ^* with vertices $(-1,-1)$, $(2,-1)$, $(-1,2)$. It turns out that $X_\sigma = \mathrm{Spec}(\mathbb{C}[C(\sigma)^\vee \cap \mathbb{Z}^3])$ is the cyclic quotient $\mathbb{A}^2/\mathbb{Z}_3$ with $\mathbb{Z}_3$ acting diagonally on the coordinates by multiplication with third roots of unity. Taking the polyhedral decomposition as shown in Figure 2.1 yields for X_Σ the blowing up of the origin of X_σ. One can show that X_Σ is the total space of $K_{\mathbb{P}^2}$ and the map to X_σ is the contraction of the zero section. Note also that the projection $C(\sigma) \to M_{\mathbb{R}}$ defines a map from Σ to the fan of $\mathbb{P}^2$, which indeed corresponds to the bundle projection $X_\Sigma \to \mathbb{P}^2$.

In general, the map $X_\Sigma \to X_\sigma$ has a reducible exceptional locus, with one component for each vertex of $\overline{\mathscr{P}}$ that is not a vertex of σ, and the explicit description of the geometry is more complicated.

It turns out that constructing a mirror to X_Σ does not fit well with our program. The reason is that X_Σ does not seem to possess a fibration by Lagrangian tori of the kind expected by mirror symmetry [16]. Rather, such a fibration will exist only after removal of a hypersurface in X_Σ that is disjoint from the exceptional fibre of $X_\Sigma \to X_\sigma$. To run our program we could give an ad hoc construction of an affine manifold with singularities derived from the fan Σ or write down a toric degeneration of X_Σ. The local $\mathbb{P}^2$ case has been discussed from the former point of view in [21], Examples 5.1 and 5.2. Since it can be done easily in the present case we follow the latter method here. This method is motivated by the construction of toric degenerations of hypersurfaces in toric varieties in [17].

To exhibit X_Σ as an anticanonical hypersurface in a toric variety we embed the fan Σ in $M_{\mathbb{R}} \oplus \mathbb{R}$ as a subfan of a fan $\tilde{\Sigma}$ in $M_{\mathbb{R}} \oplus \mathbb{R}^2$. For each maximal cone $C \in \Sigma$ the fan $\tilde{\Sigma}$ has two maximal cones

$$C_1 = C \times 0 + \mathbb{R}_{\geq 0} \cdot (0,1,-1), \quad C_2 = C \times 0 + \mathbb{R}_{\geq 0} \cdot (0,0,1).$$

Then Σ is the subfan of $\tilde{\Sigma}$ consisting of cones lying in the hyperplane $M_{\mathbb{R}} \oplus \mathbb{R} \oplus 0 \subset M_{\mathbb{R}} \oplus \mathbb{R}^2$. The fan $\tilde{\Sigma}$ only has two rays not contained in Σ, with generators $(0,0,1)$ and $(0,1,-1)$. The inclusion $M_{\mathbb{R}} \oplus \mathbb{R} \oplus 0 \subset M_{\mathbb{R}} \oplus \mathbb{R}^2$ induces a map of fans from Σ to $\tilde{\Sigma}$, hence an

[1] Since M, N will eventually be treated as data for the mirror side our conventions in this section are opposite to the usual ones in toric geometry.

embedding $j : X_\Sigma \hookrightarrow X_{\tilde\Sigma}$ identifying X_Σ with the closure of the orbit of the subtorus defined by this inclusion through the distinguished point (the unit of the toric variety). Note that the projection to $\mathbb{R}^2$ maps $\tilde\Sigma$ to the fan $\Sigma_{\widehat{\mathbb{A}}^2}$ of the toric blowing up $\widehat{\mathbb{A}}^2$ of $\mathbb{A}^2$, with rays generated by $(0,1),(1,0),(1,-1)$. Under this map the subfan $\Sigma \subset \tilde\Sigma$ maps to the interior ray $\mathbb{R}_{\geq 0}\cdot(1,0)$. Viewing this interior ray as giving a map of fans, from the one-dimensional fan defining $\mathbb{A}^1$ to the two-dimensional fan defining $\widehat{\mathbb{A}}^2$, we obtain an embedding $i : \mathbb{A}^1 \hookrightarrow \widehat{\mathbb{A}}^2$.

We thus obtain a cartesian diagram of toric morphisms

$$\begin{array}{ccc} X_\Sigma & \xrightarrow{\ j\ } & X_{\tilde\Sigma} \\ {\scriptstyle p}\downarrow & & \downarrow{\scriptstyle q} \\ \mathbb{A}^1 & \xrightarrow{\ i\ } & \widehat{\mathbb{A}}^2 \end{array}$$

The left vertical arrow is induced by the projection $M_\mathbb{R} \oplus \mathbb{R} \to \mathbb{R}$, hence is given by the pull-back to X_Σ of the distinguished monomial x on X_σ defining the toric boundary as a reduced subscheme.

Explicitly, write x, y for the toric coordinates on $\mathbb{A}^2$ and $\widehat{\mathbb{A}}^2 = (xu - yv = 0) \subset \mathbb{A}^2 \times \mathbb{P}^1$ for the blowing up. Then $\mathrm{im}(i)$ is the strict transform of the diagonal $x = y$. Dehomogenizing $u = 1$ or $v = 1$ we obtain the usual two coordinate patches with coordinates y, v and x, u respectively with the transitions $v = u^{-1}$ and $x = yv$ or $y = xu$. We use the same notation for the pull-back of x, y, u, v to the corresponding two types of affine patches with $u \neq 0$ or $v \neq 0$ of $X_{\tilde\Sigma}$.

To describe $X_{\tilde\Sigma}$ let $C \in \Sigma$ be a maximal cone. Then if $(m, a) \in N \oplus \mathbb{Z}$ defines a facet $C' \subset C$, that is, (m, a) generates an extremal ray of $C^\vee$, the element $(m, a, a) \in N \oplus \mathbb{Z}^2$ defines the facet $C' + \mathbb{R}_{\geq 0}(0, 1, -1)$ of C_1. There is only one more facet of C_1, namely C itself, defined by $(0, 0, -1)$, and hence

$$C_1^\vee = \{(m, a, a) \,|\, (m, a) \in C^\vee\} + \mathbb{R}_{\geq 0} \cdot (0, 0, -1).$$

The rays of $C_2^\vee$ are generated by $(m, a, 0)$ for (m, a) an extremal ray of $C^\vee$, and by $(0, 0, 1)$, so $C_2^\vee = C^\vee \times 0 + \mathbb{R}_{\geq 0}(0, 0, 1)$. In either case, we have an identification

$$\mathrm{Spec}\, \Bbbk[C_i^\vee \cap (N \oplus \mathbb{Z}^2)] = \mathrm{Spec}\, \Bbbk[C^\vee \cap N] \times \mathbb{A}^1 \subset X_\Sigma \times \mathbb{A}^1.$$

The toric coordinate for $\mathbb{A}^1$ is $v = z^{(0,0,-1)}$ for C_1 and $u = z^{(0,0,1)}$ for C_2. From this description it is clear that the embedding of X_Σ in $X_{\tilde\Sigma}$ is given by $u = 1$ in affine patches with $v \neq 0$ and by $v = 1$ in the affine patches with $u \neq 0$.

To write down a degeneration of X_Σ to the toric boundary $\partial X_{\tilde\Sigma} \subset X_{\tilde\Sigma}$ view u, v as sections of the line bundle $q^*\mathcal{O}(-E)$ where $E \subset \widehat{\mathbb{A}}^2$ is the exceptional curve. Then X_Σ is the zero locus of $s := u - v$. On the other hand, $xu = yv$ defines a section s_0 of $q^*\mathcal{O}(-E)$ with zero locus $\partial X_{\tilde\Sigma}$. Thus the hypersurface $\mathcal{X} \subset X_{\tilde\Sigma} \times \mathbb{A}^1$ with equation

$$ts + s_0 = 0$$

defines a pencil in $X_{\tilde\Sigma}$ with members X_Σ at $t = \infty$ and with the toric boundary $\partial X_{\tilde\Sigma}$ at $t = 0$. Note this pencil is the preimage of the pencil on $\widehat{\mathbb{A}}^2$ defined by the same equations. In particular, by direct computation $\mathcal{X}_t$ is completely contained in either type of coordinate patch for $t \neq 0$. Working in a patch with $v \neq 0$ we have $s = u - 1$, $s_0 = xu$ and the equation

$$0 = ts + s_0 = t(u - 1) + xu = u(t + x) - t$$

shows $u(t+x) = t \neq 0$. Thus $t + x \neq 0$ and u can be eliminated. In other words, $\mathcal{X}_t \simeq X_\Sigma \setminus Z_t$ with $Z_t \subset X_\Sigma$ the hypersurface $x = -t$. Note also that our notation is consistent in that x indeed descends to the defining equation of the toric boundary of X_σ.

It is not difficult to show that $\mathcal{X} \to \mathbb{A}^1$ is a toric degeneration. Indeed, we have already checked that $\mathcal{X}_0$ is the toric boundary of $X_{\tilde{\Sigma}}$. Some harder work shows that locally near the zero-dimensional strata of X_0, the projection $\mathcal{X} \to \mathbb{A}^1$ is toric. We omit the details, but this can be done similarly to arguments given in [17].

The dual intersection complex is then easily described along the lines given in [17], where, for a Calabi-Yau hypersurface in a toric variety, B was described as the boundary of a reflexive polytope, with the cones over the faces of the polytope yielding the fan defining the ambient toric variety. Topologically, we can write $B \subseteq M_\mathbb{R} \oplus \mathbb{R}^2$ as

$$B = \tilde{\sigma}_1 \cup \tilde{\sigma}_2$$

where

$$\begin{aligned} \tilde{\sigma}_1 &= \operatorname{Conv}\big((0,1,-1) \cup (\sigma \times \{(1,0)\})\big), \\ \tilde{\sigma}_2 &= \operatorname{Conv}\big((0,0,1) \cup (\sigma \times \{(1,0)\})\big). \end{aligned}$$

Note that the support of the fan $\tilde{\Sigma}$ above is the cone over $\tilde{\sigma}_1 \cup \tilde{\sigma}_2$. We then take $\mathscr{P} = \{C \cap B \,|\, C \in \tilde{\Sigma}\}$.

Finally, the affine structure on B is defined as follows. Identify σ with $\sigma \times \{(1,0)\} \subseteq B$, and take the discriminant locus Δ to be the union of cells of the first barycentric subdivision of $\overline{\mathscr{P}}$ not containing vertices of $\overline{\mathscr{P}}$, see Figure 2.1. We then define affine charts as follows. First, we define affine charts $\iota_i : \tilde{\sigma}_i \setminus \sigma \hookrightarrow \mathbb{A}_i$ as the inclusions, where $\mathbb{A}_i$ denotes the affine hyperplane in $M_\mathbb{R} \oplus \mathbb{R}^2$ spanned by $\tilde{\sigma}_i$. Second, for each vertex $v \in \overline{\mathscr{P}}$, choose a neighbourhood U_v of $(v,1,0) \in B$. These neighbourhoods can be chosen so that $U_v \cap U_{v'} = \emptyset$ if $v \neq v'$ and the two sets $\tilde{\sigma}_i \setminus \sigma$ along with the open sets U_v cover $B \setminus \Delta$. Define a chart $\iota_v : U_v \to (M_\mathbb{R} \oplus \mathbb{R}^2)/\mathbb{R}(v,1,0)$ via the inclusion followed by the projection. It is easy to check that these charts give an integral affine structure. This again precisely follows the procedure for Calabi-Yau hypersurfaces in toric varieties considered in [17]. This gives rise to the pair $(B, \mathscr{P})$.

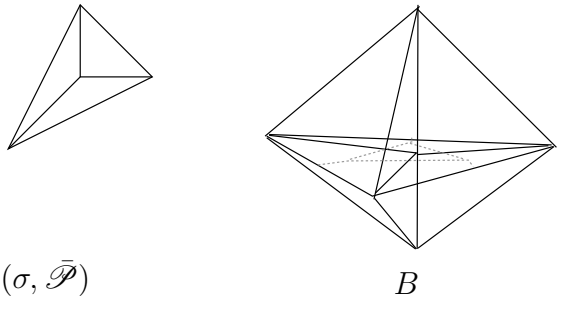

Figure 2.1. On the left is the initial polytope with its decomposition. We take the vertices of σ to be $(1,0)$, $(0,1)$ and $(-1,-1)$. On the right is the resulting B with its discriminant locus Δ, indicated by the dotted line.

In general, a pair $(B, \mathscr{P})$ can be described by specifying the lattice polytopes in $\mathscr{P}$ and specifying a *fan structure* at each vertex v, that is, the identification of a neighbourhood of

each vertex with the neighbourhood of 0 in a fan Σ_v. This identification gives a one-to-one inclusion preserving correspondence between cells of $\mathscr{P}$ containing v and cones of Σ_v, along with integral affine identifications of the tangent wedges of each cell $\tau \in \mathscr{P}$ containing v with the corresponding cone of Σ_v. These identifications patch together to give an affine chart in a neighbourhood of the vertex v.

In our example, it is worth describing the fan structure at a vertex $v \in \sigma$. Since the fan structure at a vertex must be the fan yielding the corresponding irreducible component of $\mathcal{X}_0$, toric geometry tells us this fan structure must be given as the quotient fan obtained from $\tilde{\Sigma}$ by dividing out by the ray generated by this vertex. Explicitly, we use the chart

$$\iota_v : U_v \to (M_{\mathbb{R}} \oplus \mathbb{R}^2)/\mathbb{R} \cdot (v, 1, 0) \cong M_{\mathbb{R}} \oplus \mathbb{R}, \tag{2.1}$$

the latter isomorphism given by $(m, r_1, r_2) \mapsto (m - r_1 v, r_2)$. The fan Σ_v can then be described as the fan of tangent wedges to images of cells $\tau \in \mathscr{P}$ containing v. The set of maximal cones of this fan, described as subsets of $M_{\mathbb{R}} \oplus \mathbb{R}$, is

$$\{T_v\tau + \mathbb{R}_{\geq 0}(-v, -1) \,|\, v \in \tau \in \overline{\mathscr{P}}_{\max}\} \cup \{T_v\tau + \mathbb{R}_{\geq 0}(0, 1) \,|\, v \in \tau \in \overline{\mathscr{P}}_{\max}\}, \tag{2.2}$$

where $T_v\tau$ denotes the tangent wedge to $v \in \tau$ in $M_{\mathbb{R}} \oplus 0$. Figure 2.2 shows some of the fan structures when σ is an interval $[-1, 1]$ of length two.

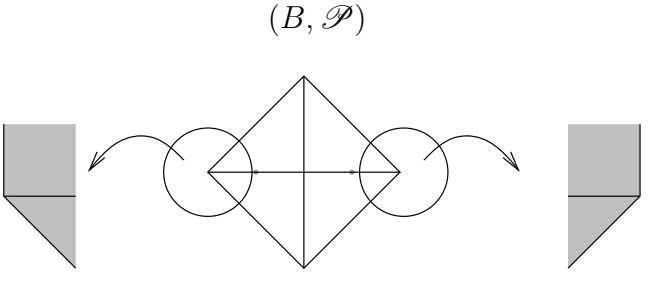

Figure 2.2.

One can understand the nature of the singularities of B by studying the local system Λ of integral vector fields on B_0. Given integral affine coordinates $y_1, \ldots, y_n$, Λ is locally the family of lattices in the tangent bundle of B_0 generated by $\partial/\partial y_1, \ldots, \partial/\partial y_n$. If $v, v' \in \overline{\mathscr{P}}$ are adjacent vertices, consider a path γ passing from v through $\check{\sigma}_1$ to v' and then through $\check{\sigma}_2$ back to v. To identify Λ_v, we can use the chart (2.1), which gives an identification of Λ_v with $M \oplus \mathbb{Z}$. It is an easy exercise to check that parallel transport in Λ around γ yields a *monodromy transformation*

$$\begin{aligned} T_{vv'} : \Lambda_v &\to \Lambda_v \\ (m, r) &\mapsto (m + r(v - v'), r) \end{aligned} \tag{2.3}$$

The final piece of data for the dual intersection complex $(B, \mathscr{P}, \varphi)$ of $\mathcal{X} \to \mathbb{A}^1$ is a multi-valued piecewise linear function φ describing aspects of the Kähler geometry of the situation.

In the next section, we will build the mirror family over some base scheme. The natural choice for this base is related to the Kähler cone of X_Σ, or the Picard group. By toric

geometry, $\mathrm{Pic}(X_\Sigma)$ equals piecewise linear functions on Σ modulo linear functions. It will thus be convenient to normalize the piecewise linear functions as follows. Choose a maximal cell $\tau \in \overline{\mathscr{P}}_{\max}$ which has 0 as a vertex. Let P be the monoid of integral convex piecewise linear functions on the fan Σ which take the value 0 on the cone $C(\tau)$. Note that $P^{\mathrm{gp}} \cong \mathrm{Pic}\, X_\Sigma$. Setting $Q := \mathrm{Hom}(P, \mathbb{N})$, there is a universal piecewise linear function $\psi : |\Sigma| \to Q^{\mathrm{gp}}_{\mathbb{R}}$, with

$$\psi(x) = (P \ni \varphi \mapsto \varphi(x)).$$

This function is strictly convex in the sense of [14], Definition 1.12. In the local $\mathbb{P}^2$ case normalized piecewise linear functions are determined by the value at the one remaining vertex of σ not contained in τ and hence $Q = \mathbb{N}$.

The multi-valued piecewise linear function φ comes from the universal piecewise linear function ψ on $|\Sigma|$ by descent to a quotient fan, or rather from a choice of extension of this function to $\widetilde{\Sigma}$. This choice can be made by choosing an element $q \in Q \setminus \{0\}$. While the choice of q affects the family of polarizations on $X_{\tilde{\Sigma}}$, it does not affect the family after restriction to $\mathcal{X}_t$ for $t \neq 0$. However, it does affect the polarization on $\mathcal{X}$, and hence will play some role in the mirror, seen explicitly in (3.7). We take $\widetilde{\psi}$ to be the $Q^{\mathrm{gp}}_{\mathbb{R}}$-valued piecewise linear extension of ψ which takes the value 0 at $(0, 1, -1)$ and the value q at $(0, 0, 1)$. One can check that this function is strictly convex in the sense of [14], Definition 1.12.

We can then construct φ from $\widetilde{\psi}$ as follows. For each $C \in \tilde{\Sigma}$, let $\tau = C \cap B$ be the corresponding cell of $\mathscr{P}$. The function $\widetilde{\psi}$ induces a function on the quotient fan of $\widetilde{\Sigma}$ along C (this quotient fan determining the fan structure of B along τ) as follows. Let $\widetilde{\psi}_\tau \in \mathrm{Hom}(M \oplus \mathbb{Z}^2, Q)$ be a linear extension of $\widetilde{\psi}|_C$. Then $\widetilde{\psi} - \widetilde{\psi}_\tau$ is a piecewise affine function on $\tilde{\Sigma}$ vanishing on C, hence descending to the quotient fan of $\tilde{\Sigma}$ along C. We take $(\widetilde{\psi} - \widetilde{\psi}_\tau)|_B$ as a representative of φ on a small open neighbourhood of $\mathrm{Int}(\tau)$ in B; this is clearly the pull-back of the corresponding function on the quotient fan of $\tilde{\Sigma}$ along C under the projection to $(M_{\mathbb{R}} \oplus \mathbb{R}^2)/\mathbb{R}C$.

3. The mirror degeneration and slab functions

Having described $(B, \mathscr{P}, \varphi)$ in our example as the dual intersection complex of a degeneration of the local Calabi-Yau X_Σ, we turn to the construction of the mirror, which shall be a family $\mathcal{Y} \to \mathrm{Spec}\, \widehat{\Bbbk[Q]}$ over a generally higher-dimensional base.

This family is constructed by constructing families $\mathcal{Y}_k \to \mathrm{Spec}\, \Bbbk[Q]/\mathfrak{m}^{k+1}$ to each order k, giving rise to a formal scheme $\widehat{\mathcal{Y}} \to \mathrm{Spf}\, \widehat{\Bbbk[Q]}$. As the case at hand will be projective, the Grothendieck existence theorem gives rise to the desired family. Alternatively, $\mathcal{Y}$ can be constructed using a graded ring of theta functions, following [15].

Here is a brief summary of the construction. The central fibre Y_0 can be described as

$$Y_0 = \bigcup_{\sigma \in \mathscr{P}_{\max}} \mathbb{P}_\sigma$$

where $\mathscr{P}_{\max}$ denotes the maximal cells of $\mathscr{P}$ and $\mathbb{P}_\sigma$ is the toric variety (projective if σ is compact) determined by the polyhedron σ. These toric varieties are glued together in a manner reflecting the combinatorics of $\mathscr{P}$: if $\sigma_1 \cap \sigma_2 = \tau$, then the strata $\mathbb{P}_\tau \subseteq \mathbb{P}_{\sigma_1}$, $\mathbb{P}_\tau \subseteq \mathbb{P}_{\sigma_2}$ are identified.

Local models for the k^{th} order deformation of Y_0 are determined by the function φ. A key point of the construction involves an invariant description for the local models, which we explain here. The function φ, defined on an open cover $\{U_i\}$ by single-valued functions $\varphi_i : U_i \to Q^{\mathrm{gp}}_{\mathbb{R}}$, determines an extension of Λ by $\underline{Q}^{\mathrm{gp}}$, the constant sheaf with coefficients in Q^{gp}. Indeed, on $U_i \cap B_0$, this extension will split as $\Lambda|_{U_i} \oplus \underline{Q}^{\mathrm{gp}}$, and on the overlap, (m, r) as a section of $\Lambda|_{U_i} \oplus \underline{Q}^{\mathrm{gp}}$ is identified on $U_i \cap U_j$ with $(m, r + d(\varphi_j - \varphi_i)(m))$ as a section of $\Lambda|_{U_j} \oplus \underline{Q}^{\mathrm{gp}}$, interpreting $d(\varphi_j - \varphi_i) \in \mathrm{Hom}(\Lambda|_{U_i}, Q^{\mathrm{gp}})$. We then have an exact sequence

$$0 \to \underline{Q}^{\mathrm{gp}} \to \mathcal{P} \to \Lambda \to 0 \tag{3.1}$$

on B_0. We write the map $\mathcal{P} \to \Lambda$ as $m \mapsto \bar{m}$. After choosing a representative φ_i of φ in a neighbourhood of a point $x \in B_0$, the stalk $\mathcal{P}_x$ is identified with $\Lambda_x \oplus Q^{\mathrm{gp}}$. There is a fan $\Sigma_x = \{T_x\sigma \,|\, x \in \sigma \in \mathscr{P}\}$ (of not-necessarily strictly convex cones), where $T_x\sigma$ denotes the tangent wedge to σ at x. This allows us to define a convex PL function $\varphi_x : |\Sigma_x| \to Q^{\mathrm{gp}}_{\mathbb{R}}$ whose slope on $T_x\sigma$ coincides with the slope of $\varphi_i|_\sigma$. We then set

$$P_x := \{(m, q) \,|\, m \in \Lambda_x \cap |\Sigma_x|, q \in Q^{\mathrm{gp}}, q - \varphi_x(m) \in Q\} \subseteq \mathcal{P}_x \tag{3.2}$$

While this definition as described inside of $\Lambda_x \oplus Q$ depends on the choice of representative, in fact it is independent of this choice when viewed as a submonoid of $\mathcal{P}_x$.

Note that Q acts naturally on P_x, giving $\Bbbk[P_x]$ a $\Bbbk[Q]$-algebra structure. For a vertex v, we can now view $\mathrm{Spec}\,\Bbbk[P_v]/\mathfrak{m}^{k+1}$ as a local model for the k^{th} order deformation of Y_0 in a neighbourhood of the stratum of Y_0 corresponding to v. In addition, the local system $\mathcal{P}$ gives a method of defining parallel transport of monomials.

Let us describe certain aspects of this construction for our local mirror symmetry example. Using the fan structure given by (2.2), we can describe the monoid $P_v \subseteq \mathcal{P}_v$ as $\{(m, r, s) \,|\, s - \varphi_v(m, r) \in Q\} \subseteq M \oplus \mathbb{Z} \oplus Q^{\mathrm{gp}}$ using the identifications

$$\mathcal{P}_v \cong \Lambda_v \oplus Q^{\mathrm{gp}} \cong M \oplus \mathbb{Z} \oplus Q^{\mathrm{gp}} \tag{3.3}$$

induced first by the representative φ_v at v and second by the affine coordinate chart on U_v. In particular, for the purposes of the discussion below, we can describe the most relevant part of P_v as follows. First, we choose the representative φ_v by choosing the linear function $\widetilde{\psi}_v$ to be $(0, \bar{\psi}(v), 0) \in (N \oplus \mathbb{Z}^2) \otimes_{\mathbb{Z}} Q^{\mathrm{gp}}$, with $\bar{\psi} = \psi|_{\sigma \times \{1\}}$. Let $\bar{P}_v \subseteq P_v$ be the submonoid consisting of $m \in P_v$ with $\bar{m}$ tangent to σ. Then $\bar{P}_v$ is naturally described in terms of $\bar{\psi}$. Indeed, consider the convex hull of the graph of $\bar{\psi}$,

$$\Xi_{\bar{\psi}} := \{(m, 0, s) \,|\, m \in \sigma, s - \bar{\psi}(m) \in Q\} \subseteq M_{\mathbb{R}} \oplus \mathbb{R} \oplus Q^{\mathrm{gp}}_{\mathbb{R}},$$

an unbounded polyhedron with vertices mapping to vertices of $\overline{\mathscr{P}}$ under the projection $M_{\mathbb{R}} \oplus \mathbb{R} \oplus Q^{\mathrm{gp}}_{\mathbb{R}} \to M_{\mathbb{R}}$. Then we can identify $\bar{P}_v$ with the integral points in the tangent wedge of $\Xi_{\bar{\psi}}$ at $(v, 0, \bar{\psi}(v))$.

We also note that under the identification (3.3) of $\mathcal{P}_v$, the monodromy of Λ described in (2.3) lifts to a monodromy transformation of $\mathcal{P}_v$ given by

$$\begin{aligned} &T_{vv'} : \mathcal{P}_v \to \mathcal{P}_v \\ &(m, r, q) \to (m + r(v - v'), r, q + r(\bar{\psi}(v) - \bar{\psi}(v'))) \end{aligned} \tag{3.4}$$

The key additional (and usually most complex) ingredient for constructing $\mathcal{Y}_k$ is a *structure* $\mathscr{S}$. A structure encodes data about how certain forms of these local models are glued

together. We will explain this structure in our example, but not go into too much detail. A more detailed explanation for how this works is given in the expository paper [21].

The structure takes a particularly simple form here. In general, a structure is a collection of walls, polyhedral cells in B of codimension one each contained in a cell of $\mathscr{P}$ carrying the additional data of certain formal power series. In [20] we distinguish a special sort of wall, namely those contained in codimension one cells, and call them *slabs*. They tend to have a different behaviour. In the case at hand, only slabs appear, and these cover σ. The functions attached to the slabs are determined from the monodromy around the discriminant locus Δ.

In this example, the slabs are the sets $\tau \times \{(1,0)\}$ for $\tau \in \overline{\mathscr{P}}_{\max}$. For a slab $\mathfrak{b}$, associated to any point $x \in \mathfrak{b} \setminus \Delta$ is a formal power series $f_{\mathfrak{b},x} = \sum_{m \in P_x} c_m z^m$. This should only depend on the connected component of $\mathfrak{b} \setminus \Delta$ containing x, so there is in fact one such expression for each vertex v of τ, and we can write $f_{\mathfrak{b},v} = \sum_{m \in P_v} c_m z^m$. Furthermore, $c_m \neq 0$ implies $\bar{m}$ is tangent to $\mathfrak{b}$, so in fact the sum is over $m \in \bar{P}_v$.

The series $f_{\mathfrak{b},v}$ are completely determined by a number of simple properties. This follows in the case under consideration from having chosen $\overline{\mathscr{P}}$ to consist of *standard* simplices. In what follows we will want to compare $f_{\mathfrak{b},v}$ with $f_{\mathfrak{b},v'}$ for different vertices v, v' of $\mathfrak{b}$. To do so, we use parallel transport in $\mathcal{P}$ from v to v'. Given the identification $\mathcal{P}_v$ with $M \oplus \mathbb{Z} \oplus Q^{\mathrm{gp}}$ used to give the formula (3.4) and noting that only monomials of the form $z^{(m,0,p)}$ can appear in $f_{\mathfrak{b},v}$, we see that the particular path chosen between v and v' is irrelevant.

We can now state the conditions determining the $f_{\mathfrak{b},v}$:

1. The constant term of each $f_{\mathfrak{b},v}$ is 1.
2. If v and v' are adjacent vertices of $\mathfrak{b}$, then the corresponding slab functions are related by
$$f_{\mathfrak{b},v'} = z^{(v-v',0,\bar{\psi}(v)-\bar{\psi}(v'))} f_{\mathfrak{b},v}. \tag{3.5}$$
Here the equality makes sense after parallel transport of the exponents from v to v' in the local system $\mathcal{P}$, and $(v - v', 0, \bar{\psi}(v) - \bar{\psi}(v')) \in P_{v'}$ using the identification of $\mathcal{P}_{v'}$ given by (3.3).
3. $\log f_v$ contains no terms of the form z^q for $q \in Q \setminus \{0\}$. Here we view $Q \subseteq P_v$ via the natural inclusion $Q^{\mathrm{gp}} \subseteq \mathcal{P}_v$.
4. If v lies in slabs $\mathfrak{b}, \mathfrak{b}'$, then $f_{\mathfrak{b},v} = f_{\mathfrak{b}',v}$.

Item 1 is a normalization which originated in [18], Def. 4.23. However, we shall see its enumerative importance in §4. Item 2 is the crucial point of slabs: they allow us to define parallel transport of monomials through slabs in a way which cancels the effects of monodromy. We shall say more about this shortly. The condition 3 is interpreted by writing $f_v = 1 + \cdots$ and using the Taylor expansion for $\log(1+x) = \sum_{i=1}^{\infty} (-1)^{i+1} x^i / i$. This can be interpreted inside some suitably completed ring. After expanding out each expression $(\cdots)^i$, one demands that no monomials of the form z^q appear for any $q \in Q \setminus \{0\}$. Finally, 4 tells us how expressions propagate across $\sigma \times \{1\}$.

To see the significance of the second condition, let $w \in \mathrm{Int}(\tilde{\sigma}_1)$, $w' \in \mathrm{Int}(\tilde{\sigma}_2)$. Suppose we want to compare monomials defined at w (that is, monomials with exponent in P_w) with monomials defined at w' (that is, monomials with exponent in $P_{w'}$). If we parallel transport from $\mathcal{P}_w$ to $\mathcal{P}_{w'}$, the result depends on the path. For example, let v, v' be adjacent vertices of $\tau \in \overline{\mathscr{P}}_{\max}$. Let $T_v, T_{v'}$ denote parallel transport in Λ from w to w' via the vertices v and

v' respectively. Then from (3.4), it follows that for $(m,r,q) \in \mathcal{P}_w = M \oplus \mathbb{Z} \oplus Q$,

$$T_{v'}(m,r,q) - T_v(m,r,q) = \big(r(v-v'), 0, r(\bar\psi(v) - \bar\psi(v'))\big).$$

For convenience, we can identify $\mathcal{P}_w$ and $\mathcal{P}_{w'}$ with $\mathcal{P}_v$ so that T_v is the identity. This difference between T_v and $T_{v'}$ creates problems for comparing the rings $\Bbbk[P_w]$ and $\Bbbk[P_{w'}]$. However, we can follow the rule that if we wish to transport a monomial $z^{(m,r,q)}$ along a path between w and w' which crosses a slab $\mathfrak{b}$ in a connected component of $\mathfrak{b} \setminus \Delta$ containing a vertex v, we apply an automorphism

$$z^{(m,r,q)} \mapsto z^{(m,r,q)} f_{\mathfrak{b},v}^{-r}. \tag{3.6}$$

Here r represents the result of projecting $\overline{(m,r,q)} = (m,r)$ via the projection $\pi : \Lambda_v \to \mathbb{Z}$ obtained by dividing out by the tangent space to the slab. If instead we pass through the slab $\mathfrak{b}$ via the connected component of $\mathfrak{b} \setminus \Delta$ containing v', we get

$$z^{(m,r,q)} \longmapsto z^{(m+r(v-v'),r,q+r(\bar\psi(v)-\bar\psi(v')))} f_{v'}^{-r} = z^{(m,r,q)} f_v^{-r},$$

coinciding with (3.6). Here we use the above expression for $T_v - T_{v'}$ and (3.5). Hence we see that the ambiguity produced by monodromy is resolved by the slab functions.

Examples 3.1. In the following examples, we express the various functions $f_{\mathfrak{b},v}$ as formal power series with exponents appearing in $\bar P_v$, using the representation of $\bar P_v$ as the integral points of the tangent wedge of $\Xi_{\bar\psi}$ at $(v,0,\bar\psi(v))$.

(1) Take σ to be the interval $[-1,1]$ as in Figure 2.2, with $\mathscr{P}$ as given there. The monoid of convex piecewise linear functions on Σ is generated by the function which takes the values 0, 0 and 1 respectively at $(-1,1)$, $(0,1)$ and $(1,1)$. Thus we have $Q = \mathbb{N}$, and the universal piecewise linear function ψ coincides with the above generator. For a vertex v, with $\bar P_v \subseteq M \oplus 0 \oplus Q^{\mathrm{gp}}$, write $x = z^{(1,0,0)}$, $t = z^{(0,0,1)}$, t being the generator of $\Bbbk[Q]$. Then we have

$$\begin{aligned} f_{[-1,0],-1} &= 1 + x + x^2t + xt, \\ f_{[-1,0],0} = f_{[0,1],0} &= 1 + x^{-1} + xt + t, \\ f_{[0,1],1} &= 1 + x^{-1}t^{-1} + x^{-2}t^{-1} + x^{-1}. \end{aligned}$$

Note that $\log f_{[-1,0],-1}$, $\log f_{[0,1],1}$ are clearly devoid of pure powers of t as any power, say, of $x+x^2t+xt$ clearly produces only terms with positive powers of x. On the other hand, $f_{[-1,0],0} = (1+x^{-1})(1+xt)$, and taking logs we get $\log(1+x^{-1})+\log(1+xt)$ which will again involve no pure t power. The t term in $f_{[0,1],0}$ was necessary to achieve this.

(2) Take σ to be as in Figure 2.1. Again, the monoid of convex piecewise linear functions on the fan Σ is generated by, say, the function taking the values 0 at $(0,0,1)$, $(1,0,1)$ and $(0,1,1)$ and the value 1 at $(-1,-1,1)$. So again $Q = \mathbb{N}$, with the universal function ψ agreeing with this generator. Writing $x = z^{(1,0,0,0)}$, $y = z^{(0,1,0,0)}$, $t = z^{(0,0,0,1)}$, it is easy to see that the terms of the slab function $f_{\mathfrak{b},(0,0)}$ (independent of $\mathfrak{b}$ by the fourth condition) required by conditions 1 and 2 are $1 + x + y + tx^{-1}y^{-1}$. The normalization condition forces us to add some additional terms:

$$f_{\mathfrak{b},(0,0)} = 1 + x + y + tx^{-1}y^{-1} + \sum_{k\geq 1} a_k t^k,$$

where the a_k are uniquely determined by the requirement that

$$\sum_{i=1}^{\infty}(-1)^{i+1}\frac{(x+y+tx^{-1}y^{-1}+\sum_{k\geq 1}a_kt^k)^i}{i}$$

contains no pure powers of t. This series in t begins as

$$-2t+5t^2-32t^3+286t^4-3038t^5+\cdots.$$

(3) Let σ be the convex hull of the points $(\pm 1,0)$, $(0,\pm 1)$ and take $\mathscr{P}$ to be the star subdivision at the origin. Now the monoid P of convex piecewise linear functions which are 0 on $(0,0,1)$, $(1,0,1)$ and $(0,1,1)$ is isomorphic to $\mathbb{N}^2$, determined by the values α_1,α_2 of the function at generators of the other two rays. Thus we can write $Q=\mathbb{N}^2$, $t_1=z^{(1,0)}\in\Bbbk[Q]$, $t_2=z^{(0,1)}\in\Bbbk[Q]$. Using x,y as defined in the previous example, one can check that for any slab $\mathfrak{b}$,

$$f_{\mathfrak{b},0}:=1+x+y+t_1x^{-1}+t_2y^{-1}+t_1+t_2+3t_1t_2+5t_1^2t_2+5t_1t_2^2+\cdots.$$

The additional terms represented by $\cdots$ give a power series in t_1,t_2.

We now describe the degeneration $\mathcal{Y}\to\operatorname{Spec}\widehat{\Bbbk[Q]}$ produced by the above data. In fact, it is not difficult to do this in terms of equations, as follows. First, define

$$C(\Xi_{\bar\psi}):=\overline{\{((um,0,uq,u)\,|\,(m,0,q)\in\Xi_{\bar\psi},\ u\in\mathbb{R}_{\geq 0}\}}\subseteq M_{\mathbb{R}}\oplus\mathbb{R}\oplus Q^{\mathrm{gp}}_{\mathbb{R}}\oplus\mathbb{R}.$$

Here the closure is necessary because $\Xi_{\bar\psi}$ is unbounded. We then obtain a graded ring

$$S_{\bar\psi}:=\Bbbk[C(\Xi_{\bar\psi})\cap(M\oplus\mathbb{Z}\oplus Q^{\mathrm{gp}}\oplus\mathbb{Z})]$$

where the grading is given by the projection from $M\oplus\mathbb{Z}\oplus Q^{\mathrm{gp}}\oplus\mathbb{Z}$ onto the last copy of $\mathbb{Z}$. Note the closure in the definition of cone adds the cone $\{0\}\times\{0\}\times\mathbb{R}_{\geq 0}Q\times\{0\}$ to the set, so we see the degree 0 part of $S_{\bar\psi}$ is $\Bbbk[Q]$. We can then complete, with

$$\widehat{S}_{\bar\psi}:=S_{\bar\psi}\otimes_{\Bbbk[Q]}\widehat{\Bbbk[Q]}.$$

It is then natural to think of the slab functions as being given by a single degree 1 element of $\widehat{S}_{\bar\psi}$. Indeed, given a vertex $v\in\overline{\mathscr{P}}$, we obtain from $f_{\mathfrak{b},v}$ an element of degree 1 by multiplying all monomials of $f_{\mathfrak{b},v}$ by $z^{(v,0,\bar\psi(v),1)}$. It follows from (3.5) that this is independent of the choice of v and gives an element $F\in\widehat{S}_{\bar\psi}$ of degree 1. One can then show that

$$\mathcal{Y}=\operatorname{Proj}\widehat{S}_{\bar\psi}[U,W]/(UW-z^qV_0F). \tag{3.7}$$

Here U,W are of degree 1, $V_0\in\widehat{S}_{\bar\psi}$ is the element corresponding to $(0,0,0,1)$ (which lies in $\Xi_{\bar\psi}$ by the assumption that $0\in\sigma$ and ψ has been chosen so that $\bar\psi(0)=0$). The element $q\in Q$ is the element chosen in the definition of $\widetilde{\psi}$ at the end of §2. This can be shown in much the way the special case discussed in [21], Example 5.2, being the case of Examples 3.1, (2). Note that after localizing at z^q, this family does not depend on the choice of q up to isomorphism, just as the choice of q did not affect the polarization on the general fibres of $\mathcal{X}\to\mathbb{A}^1$.

The homogeneous coordinate ring of $\mathcal{Y}$ is generated in degree 1 by *theta functions*, as explored in [15]. Each point of $B(\mathbb{Z})$ (the set of points of B with integral coordinates) corresponds to a generator of this ring as a $\widehat{\Bbbk[Q]}$-algebra. Explicitly, the integral points in this example are the integral points of σ and the apexes of the pyramids $\tilde{\sigma}_1$ and $\tilde{\sigma}_2$. If v is an integral point of σ, then $z^{(v,0,\bar{\psi}(v),1)} \in \widehat{S}_{\bar{\psi}}$ is the corresponding theta function. On the other hand, the monomials U and W correspond to the two apexes.

This description of $\mathcal{Y}$ can be related to the more traditional mirror to X_Σ as described in [11]. Here $\mathcal{Y}$ can be decompactified by setting $V_0 = 1$, obtaining an open subset $\mathcal{Y}^o$. Passing to the generic fibre $\mathcal{Y}^o_\eta$ of $\mathcal{Y}^o \to \operatorname{Spec} \widehat{\Bbbk[Q]}$, we obtain a variety defined over the field of fractions K of $\widehat{\Bbbk[Q]}$. We can describe $\mathcal{Y}^o$ as a subvariety of $\mathbb{A}^2 \times (N \otimes_{\mathbb{Z}} \mathbb{G}_m)$ over the field K given by the equation

$$uw = z^q f_{\mathfrak{b},0}, \tag{3.8}$$

where $\mathfrak{b}$ is any slab containing $0 \in \sigma$. Here u, w are coordinates on $\mathbb{A}^2$. Without the normalization condition, we could take $f_{\mathfrak{b},0} = \sum_{m \in \sigma \cap M} z^{(m,\bar{\psi}(m))}$, which would lead to the mirror of X_Σ being precisely that given in [11].

Remark 3.2. The crucial feature of the mirror family we have just described, as opposed to the one given in [11], is that the monomial coordinates on the base $\operatorname{Spec} \widehat{\Bbbk[Q]}$ are canonical in the sense of mirror symmetry. To describe this briefly, we work over the field $\Bbbk = \mathbb{C}$, and assume that the power series $f := f_{\mathfrak{b},0}$ is convergent in some analytic neighbourhood U of the zero-dimensional stratum in $\operatorname{Spec} \mathbb{C}[Q]$. Let $U^* = U \setminus \partial \operatorname{Spec} \mathbb{C}[Q]$, the complement of the union of toric divisors. Thus we can view $\mathcal{Y}^o$ as giving an analytic family $\mathcal{Y}^o \to U^*$. We write $\mathcal{Y}^o_t$ for the fibre over $t \in U^*$. On such a fibre, one has the holomorphic volume form on the fibres of $\mathcal{Y}^o \to \operatorname{Spec} \widehat{\Bbbk[Q]}$ given by

$$\Omega = (2\pi i)^{-n-1} d\log u \wedge d\log x_1 \wedge \cdots \wedge d\log x_n.$$

One then finds that there is a monodromy invariant cycle $\alpha_0 \in H_{n+1}(\mathcal{Y}^o_t, \mathbb{Z})$ such that $\int_{\alpha_0} \Omega = 1$, so that Ω is a normalized holomorphic form in the sense of mirror symmetry. Further, if $q_1, \ldots, q_r \in Q^{\mathrm{gp}}$ are a basis for Q^{gp}, one can find (multi-valued) flat families of $(n+1)$-cycles $\alpha_1, \ldots, \alpha_r$ with $\int_{\alpha_i} \Omega = \log z^{q_i}$. The key point of this calculation is to take the logarithmic derivative of these period integrals and reduce the resulting integral to an integral on the hypersurface $f_{\mathfrak{b},v} = 0$ in $N \otimes_{\mathbb{Z}} \mathbb{G}_m$. Via residues, this is translated into an integral of the derivative of $\log f_{\mathfrak{b},0}$ over various tori in $N \otimes_{\mathbb{Z}} \mathbb{G}_m$. The fact that these integrals are then constant follows precisely from the normalization condition on $f_{\mathfrak{b},0}$.

4. Enumerative predictions

So far we have seen two interpretations of the slab functions and the normalization condition. The first came from the desire to write down a correction to the patching of the naive toric models for the mirror degeneration $\mathcal{Y} \to \operatorname{Spec} \widehat{\Bbbk[Q]}$ in a way consistent with local monodromy of the affine structure on B. We discussed in §2 how this condition along with the normalization condition determines the slab functions uniquely. Then in Remark 3.2 we saw that the normalization condition is responsible for making our families canonically parametrized in the sense of mirror symmetry. Both of these arguments concern the *complex geometry* of the mirror degeneration $\mathcal{Y} \to \operatorname{Spec} \widehat{\Bbbk[Q]}$.

In the following two sections we will give two related interpretations of normalized slab functions related to the *symplectic geometry* of the degeneration $\mathcal{X} \to \mathbb{A}^1$ of the local Calabi-Yau variety X_Σ we started with. The interpretation supports the view that the degenerations constructed by structures are indeed the ones expected from homological mirror symmetry and open-closed string theory.

Since the completion of [20], a clearer idea emerged as to the precise meaning of structures. This picture has arisen from several converging points of view: (1) The heuristic correspondence between tropical Morse trees and Floer homology emerging in discussions between us and Mohammed Abouzaid. Some of these ideas were discussed in [3] and [22]. (2) Auroux's work [4] on T-duality on complements of anti-canonical divisors, describing the complex structure on the SYZ dual of a Lagrangian fibration using counts of Maslov index two disks. This has inspired quite a bit of work, which is realising Fukaya's original dream of correcting the complex structure of the mirror via counts of holomorphic disks. (3) [24] made explicit the enumerative content of the key part of the algorithm of [26] (or the two-dimensional version of [20]). In particular, this established an enumerative meaning for functions attached to walls of a structure.

Heuristically, one expects the following interpretation in the SYZ picture of mirror symmetry. Suppose given a (special) Lagrangian fibration $f : X \to B$ from a Calabi-Yau X, with the general fibre being a torus. Consider Maslov index zero holomorphic disks with boundary a fibre of f. For dimensional reasons the expectation is that the set of points $x \in B$ such that $f^{-1}(x)$ bounds a Maslov index zero holomorphic disk is real codimension one in B, forming a collection of walls. These walls should determine the structure necessary to build the mirror to X, but one needs to attach functions to the walls. Again, heuristically, these functions are expected to take the shape, at a point $x \in B$ with $L = f^{-1}(x)$,

$$\exp\left(\sum_{\substack{\beta \in \pi_2(X,L) \\ \partial\beta \neq 0}} k_\beta n_\beta z^\beta\right). \tag{4.1}$$

Here the sum is over all relative homotopy classes β such that $\partial\beta \in \pi_1(L)$ is non-zero, k_β is the index of $\partial\beta \in \pi_1(L)$ and n_β is some count of Maslov index zero disks with boundary on L. This series should be defined as a formal power series in some suitable ring. One can note that as $x \in B$ varies, the groups $\pi_2(X, L)$ vary forming a local system on B_0 (where $B_0 = \{x \in B \mid f^{-1}(x) \text{ is non-singular}\}$). This local system is analogous to the sheaf $\mathcal{P}$ of §2, with the exact sequence of homotopy groups

$$\pi_2(L) = 0 \to \pi_2(X) \to \pi_2(X, L) \to \pi_1(L) \to \pi_1(X)$$

being analogous to the exact sequence (3.1).

It is difficult to give exact definitions for the numbers n_β. There have been several approaches to dealing with this. For example, Auroux [4] pioneered, in the case of an effective anti-canonical divisor, the use of counts of Maslov index two disks to define holomorphic coordinates which are then transformed by wall-crossing automorphisms as we cross walls in B over which Maslov index zero disks live.

A different approach, using log geometry, originates in [24]. There, working with Pandharipande, we used relative Gromov-Witten invariants to make sense of the formula (4.1). The situation there was effectively that of a rational surface with an anti-canonical divisor D, and the n_β of (4.1) are replaced with counts of curves meeting the divisor D in one point. This was used for a general mirror symmetry construction for such surfaces in [14].

It is interesting to note how these two points of view apply to the case of local mirror symmetry considered in this paper. Auroux's point of view was used effectively in a sequence of papers [7–9] to study the same local mirror symmetry situation as discussed in this paper. Wall-crossing formulas for counts of Maslov index two disks are used to obtain what should be the same slab functions as discussed in this paper. The count of Maslov index two disks is reduced to a closed Gromov-Witten invariant on a toric variety, which can then be calculated via known mirror symmetry results. This allows one to show show that the slab functions defined using their counts give rise to canonical coordinates just as our slab functions do.

On the other hand, generalising the idea of replacing holomorphic disks with relative curves, one should be able to work with a certain kind of logarithmic curve called a *punctured curve*, the theory of which is currently being developed in a joint project with Abramovich and Chen [2]. These curves will live in the central fibre of the toric degeneration $\mathcal{Y} \to \mathbb{A}^1$ constructed in §2, and can be viewed as a substitute for holomorphic curves with boundary in an algebro-geometric context. Then (4.1) can be used to define slab functions, where now n_β is a count of genus 0 logarithmic curves with one puncture.

We do not propose calculating the slab functions in this way. Rather, we should be able to show that the slab functions defined in this way satisfy the same determining properties that the slab functions of §2 did. This is done by probing slabs by broken lines (see [6, 14, 15]) and interpreting these enumeratively using a different type of punctured curve, roughly corresponding to cylinders. These punctured curves play the same role that Maslov index two disks play in the analysis of slab functions of [7–9]. Crucially, we need to use the gluing formula of [2] to relate broken lines and punctured curves.

While the details of this approach will be given elsewhere, let us demonstrate this using the simple example from Examples 3.1, (1). We depict in Figure 4.1 the central fibre of the degeneration $\mathcal{X} \to \mathbb{A}^1$ constructed in §2 in this case. The total space $\mathcal{X}$ has two ordinary double points, situated on the singular locus of $\mathcal{X}_0$, where the map $\mathcal{X} \to \mathbb{A}^1$ is not normal crossings. The inclusion $\mathcal{X}_0 \subseteq \mathcal{X}$ induces a log structure on $\mathcal{X}_0$, but the log structure is not well-behaved at the two points (not *fine* in the sense of log geometry). In particular, the theory of log Gromov-Witten invariants as developed in [1, 10, 23] cannot be used directly. While a theory of invariants which can deal directly with this poorly behaved log structure is under development, for the moment we will deal with it via a small resolution of the ordinary double points. There are four choices of such resolutions, one of which is shown on the right in Figure 4.1. These choices can be thought of in terms of the affine geometry of the dual intersection complex B, with the resolutions corresponding to sliding the two singularities of the affine structure along σ to various choices of vertices.

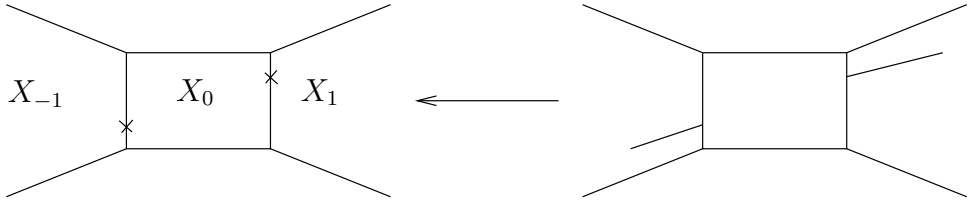

Figure 4.1. The left-hand figure shows the five irreducible components of $\mathcal{X}_0$, with the three labelled components indexed by the vertices of σ. Here $X_0 \cong \mathbb{P}^1 \times \mathbb{P}^1$ and X_{-1}, X_1 are isomorphic to the blow-up of $\mathbb{A}^2$ at a point.

We have different slab functions $f_{\mathfrak{b},v}$ for the vertices $v = -1, 0, 1$. To identify the slab function at a vertex v as a generating function, we choose a small resolution $\widetilde{\mathcal{X}} \to \mathcal{X}$ so that the irreducible component indexed by v remains toric. This effectively slides the singularities away from the vertex. The resolution in Figure 4.1 is used for the vertex $v = 0$. The slab function is given by (4.1) where n_β is a count of log curves of genus 0 with one puncture mapping to the boundary of the component X_v indexed by v. In Figure 4.2 we show the two obvious such curves for $v = 0$. However, multiple covers of these curves totally ramified at the puncture points are also possible, and a d-fold cover will contribute with multiplicity $(-1)^{d+1}/d^2$. The slab function is then, following (4.1),

$$(1 + x^{-1})(1 + xt) = \exp\left(\sum_{d=1}^{\infty} d \cdot \frac{(-1)^{d+1}}{d^2} x^{-d} + \sum_{d=1}^{\infty} d \cdot \frac{(-1)^{d+1}}{d^2} (tx)^d\right),$$

with the monomials x^{-1} and tx and their powers playing the role of z^β.

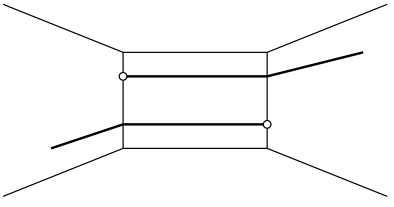

Figure 4.2. The two punctured curves corresponding to holomorphic disks. The curves include the exceptional divisors of the small resolution, and the punctures are represented by the white circles.

To prove this formula without a direct calculation, we show the slab functions defined by these counts satisfy conditions 1-4 of §3. Conditions 1 and 3 are obvious from (4.1), as the statement that only monomials z^β with $\partial\beta \neq 0$ appear is analogous to the statement that no terms of the form z^q for $q \in Q \setminus \{0\}$ appear inside the exponential. Condition 4 is automatic because in this situation the slab function only depends on the vertex. It remains to show condition 2, and we use broken lines for this, which can be reviewed in [22]. A broken line is a piecewise linear path with monomials $c_L z^{m_L}$ attached to each domain of linearity, and the derivative of the line in the domain L is $-\bar{m}_L$. When the broken line crosses a wall, we may change the monomial by applying the wall-crossing automorphism (3.6) to the monomial and choosing a new monomial being one of the terms in the expression obtained after applying this automorphism. In Figure 4.3, we consider germs of broken lines which come vertically from below with initial monomial z^m with $\bar{m} = (0, -1) \in M_{\mathbb{R}} \oplus \mathbb{R}$. We define $\mathrm{Lift}_Q(m)$ to be the sum over all broken lines ending at a basepoint Q of the final attached monomials. Note that if Q is near a vertex v of σ, then in fact $\mathrm{Lift}_Q(m) = z^m f_{\mathfrak{b},v}$. It is then not difficult to show that (3.5) holds for all pairs of adjacent vertices if and only if $\mathrm{Lift}_Q(m)$ is independent of Q chosen above the slabs as in Figure 4.3.

Broken lines can be viewed as a purely combinatorial (tropical) way to count holomorphic cylinders. But we can actually count logarithmic curves of genus 0 with two punctures to emulate cylinders, and there will be a correspondence between such twice-punctured logarithmic curves and broken lines. Varying the basepoint can be achieved by varying a point constraint for one of the punctures. The key point is that various ways of degenerating the

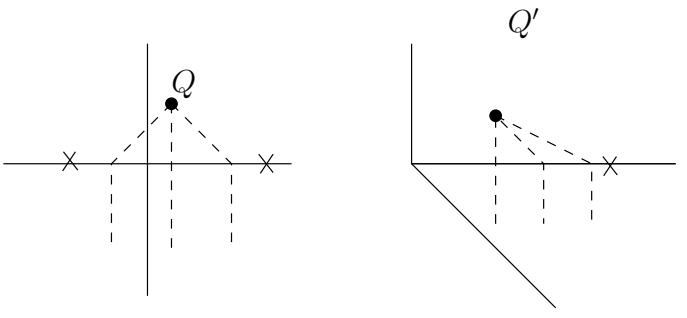

Figure 4.3. There are four broken lines with endpoints Q on the left, two of which don't bend. All have initial monomial z^m with $\bar{m} = (0, -1)$. Once the broken line crosses the slab, there are four possible attached monomials: z^m, tz^m, $x^{-1}z^m$, xtz^m. The right-hand picture shows a different choice of basepoint Q', and there are again four broken lines.

point constraint can lead to different broken lines with different endpoints. However, the count of these punctured curves will be independent of the constraint.

To see this explicitly, let's look at the example of the straight line in the left-hand diagram in Figure 4.3 with attached monomial z^m. To understand what happens when we move this broken line through the singularity, it is helpful to move the singularity to the vertex 0 by using the small resolution depicted in Figure 4.4. Consider the family of twice-punctured curves given by the vertical fibres of X_0, the blowup of $\mathbb{P}^1 \times \mathbb{P}^1$. Any curve in this family has a tropicalization (see [23], §3). The tropicalization of a general curve in this family is just the vertical line through the singularity on the right-hand side of Figure 4.4. Combinatorially, this just indicates that the curve intersects the upper and lower boundary divisors of X_0. However, the family has two special members which are degenerate with respect to the log structure on the central fibre. The tropicalization of the punctured curve when it falls into $X_0 \cap X_1$ is the straight broken line depicted in Figure 4.4 to the right of the vertex. If on the other hand we move the punctured curve to the left, it becomes reducible, the union of $X_{-1} \cap X_0$ and the exceptional curve of the small resolution. This curve tropicalizes to the tropical curve depicted on the left, now with two vertices corresponding to the two components. The bend is a consequence of gluing the once-punctured curve with support the exceptional curve to the thrice-punctured curve with support $X_0 \cap X_{-1}$. The broken line is then a subset of this tropical curve.

The point is that the two broken lines make the same contribution to $\mathrm{Lift}_Q(m)$ as Q varies because they can both be viewed as counting the number of curves in the one-parameter family described passing through some point in X_0. The point can degenerate into $X_{-1} \cap X_0$ or $X_0 \cap X_1$, giving the two types of broken line behaviour. Thus the invariance of $\mathrm{Lift}_Q(m)$ can be viewed as the fact that these lifts are generating functions for counts of certain types of punctured curves.

The key point for the argument is then to prove that broken lines really calculate Gromov-Witten invariants of punctured curves. This shall be shown using a general gluing formula [2].

Note so far we have not actually calculated the Gromov-Witten invariants of X_Σ. These should be extracted in the B-model from some additional period integrals past the ones discussed in Remark 3.2. A significant challenge remaining is to give a tropical description

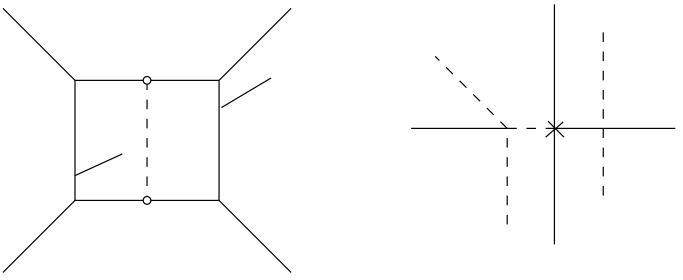

Figure 4.4.

for these period integrals and Gromov-Witten invariants.

Remark added in proof. After the initial release of this paper, Lau in [25] completed the proof that the analogue of the slab functions considered in [7–9] in fact satisfy our normalization condition, and hence agree with our slab functions.

5. Tropical disks and slab functions

The picture of counting holomorphic disks and cylinders from §4 suggests an interpretation of the slab functions in terms of tropical curves. In this section we give a surprisingly simple interpretation of this sort. The arguments are by algebraic manipulations of the slab functions. We are thus lead to the challenge of interpreting the tropical counts in terms of the counting of holomorphic disks on X_Σ.

We study the collection of slab functions at a vertex $v \in \overline{\mathscr{P}}$ with $v \in \operatorname{Int}\sigma$. By Condition (4) of slab functions all the $f_{\mathfrak{b},v}$ for slabs $\mathfrak{b}$ containing v agree. Dehomogenizing (3.7) at v we are thus left with the local model $uw - ft = 0$ for the mirror degeneration for some $f \in \widehat{\Bbbk[P]}$. Here $P = \bar{P}_v$ is a toric submonoid of $M \oplus Q^{\mathrm{gp}}$ with $P^\times = \{0\}$ and the completion is with respect to $P \setminus \{0\}$. Recall also the projection

$$M \oplus Q^{\mathrm{gp}} \longrightarrow M, \quad m \longmapsto \bar{m}.$$

For example, for the mirror of local $\mathbb{P}^2$ we had $Q = \mathbb{N}$, $P \subset \mathbb{N}^3$ generated by $(1,0,0)$, $(0,1,0)$, $(-1,-1,1)$, hence $\widehat{\Bbbk[P]} = \Bbbk[x,y,z][\![t]\!]/(xyz - t)$, and

$$f = 1 + x + y + z - 2t + 5t^2 - 32t^3 + 286t^4 - 3038t^5 + \cdots.$$

In general we assume $f = 1 + \sum_{i=1}^r z^{m_i} + g$ with $\bar{m}_i \neq 0$ for all i and $g = \sum_q b_q \cdot z^q \in \widehat{\Bbbk[Q]}$ taking care of the normalization condition.[2] Under this assumption we are going to give an infinite product expansion

$$f = \prod_{\{m \,|\, \bar{m} \neq 0\}} (1 + a_m z^m)$$

in $\widehat{\Bbbk[P]}$, with each a_m having an interpretation in terms of tropical disks in $M_{\mathbb{R}}$ with root

[2]Note that by the universal nature of Q the sum over z^{m_i} implicitly comprises a universal choice of coefficients.

weight m. Moreover, each coefficient b_q of g has an interpretation in terms of pointed tropical curves of genus zero.[3]

To this end consider the following definition of the *type of a tropical disk*. A *rooted tree* is a partially ordered finite set with a unique maximal element, called the *root vertex*, which is connected and without cycles when viewed as a graph. The *predecessors* of a vertex v are the adjacent vertices that are smaller than v. The minimal elements of a tree are called its *leaves*, so these are the elements without predecessors. We require that there are no elements with only one predecessor. In graph theory language this means that the interior vertices are at least trivalent and the leaves are the unique univalent vertices.

We now define types of tropical trees weighted by elements of P. Note that Q can be identified with the submonoid $\{m \in P \mid \bar{m} = 0\}$ of P.

Definition 5.1. The *type of a P-labelled tropical disk* is a rooted tree Γ with sets V_Γ of vertices and E_Γ of edges along with a *vertex-labeling* map

$$w : V_\Gamma \longrightarrow P \setminus Q, \quad v \longmapsto m_v$$

fulfilling the following conditions:

1. For any non-leaf vertex $v \in V_\Gamma$ with predecessors $v_1, \ldots, v_\ell$ the balancing condition

$$m_v = m_{v_1} + \cdots + m_{v_\ell}$$

holds.

2. For any vertex v the weights $m_1, \ldots, m_\ell$ of the adjacent predecessor vertices are pairwise distinct.

By abuse of notation we suppress the labelling function in the notation and write just Γ for the type of a tropical disk. The set of non-leaf vertices is denoted $\hat{V}_\Gamma$.

If we take the weight m_Γ of the root vertex in Q rather than in $P \setminus Q$ and otherwise leave the definition unchanged we arrive at the notion of *type of P-labelled pointed rational tropical curve*.

Each type of tropical disk or rational tropical curve determines an isotopy class of traditional tropical curves in $M_\mathbb{R}$ with edges labelled by lifts of the direction vector (an element of M) to P, the labelling of the predecessor vertex. In the disk case one may add another edge to force the balancing condition at the root vertex.

The balancing condition for a tropical disk implies that the labelling function is uniquely determined by its values on the leaf vertices $v_1, \ldots, v_\ell$. In particular, for the weight of the root vertex we have

$$m_\Gamma = m_{v_1} + \cdots + m_{v_\ell}.$$

Let now $S = \{m_1, \ldots, m_r\}$ be the set of exponents m occuring in f with $\bar{m} \neq 0$. For $m \in P$ with $\bar{m} \neq 0$ denote by $\mathscr{T}_m(S)$ the set of types of P-labelled tropical disks Γ with $m_\Gamma = m$ and with leaf labels in S. Similarly $\mathscr{R}_q(S)$ denotes the set of types of P-labelled pointed rational tropical curves with leaf labels in S and $m_\Gamma = q$.

[3] If σ has several interior integral points the change of vertex formula (3.4) provides a non-trivial identity between expressions labelled by different sets of tropical trees. It would be interesting to give an interpretation of this formula within the following discussion.

Proposition 5.2. *For $f = 1 + \sum_{m\in S} z^m + g$ with $g = \sum_{q\neq 0} b_q z^q$ as above it holds*

$$f = \prod_{\{m\,|\,\bar m\neq 0\}} (1 + a_m z^m) \tag{5.1}$$

with

$$a_m = \sum_{\Gamma\in\mathscr{T}_m(S)} (-1)^{|\hat V_\Gamma|} \quad \textit{and} \quad b_q = \sum_{\tilde\Gamma\in\mathscr{R}_q(S)} (-1)^{|V_{\tilde\Gamma}|-1}.$$

Proof. Expanding the infinite product in the statement and gathering according to monomials yields

$$\prod_{\{m\,|\,\bar m\neq 0\}} (1 + a_m z^m) = \sum_{m\in P} \left(\sum_{\ell=1}^{\infty} \sum_{\substack{m=m_1+\cdots+m_\ell \\ \Gamma_i\in\mathscr{T}_{m_i}(S)}} (-1)^{|\hat V_{\Gamma_1}|}\cdots(-1)^{|\hat V_{\Gamma_\ell}|} \right) z^m. \tag{5.2}$$

In this expansion ℓ is the number of a_m-terms in the infinite product to be multiplied. Thus the third sum on the right-hand side is over all decompositions $m = m_1 + \cdots + m_\ell$ of m into ℓ *pairwise distinct* summands in P. Recall that $\hat V_\Gamma$ is the set of non-leaf vertices. Fix m with $\bar m \neq 0$ now and consider the coefficient of z^m. Then for $\ell \geq 2$ any collection $\Gamma_1, \ldots, \Gamma_\ell$ of types of tropical disks with $m = m_{\Gamma_1} + \cdots + m_{\Gamma_\ell}$ can be merged into a new type of tropical disk $\Gamma \in \mathscr{T}_m(S)$ by connecting the root vertex of each Γ_i by one edge to the root vertex $v_0 \in V_\Gamma$. Thus the root vertex of Γ is ℓ-valent with adjacent predecessor trees $\Gamma_1, \ldots, \Gamma_\ell$. Now this merged tree Γ contributes to the coefficient of z^m as one term for $\ell = 1$. Since the vertices of Γ other than the root vertex are in bijection with the vertices of $\Gamma_1, \ldots, \Gamma_\ell$ it holds

$$(-1)^{|\hat V_\Gamma|} = -(-1)^{|\hat V_{\Gamma_1}|}\cdots(-1)^{|\hat V_{\Gamma_\ell}|}.$$

Thus each term with $\ell \geq 2$ in the sum of the right-hand side of (5.2) cancels with one term for $\ell = 1$. Conversely, if the root vertex of the type of a tropical disk Γ has valency $\ell \geq 2$ then Γ is obtained by this merging procedure. On the right-hand side of (5.2) we are thus left only with those m with $\bar m = 0$ and in addition with those trees with only one vertex. The latter condition means that the root vertex is also a leaf vertex. These terms yield the sum $\sum_{m\in S} z^m$. The terms with $\bar m = 0$ define a power series $1 + h \in \widehat{\Bbbk[Q]}$. We have thus shown

$$\prod_{\{m\,|\,\bar m\neq 0\}} (1 + a_m z^m) = 1 + \sum_{i=1}^{r} z^{m_i} + h,$$

with $h \in \widehat{\Bbbk[Q]}$. Since the left-hand side of this equation is clearly normalized we see that $h = g$. Tropically, the coefficient of z^q in g is the weighted sum of types of P-labelled pointed rational tropical curves, with the marked point (of valency $\ell \geq 2$) the merging point of ℓ tropical trees $\Gamma_1, \ldots, \Gamma_\ell$. The balancing condition of an underlying tropical curve at the marked point is the statement

$$\bar m_{\Gamma_1} + \cdots + \bar m_{\Gamma_\ell} = \bar m = 0. \qquad \square$$

For $f = 1 + x + y + z + g$ the expansion up to order 4 is

$$(1 + x)(1 + y)(1 + z)(1 - xy)(1 - yz)(1 - xz)(1 + x^2 y)$$

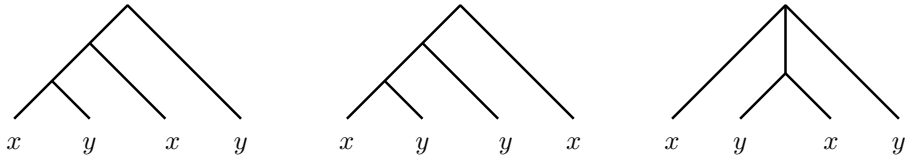

Figure 5.1.

$$\cdot(1+xy^2)\dots(1+yz^2)(1-x^2y^2)(1-y^2z^2)(1-x^2z^2)$$
$$\cdot(1-x^2yz)(1-xy^2z)(1-xyz^2)(1-xz^3)\dots(1-yz^3)$$

Figure 5.1 shows the tropical trees contributing to the coefficient $-1=(-1)^3+(-1)^3+(-1)^2$ of x^2y^2. Note that many labelled trees with four leaves are ruled out because of the third condition in Definition 5.1 that no two predecessor subtrees at some vertex be isomorphic.

We finish this section with two remarks on a possible enumerative interpretation of the expansion in terms of tropical disks and trees. First, according to (4.1) we should write the product expansion (5.1) in exponential form. Indeed, we can also write

$$f=\exp\left(\sum_{\{m\,|\,\bar{m}\neq 0\}}\sum_{\Gamma\in\tilde{\mathscr{T}}_m(S)}\frac{(-1)^{|\hat{V}_\Gamma|}}{|\operatorname{Aut}(\Gamma)|}z^m\right).$$

Here the sum is over the space $\tilde{\mathscr{T}}_m(S)$ of tropical disks with the stability condition Definition 5.1,2 dropped. Expanding $\exp$ in a Taylor series the proof is largely the same as the one given, with extra care taken concerning automorphisms.

Second, in log Gromov-Witten theory the log structure on the moduli space only depends on the type of tropical curve associated to a stable log map [23]. It is tempting to believe in a formulation of the counting problem by a symmetric obstruction theory [5] on a moduli space with a log structure stratified by types of tropical disks, with each stratum contributing $(-1)^{|\hat{V}_\Gamma|}/|\operatorname{Aut}(\Gamma)|$.

Derived category of coherent sheaves and counting invariants

Yukinobu Toda

Abstract. We survey recent developments on Donaldson-Thomas theory, Bridgeland stability conditions and wall-crossing formula. We emphasize the importance of the counting theory of Bridgeland semistable objects in the derived category of coherent sheaves to find a hidden property of the generating series of Donaldson-Thomas invariants.

Mathematics Subject Classification (2010). Primary 14N35; Secondary 18E30.

Keywords. Donaldson-Thomas invariants, Bridgeland stability conditions.

1. Introduction

1.1. Moduli spaces and invariants. The study of the *moduli spaces* is a traditional research subject in algebraic geometry. They are schemes or stacks whose points bijectively correspond to fixed kinds of algebro-geometric objects, say curves, sheaves on a fixed variety, etc. These moduli spaces are interesting not only in algebraic geometry, but also in connection with other research fields such as number theory, differential geometry and string theory. In general it is not easy to study the geometric properties of the moduli spaces. Instead one tries to construct and study the invariants of the moduli spaces, e.g. their (weighted) Euler characteristics, virtual Poincaré or Hodge polynomials, integration of the virtual cycles via deformation-obstruction theory. It has been observed that the best way to study such invariants is taking the generating series. Sometimes the generating series defined from the moduli spaces have beautiful forms and properties. Let us observe this phenomenon for some rather amenable examples. For a quasi-projective variety X (in this article, we always assume that the varieties are defined over $\mathbb{C}$), the *Hilbert scheme of n-points* denoted by $\mathrm{Hilb}_n(X)$ is the moduli space of zero dimensional subschemes $Z \subset X$ such that $\chi(\mathcal{O}_Z) = n$. It contains an open subset corresponding to n-distinct points in X, and the geometric structures of its complement is in general complicated. Nevertheless if X is nonsingular, the generating series of the Euler characteristics of $\mathrm{Hilb}_n(X)$ have the following beautiful forms [21, 27]

$$\sum_{n\geq 0}\chi(\mathrm{Hilb}_n(X))q^n=\begin{cases}(1-q)^{-\chi(X)}, & \dim X=1\\ \prod_{m\geq 1}(1-q^m)^{-\chi(X)}, & \dim X=2\\ \prod_{m\geq 1}(1-q^m)^{-m\chi(X)}, & \dim X=3.\end{cases} \tag{1.1}$$

Proceedings of the International Congress of Mathematicians, Seoul, 2014

In the case $X = \mathbb{C}^d$, the torus localization shows that $\chi(\mathrm{Hilb}_n(\mathbb{C}^d))$ coincides with the number of d-dimensional partitions of n. The resulting product formulas are consequences of enumerative combinatorics, as in [64]. A general case is reduced to the case $X = \mathbb{C}^d$.

1.2. Curve counting invariants. The study of the invariants of the moduli spaces of curves inside a variety is more important and interesting, because of its connection with *world sheet counting* in string theory. A particularly important case is when X is a *Calabi-Yau 3-fold*, i.e. X has a trivial canonical line bundle with $H^1(X, \mathcal{O}_X) = 0$, as the string theory predicts our universe to be the product of the four dimensional space time with a Calabi-Yau 3-fold. Similarly to $\mathrm{Hilb}_n(X)$, we denote by $\mathrm{Hilb}_n(X, \beta)$ the *Hilbert scheme of curves* inside X, that is the moduli space of projective subschemes $C \subset X$ with $\dim C \leq 1$, $[C] = \beta$ and $\chi(\mathcal{O}_C) = n$. The following result was obtained by the author in 2008, and plays a key role in this article:

Theorem 1.1 ([77, 78]). *Let X be a smooth projective Calabi-Yau 3-fold. Then for fixed $\beta \in H_2(X, \mathbb{Z})$, the quotient series*

$$\frac{\sum_{n \in \mathbb{Z}} \chi(\mathrm{Hilb}_n(X, \beta)) q^n}{\sum_{n \geq 0} \chi(\mathrm{Hilb}_n(X)) q^n} \tag{1.2}$$

is the Laurent expansion of a rational function of q, invariant under $q \leftrightarrow 1/q$.

Note that the denominator of (1.2) is given by the formula (1.1). A typical example of a rational function of q invariant under $q \leftrightarrow 1/q$ is $q/(1+q)^2 = q - 2q^2 + 3q^3 - \cdots$. We remark that the invariance of $q \leftrightarrow 1/q$ does not say the invariance of the generating series after the formal substitution $q \mapsto 1/q$, but so after taking the analytic continuation of the function (1.2) from $|q| \ll 1$ to $|q| \gg 1$. The above result was conjectured in [45] as the *unweighted version* of the rationality conjecture of rank one Donaldson-Thomas (DT) invariants by Maulik-Nekrasov-Okounkov-Pandharipande (MNOP) [48]. The rationality conjecture was proposed in order to formulate the *Gromov-Witten/Donaldson-Thomas correspondence conjecture* comparing two kinds of curve counting invariants on Calabi-Yau 3-folds.

The DT invariant was introduced by Thomas [67], as a holomorphic analogue of Casson invariants of real 3-manifolds. It counts stable coherent sheaves on a Calabi-Yau 3-fold, and is a higher dimensional generalization of Donaldson invariants on algebraic surfaces. For a Calabi-Yau 3-fold X, an ample divisor H on X and a cohomology class $v \in H^*(X, \mathbb{Q})$, the DT invariant $\mathrm{DT}_H(v) \in \mathbb{Z}$ is defined to be the degree of the zero dimensional virtual fundamental cycle on the moduli space of H-stable coherent sheaves E on X with $\mathrm{ch}(E) = v$. It also coincides with the weighted Euler characteristic with respect to the Behrend's constructible function on that moduli space [6]. The DT invariants were later generalized by Joyce-Song [36] and Kontsevich-Soibelman [40] so that they also count strictly H-semistable sheaves. The generalized DT invariants involve the Behrend functions and the motivic Hall algebras in the definition, and they are $\mathbb{Q}$-valued.

The Hilbert scheme of points or curves on a Calabi-Yau 3-fold is also interpreted as a moduli space of stable sheaves, by assigning a subscheme $C \subset X$ with its ideal sheaf $I_C \subset \mathcal{O}_X$. The resulting DT invariant is the weighted Euler characteristic of the Hilbert scheme of points or curves, and in particular it is independent of H. In this sense, the invariant $\chi(\mathrm{Hilb}_n(X, \beta))$ is the unweighted version of the DT invariant, which coincides with the honest DT invariant up to sign if $\mathrm{Hilb}_n(X, \beta)$ is non-singular. The result of Theorem 1.1 for the weighted version was later proved by Bridgeland [19]. The rationality property and the

invariance of $q \leftrightarrow 1/q$ of the series (1.2) are not visible if we just look at the moduli spaces of curves or points. Such hidden properties of the series (1.2) are visible after we develop new moduli theory and invariants of objects in the derived category of coherent sheaves.

1.3. Derived category of coherent sheaves. Recall that for a variety X, the bounded derived category of coherent sheaves $D^b\mathrm{Coh}(X)$ is defined to be the localization by quasi-isomorphisms of the homotopy category of the bounded complexes of coherent sheaves on X. The derived category is no longer an abelian category, but has a structure of a triangulated category. It was originally introduced by Grothendieck in 1960's in order to formulate the relative version of Serre duality theorem, known as Grothendieck duality theorem. Later it was observed by Mukai [51] that an abelian variety and its dual abelian variety, which are not necessary isomorphic in general, have the equivalent derived categories of coherent sheaves. This phenomena suggests that the category $D^b\mathrm{Coh}(X)$ has more symmetries than the category of coherent sheaves, as the latter category is known to reconstruct the original variety. Such a phenomena has drawn much attention since Kontsevich proposed the *Homological mirror symmetry conjecture* in [39]. It predicts an equivalence between the derived category of coherent sheaves on a Calabi-Yau manifold and the derived Fukaya category of its mirror manifold, based on an insight that the derived category $D^b\mathrm{Coh}(X)$ is a mathematical framework of D-branes of type B in string theory. There have been several developments in constructing Mukai type derived equivalences between non-isomorphic varieties [5, 14, 38, 55], and non-trivial autequivalences [34, 62], based on the ideas from mirror symmetry. Furthermore such Mukai type equivalences have been discovered beyond algebraic geometry. For instance, derived McKay correspondence [10] gives an equivalence between the derived category of finite group representations and the derived category of coherent sheaves on the crepant resolution of the quotient singularity. This is now interpreted as a special case of equivalences between usual commutative varieties and non-commutative varieties in the context of Van den Bergh's non-commutative crepant resolutions [22]. There also exists an Orlov's equivalence [56] between the derived category of coherent sheaves on a Calabi-Yau hypersurface in the projective space and the category of graded matrix factorizations of the defining equation of it. This result, called Landau-Ginzbrug/Calabi-Yau correspondence, was also motivated by mirror symmetry. Now it is understood that the derived categories have more symmetries than the categories of coherent sheaves. Our point of view is to make the hidden properties of the generating series of DT type invariants visible via symmetries in the derived categories.

1.4. Bridgeland stability conditions. The idea of applying derived categories to the study of generating series of DT type invariants suggests an importance of constructing moduli spaces and invariants of objects in the derived categories. Note that in constructing the original DT invariants, we need to fix an ample divisor on a Calabi-Yau 3-fold X, and the associated stability condition on $\mathrm{Coh}(X)$ in order to construct a good moduli space of stable sheaves. The notion of stability conditions on triangulated categories, in particular on derived categories of coherent sheaves, was introduced by Bridgeland [16] as a mathematical framework of Douglas's Π-stability [24] in string theory. For a triangulated category $\mathcal{D}$, a Bridgeland stability condition on it roughly consists of data $\sigma = (Z, \{\mathcal{P}(\phi)\}_{\phi\in\mathbb{R}})$ for a group homomorphism $Z\colon K(\mathcal{D}) \to \mathbb{C}$ called the *central charge*, and the collection of subcategories $\mathcal{P}(\phi) \subset \mathcal{D}$ for $\phi \in \mathbb{R}$ whose objects are called *σ-semistable objects with phase ϕ*. The main result by Bridgeland [16] is to show that the set of 'good' stability conditions

on $\mathcal{D}$ forms a complex manifold. This complex manifold is in particular important when $\mathcal{D} = D^b\mathrm{Coh}(X)$ for a Calabi-Yau manifold X. In this case, the space of stability conditions $\mathrm{Stab}(X)$ is expected to contain the universal covering space of the moduli space of complex structures of a mirror manifold of X. So far the space $\mathrm{Stab}(X)$ has been studied in several situations, e.g. X is a curve [16, 47], X is a K3 surface [17], X is a some non-compact Calabi-Yau 3-fold [11, 15, 74, 76]. On the other hand, there has been a serious issue in studying Bridgeland stability conditions on projective Calabi-Yau 3-folds which are likely to be the most important case: we are not able to prove the existence of Bridgeland stability conditions on smooth projective Calabi-Yau 3-folds. In [12], the existence problem is reduced to showing a conjectural Bogomolov-Gieseker type inequality evaluating the third Chern character of certain two term complexes of coherent sheaves. However proving that inequality conjecture seems to require a new idea.

1.5. New invariants via derived categories. Let X be a smooth projective Calabi-Yau 3-fold. We expect that, for a given $\sigma \in \mathrm{Stab}(X)$ and $v \in H^*(X, \mathbb{Q})$, there exists the DT type invariant $\mathrm{DT}_\sigma(v) \in \mathbb{Q}$ which counts σ-semistable objects $E \in D^b\mathrm{Coh}(X)$ with $\mathrm{ch}(E) = v$. As we mentioned, there is a serious issue in constructing a Bridgeland stability condition on projective Calabi-Yau 3-folds, but let us ignore this for a while. For an ample divisor H on X, we expect that the classical H-stability appears as a certain special limiting point in $\mathrm{Stab}(X)$ called the *large volume limit*. If we take $\sigma \in \mathrm{Stab}(X)$ near the large volume limit point, then we expect the equality $\mathrm{DT}_\sigma(v) = \mathrm{DT}_H(v)$. On the other hand, suppose that there is an autequivalence Φ of $D^b\mathrm{Coh}(X)$ and $\tau \in \mathrm{Stab}(X)$ so that the equality $\mathrm{DT}_\tau(v) = \mathrm{DT}_\tau(\Phi_* v)$ holds for any v. Then the generating series of the invariants $\mathrm{DT}_\tau(v)$ is preserved by the variable change induced by $v \mapsto \Phi_* v$. If we are able to relate $\mathrm{DT}_\sigma(v)$ and $\mathrm{DT}_\tau(v)$, then it would imply the hidden symmetry of the generating series of classical DT invariants $\mathrm{DT}_H(v)$ with respect $v \mapsto \Phi_* v$. The relationship between $\mathrm{DT}_\sigma(v)$ and $\mathrm{DT}_\tau(v)$ is studied by the wall-crossing phenomena: there should be a wall and chamber structure on the space $\mathrm{Stab}(X)$ so that the invariants $\mathrm{DT}_*(v)$ are constant on a chamber but jumps if $*$ crosses a wall. The wall-crossing formula of the invariants $\mathrm{DT}_*(v)$ should be described by a general framework established by Joyce-Song [36], Kontsevich-Soibelman [40], using stack theoretic Hall algebras.

However as we mentioned, we are not able to prove $\mathrm{Stab}(X) \neq \emptyset$, so the above story is the next stage after proving the non-emptiness. The idea of proving Theorem 1.1 was to introduce 'weak' Bridgeland stability conditions on triangulated categories, and apply the above story for the space of weak stability conditions on the subcategory of $D^b\mathrm{Coh}(X)$ generated by $\mathcal{O}_X$ and one or zero dimensional sheaves. The latter subcategory is called the category of *D0-D2-D6 bound states*. The notion of weak stability conditions is a kind of limiting degenerations of Bridgeland stability conditions, and it is a coarse version of Bayer's polynomial stability conditions [2], the author's limit stability conditions [75]. It is easier to construct weak stability conditions and enough to prove Theorem 1.1 applying the above story. The derived dual $E \mapsto \mathbf{R}\mathcal{H}om(E, \mathcal{O}_X)$, an autequivalence of $D^b\mathrm{Coh}(X)$, turned out to be responsible for the hidden symmetric property of $q \leftrightarrow 1/q$ of the series (1.2) in the above story.

The idea of proving Theorem 1.1 has turned out to be useful in proving several other interesting properties of DT type invariants, say DT/PT correspondence [19, 77] conjectured by Pandharipande-Thomas [59]. We refer to [20, 52, 65, 72, 73, 79, 80, 82–84] for other works relating the above story.

1.6. Plan of this article. In Section 2, we review and survey recent developments of Donaldson-Thomas theory. In Section 3, we survey the developments on Bridgeland stability conditions. In Section 4, we discuss open problems on DT theory and Bridgeland stability conditions.

2. Donaldson-Thomas theory

2.1. Moduli spaces of semistable sheaves. Let X be a smooth projective variety and H an ample divisor on X. For an object $E \in \mathrm{Coh}(X)$, its Hilbert polynomial is given by

$$\chi(E \otimes \mathcal{O}_X(mH)) = a_d m^d + a_{d-1} m^{d-1} + \cdots$$

for $a_i \in \mathbb{Q}$ by the Riemann-Roch theorem. Here $a_d \neq 0$ and d is the dimension of the support of E. The reduced Hilbert polynomial $\overline{\chi}_H(E,m)$ is defined to be $\chi(E \otimes \mathcal{O}_X(mH))/a_d$.

Definition 2.1. An object $E \in \mathrm{Coh}(X)$ is *H-(semi)stable* if for any subsheaf $0 \neq F \subsetneq E$, we have $\dim \mathrm{Supp}(F) = \dim \mathrm{Supp}(E)$ and the inequality $\overline{\chi}_H(F,m) < (\leq) \overline{\chi}_H(E,m)$ holds for $m \gg 0$.

Remark 2.2. Note that if E is torsion free, then $\overline{\chi}_H(F,m) = m^d + c \cdot \mu_H(E) m^{d-1} + O(m^{d-2})$ where $d = \dim X$, $\mu_H(E) = c_1(E)H^{d-1}/\mathrm{rank}(E)$, and c is some constant. Hence the H-(semi)stability is the refinement of H-slope (semi)stability defined by the slope function $\mu_H(*)$.

Let $\mathcal{C}oh(X)$ be the 2-functor from the category of complex schemes to the groupoid, whose S-valued points form the groupoid of flat families of coherent sheaves on X over S. The 2-functor $\mathcal{C}oh(X)$ forms a stack, which is known to be an Artin stack locally of finite type, but neither finite type nor separated. The situation becomes better if we consider the substacks for $v \in H^*(X,\mathbb{Q})$

$$\mathcal{M}_H^{\mathrm{s}}(v) \subset \mathcal{M}_H^{\mathrm{ss}}(v) \subset \mathcal{C}oh(X).$$

Here $\mathcal{M}_H^{\mathrm{s(ss)}}(v)$ is the substack of H-(semi)stable $E \in \mathrm{Coh}(X)$ with $\mathrm{ch}(E) = v$, which is an open substack of $\mathcal{C}oh(X)$. The stack $\mathcal{M}_H^{\mathrm{ss}}(v)$ is of finite type but not separated in general. The stack $\mathcal{M}_H^{\mathrm{s}}(v)$ is of finite type, separated, and a $\mathbb{C}^*$-gerb over a quasi-projective scheme $M_H^{\mathrm{s}}(v)$. The scheme $M_H^{\mathrm{s}}(v)$ is projective if $\mathcal{M}_H^{\mathrm{s}}(v) = \mathcal{M}_H^{\mathrm{ss}}(v)$.

2.2. Donaldson-Thomas invariants. Let X be a smooth projective 3-fold. We say it is a *Calabi-Yau 3-fold* if $K_X = 0$ and $H^1(X,\mathcal{O}_X) = 0$. A typical example is a quintic hypersurface in $\mathbb{P}^4$. Let H be an ample divisor on X, v an element in $H^*(X,\mathbb{Q})$, and consider the moduli scheme $M_H^{\mathrm{s}}(v)$. A standard deformation theory of sheaves (cf. [32]) shows that the tangent space at $[E] \in M_H^{\mathrm{s}}(v)$ is given by $\mathrm{Ext}^1(E,E)$, and the obstruction space is given by $\mathrm{Ext}^2(E,E)$. The Calabi-Yau condition and the Serre duality implies that the latter space is dual to $\mathrm{Ext}^1(E,E)$. Hence the virtual dimension at $[E]$, defined to be the dimension of the tangent space minus the dimension of the obstruction space, is zero which is independent of E. Based on this observation, Thomas [67] constructed two term complex of vector bundles $\mathcal{E}^\bullet$ on $M_H^{\mathrm{s}}(v)$ and a morphism $\mathcal{E}^\bullet \to L_{M_H^{\mathrm{s}}(v)}$ in $D(M_H^{\mathrm{s}}(v))$, giving a symmetric perfect obstruction theory in the sense of Behrend-Fantechi [8, 9]. By

the construction in [8], there is the associated zero dimensional virtual cycle $[M_H^{\mathrm{s}}(v)]^{\mathrm{vir}}$ on $M_H^{\mathrm{s}}(v)$, and we are able to take its degree if $M_H^{\mathrm{s}}(v)$ is projective. The DT invariant is defined as follows:

Definition 2.3. If $\mathcal{M}_H^{\mathrm{s}}(v) = \mathcal{M}_H^{\mathrm{ss}}(v)$ holds, we define $\mathrm{DT}_H(v) \in \mathbb{Z}$ to be the degree of $[M_H^{\mathrm{s}}(v)]^{\mathrm{vir}}$.

The above construction via the virtual cycle easily shows that the DT invariant is invariant under deformations of complex structures of X. However in practice, it is more convenient to describe the DT invariant in terms of Behrend's constructible function [6]. The Behrend function is easily described if we use the following result by Joyce-Song [36]:

Theorem 2.4 ([36]). *for any $p \in M_H^{\mathrm{s}}(v)$, there is an analytic open subset $p \in U \subset M_H^{\mathrm{s}}(v)$, a complex manifold V and a holomorphic function $f \colon V \to \mathbb{C}$ such that U is isomorphic to $\{df = 0\}$.*

Using the above result, the Behrend function ν_B on $M_H^{\mathrm{s}}(v)$ is described as

$$\nu_B(p) = (-1)^{\dim V}(1 - \chi(M_p(f)))$$

where $M_p(f)$ is the Milnor fiber of f at p. The function ν_B is shown to a be well-defined constructible function on $M_H^{\mathrm{s}}(v)$.

Theorem 2.5 ([6]). *If $\mathcal{M}_H^{\mathrm{s}}(v) = \mathcal{M}_H^{\mathrm{ss}}(v)$ holds, we have the equality*

$$\mathrm{DT}_H(v) = \sum_{k \in \mathbb{Z}} k \cdot \chi(\nu_B^{-1}(k)). \tag{2.1}$$

In particular if $M_H^{\mathrm{s}}(v)$ is non-singular and connected, the invariant $\mathrm{DT}_H(v)$ coincides with $\chi(M_H^{\mathrm{s}}(v))$ up to sign.

Based on the above description of the DT invariant, Joyce-Song [36] and Kontsevich-Soibelman [40] constructed the generalized DT invariant $\mathrm{DT}_H(v) \in \mathbb{Q}$ without the condition $\mathcal{M}_H^{\mathrm{s}}(v) = \mathcal{M}_H^{\mathrm{ss}}(v)$. The construction uses the stack theoretic Hall algebra $H(\mathrm{Coh}(X))$ of $\mathrm{Coh}(X)$, and its well-definedness is highly non-trivial. A very rough description of it may be

$$\mathrm{DT}_H(v) = \int_{\log \mathcal{M}_H^{\mathrm{ss}}(v)} \nu_B \cdot d\chi.$$

The 'log' is taken in the algebra $H(\mathrm{Coh}(X))$. Some more explanation of a specific case is available in [81].

Remark 2.6. We can define another invariant $\mathrm{DT}_H^{\chi}(v) \in \mathbb{Q}$ by formally putting $\nu_B \equiv 1$ in the definition of $\mathrm{DT}_H(v)$. If $\mathcal{M}_H^{\mathrm{s}}(v) = \mathcal{M}_H^{\mathrm{ss}}(v)$, it coincides with the usual Euler characteristic $\chi(M_H^{\mathrm{s}}(v))$. When we say a result as a *weighted (resp. an unweighted) version*, it means the result for the invariants $\mathrm{DT}_H(v)$ (resp. $\mathrm{DT}_H^{\chi}(v)$).

2.3. Rank one DT invariants. In what follows, we identify $H^4(X, \mathbb{Q})$, $H^6(X, \mathbb{Q})$ with $H_2(X, \mathbb{Q})$, $\mathbb{Q}$ respectively by the Poincaré duality. Given $\beta \in H_2(X, \mathbb{Z})$ and $n \in \mathbb{Z}$, it

is easy to show that $\mathrm{Hilb}_n(X,\beta)$ is isomorphic to $M_H^{\mathrm{s}}(v)$ for $v=(1,0,-\beta,-n)$ by the assignment $C\mapsto I_C$. The resulting invariant

$$I_{n,\beta}=\mathrm{DT}_H(1,0,-\beta,-n)\in\mathbb{Z}$$

is independent of H, and it counts one or zero dimensional subschemes $C\subset X$ with $[C]=\beta$, $\chi(\mathcal{O}_C)=n$. For $\beta\in H_2(X,\mathbb{Z})$, the series $I_\beta(X)$ is defined to be

$$I_\beta(X)=\sum_{n\in\mathbb{Z}}I_{n,\beta}q^n.$$

Example 2.7. (i) If $\beta=0$, we have [9, 42, 44]

$$I_0(X)=\prod_{k\geq 1}(1-(-q)^k)^{-k\chi(X)}.$$

(ii) If $f\colon X\to Y$ is a birational contraction whose exceptional locus is $C\cong\mathbb{P}^1$ with normal bundle $\mathcal{O}_C(-1)^{\oplus 2}$, we have [3]

$$\sum_{m\geq 0}I_{m[C]}(X)t^m=\prod_{k\geq 1}(1-(-q)^k)^{-k\chi(X)}\prod_{k\geq 1}(1-(-q)^kt)^k.$$

The above example indicates that the quotient series $I_\beta(X)/I_0(X)$ is the honest curve counting series with homology class β. The following conjecture was proposed by MNOP [48]:

Conjecture 2.8 ([48]).

(i) *The quotient series $I_\beta(X)/I_0(X)$ is the Laurent expansion of a rational function of q, invariant under $q\leftrightarrow 1/q$.*

(ii) *After the variable change $q=-e^{i\lambda}$, we have the equality*

$$\sum_{\beta\geq 0}\frac{I_\beta(X)}{I_0(X)}t^\beta=\exp\left(\sum_{g\geq 0,\beta>0}\mathrm{GW}_{g,\beta}(X)\lambda^{2g-2}t^\beta\right).$$

Here $\mathrm{GW}_{g,\beta}(X)\in\mathbb{Q}$ is the Gromov-Witten invariant counting stable maps $f\colon C\to X$ from projective curves C with at worst nodal singularities with $g(C)=g$, $f_*[C]=\beta$. The variable change $q=-e^{i\lambda}$ makes sense by the rationality conjecture (i). The above conjecture was first proved for toric Calabi-Yau 3-folds in [48].

2.4. Developments on MNOP conjecture. As we mentioned in the introduction, the result of Theorem 1.1 is the unweighted version of Conjecture 2.8 (i). The weighted version was proved in [19]. We have the following result [77, 78] (unweighted version), [19] (weighted version):

Theorem 2.9. *There exist invariants $N_{n,\beta}\in\mathbb{Q}$, $L_{n,\beta}\in\mathbb{Q}$ satisfying*

- *$N_{n,\beta}=N_{-n,\beta}=N_{n+H\beta,\beta}$ for any ample divisor H on X,*
- *$L_{n,\beta}=L_{-n,\beta}$, and it is zero for $|n|\gg 0$,*

such that we have the following formula:

$$\sum_{\beta\geq 0} I_\beta(X)t^\beta = \prod_{n>0,\beta\geq 0} \exp((-1)^{n-1}nN_{n,\beta}q^n t^\beta) \left(\sum_{n,\beta} L_{n,\beta}q^n t^\beta\right).$$

Remark 2.10. The proofs for the unweighted version in the author's papers [77, 78] can be modified to show the weighted version, if once a similar result of Theorem 2.4 for the moduli spaces of complexes in [35, 43] is shown to be true (cf. [81]). This is also applied for the results below.

The rationality conjecture is an easy consequence of Theorem 2.9:

Corollary 2.11. *Conjecture 2.8 (i) is true.*

There exist geometric meanings of $N_{n,\beta}$ and $L_{n,\beta}$. The former invariant is nothing but the generalized DT invariant $\mathrm{DT}_H(0,0,\beta,n)$, which counts one or zero dimensional H-semistable sheaves F on X with $[F]=\beta$, $\chi(F)=n$. A priori, $N_{n,\beta}$ is defined using the ample divisor H, but the resulting invariant is shown to be independent of H. The latter invariant $L_{n,\beta}$ is more interesting. It counts certain two term complexes $E\in D^b\mathrm{Coh}(X)$ (indeed they are perverse coherent sheaves in the sense of [7, 37]) satisfying $\mathrm{ch}(E)=(1,0,-\beta,-n)$, which are semistable with respect to a derived self dual weak stability condition on it. The result of Theorem 2.9 is proved along with the idea stated in Subsection 1.5.

A similar idea also proves Pandharipande-Thomas conjecture [59] relating the quotient series of rank one DT invariants with the invariants counting stable pairs. The definition of stable pairs is given as follows:

Definition 2.12 ([59]). A *stable pair* is data (F,s) where F is a pure one dimensional sheaf on X, $s\colon \mathcal{O}_X\to F$ is a morphism which is surjective in dimension one.

A typical example of a stable pair is $(\mathcal{O}_C(D),s)$, where $C\subset X$ is a smooth curve, $D\subset C$ is an effective divisor and s is a natural composition $\mathcal{O}_X\twoheadrightarrow\mathcal{O}_C\subset\mathcal{O}_C(D)$. For given $\beta\in H_2(X,\mathbb{Z})$ and $n\in\mathbb{Z}$, the moduli space $P_n(X,\beta)$ of stable pairs (F,s) with $[F]=\beta$, $\chi(F)=n$ is a projective scheme with a symmetric perfect obstruction theory [59]. The PT invariant $P_{n,\beta}\in\mathbb{Z}$ is defined to be the degree of the zero dimensional virtual fundamental cycle $[P_n(X,\beta)]^{\mathrm{vir}}$ on $P_n(X,\beta)$. The invariant $P_{n,\beta}$ is deformation invariant, and coincides with the weighted Euler characteristic with respect to the Behrend function on $P_n(X,\beta)$. The following conjecture was proposed by [59], its unweighted version was proved in [63, 77], and the weighted version was proved in [19]:

Theorem 2.13. *For fixed $\beta\in H_2(X,\mathbb{Z})$, we have the equality of the generating series*

$$\frac{I_\beta(X)}{I_0(X)}=\sum_{n\in\mathbb{Z}}P_{n,\beta}q^n.$$

Finally in [58], Pandharipande-Pixton proved Conjecture 2.8 (ii) for large class of Calabi-Yau 3-folds including quintic hypersurfaces in $\mathbb{P}^4$:

Theorem 2.14 ([58]). *Conjecture 2.8 (ii) is true if X is a complete intersection Calabi-Yau 3-fold in the product of projective spaces.*

Indeed what they proved is the correspondence between Gromov-Witten invariants and stable pair invariants. Combined with Theorem 2.13, the result of Theorem 2.14 was proved. Their proof relies on the degeneration formula of GW and PT invariants, and the torus localization formula.

2.5. Non-commutative DT theory and flops. The DT theory can be also constructed for non-commutative varieties or algebras. Let Y be a quasi-projective 3-fold which admits two crepant small resolutions giving a *flop*:

$$\phi\colon X \xrightarrow{f} Y \xleftarrow{f^{\dagger}} X^{\dagger}. \tag{2.2}$$

In this situation, Van den Bergh [22] constructed sheaf of non-commutative algebras A_Y on Y and derived equivalences

$$D^b\mathrm{Coh}(X^{\dagger}) \xrightarrow{\Psi} D^b\mathrm{Coh}(A_Y) \xrightarrow{\Phi} D^b\mathrm{Coh}(X) \tag{2.3}$$

so that their composition gives Bridgeland's flop equivalence [16]. For $n \in \mathbb{Z}$ and $\beta \in H_2(X,\mathbb{Z})$, let $\mathrm{Hilb}_n(A_Y,\beta)$ be the moduli space of surjections $A_Y \twoheadrightarrow F$ in $\mathrm{Coh}(A_Y)$ such that F has at most one dimensional support and $[\Phi(F)] = \beta$, $\chi(\Phi(F)) = n$. If X is a smooth projective Calabi-Yau 3-fold, there is a symmetric perfect obstruction theory on $\mathrm{Hilb}_n(A_Y,\beta)$, and the degree of its zero dimensional virtual fundamental cycle defines the *non-commutative DT (ncDT) invariant* $A_{n,\beta} \in \mathbb{Z}$. Alternatively, $A_{n,\beta}$ is defined to be the weighted Euler characteristic of the Behrend function on $\mathrm{Hilb}_n(A_Y,\beta)$. We set $I_\beta(A_Y)$ to be

$$I_\beta(A_Y) = \sum_{n\in\mathbb{Z}} A_{n,\beta} q^n.$$

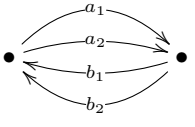
The following result was proved in [84] for the unweighted version, and [20] for the weighted version, basically along with the argument in Subsection 1.5:

Theorem 2.15. *We have the following identities:*

$$\sum_{f_*\beta=0} I_\beta(A_Y)t^\beta = \prod_{k\geq 1}(1-(-q)^k)^{k\chi(X)} \left(\sum_{f_*\beta=0} I_\beta(X)t^\beta\right)\left(\sum_{f_*\beta=0} I_{-\beta}(X)t^\beta\right)$$

$$\frac{\sum_\beta I_\beta(X)t^\beta}{\sum_{f_*\beta=0} I_\beta(X)t^\beta} = \frac{\sum_\beta I_\beta(A_Y)t^\beta}{\sum_{f_*\beta=0} I_\beta(A_Y)t^\beta} = \frac{\sum_\beta I_{\phi_*\beta}(X^{\dagger})t^\beta}{\sum_{f_*\beta=0} I_{\phi_*\beta}(X^{\dagger})t^\beta}.$$

Example 2.16. Let $Y = (xy+zw=0) \subset \mathbb{C}^4$ be the conifold singularity, and take two crepant small resolutions (2.2) by blowing up at the ideals (x,z) and (x,w). In this case, the algebra A_Y is the path algebra of the following quiver



with relation given by the derivations of the super potential $W = a_1b_1a_2b_2 - a_1b_2a_2b_1$. Although X is not projective in this case, the ncDT invariant $A_{n,m[C]} \in \mathbb{Z}$ makes sense, and coincides with the weighted Euler characteristic of the moduli space of framed A_Y-representations with dimension vector $(n, m+n)$. The proof of Theorem 2.15 also works in this situation. Using Example 2.7 (ii), the first identity of Theorem 2.15 becomes

$$\sum_{n,m} A_{n,m[C]} q^n t^m = \prod_{k\geq 1}(1-(-q)^k)^{-2k} \prod_{k\geq 1}(1-(-q)^k t)^k \prod_{k\geq 1}(1-(-q)^k t^{-1})^k.$$

The above formula was first conjectured by Szendrői [66], and later proved by Young [88], Nagao-Nakajima [54].

Remark 2.17. In general for a quiver Q with a super potential W, we are able to define the ncDT theory for (Q,W). A mutation of the pair (Q,W) defines another quiver with a super potential $(Q^{\dagger},W^{\dagger})$. The relationship between ncDT invariants on (Q,W) and $(Q^{\dagger},W^{\dagger})$ is described in terms of cluster transformations. We refer to [40, 53] for the detail.

3. Bridgeland stability conditions

3.1. Definitions. We recall the definition of Bridgeland stability conditions on a triangulated category $\mathcal{D}$. We fix a finitely generated free abelian group Γ with a norm $\| * \|$ on $\Gamma_{\mathbb{R}}$ together with a group homomorphism $\mathrm{cl}\colon K(\mathcal{D}) \to \Gamma$. A typical example is that $\mathcal{D}=D^b\mathrm{Coh}(X)$ for a smooth projective variety X, Γ is the image of the Chern character map $\mathrm{ch}\colon K(X) \to H^*(X,\mathbb{Q})$, and $\mathrm{cl}=\mathrm{ch}$. By taking the dual of cl, we always regard a group homomorhpism $\Gamma \to \mathbb{C}$ as a group homomorphism $K(\mathcal{D}) \to \mathbb{C}$.

Definition 3.1 ([16]). A *stability condition* on $\mathcal{D}$ is data $\sigma=(Z,\{\mathcal{P}(\phi)\}_{\phi\in\mathbb{R}})$, where $Z\colon \Gamma \to \mathbb{C}$ is a group homomorphism (called *central charge*), $\mathcal{P}(\phi)\subset \mathcal{D}$ is a full subcategory (called *σ-semistable objects with phase ϕ*) satisfying the following conditions:

- For $0\neq E\in \mathcal{P}(\phi)$, we have $Z(E)\in \mathbb{R}_{>0}\exp(\sqrt{-1}\pi\phi)$.
- For all $\phi\in\mathbb{R}$, we have $\mathcal{P}(\phi+1)=\mathcal{P}(\phi)[1]$.
- For $\phi_1>\phi_2$ and $E_i\in\mathcal{P}(\phi_i)$, we have $\mathrm{Hom}(E_1,E_2)=0$.
- (Harder-Narasimhan property): For each $0\neq E\in\mathcal{D}$, there is a collection of distinguished triangles $E_{i-1}\to E_i\to F_i\to E_{i-1}[1]$, $E_N=E, E_0=0$ with $F_i\in\mathcal{P}(\phi_i)$ and $\phi_1>\phi_2>\cdots>\phi_N$.

Another way defining a stability condition is to use a t-structure as follows:

Lemma 3.2 ([16]). *Giving a stability condition on $\mathcal{D}$ is equivalent to giving data $(Z,\mathcal{A})$, where $Z\colon \Gamma\to\mathbb{C}$ is a group homomorphism, $\mathcal{A}\subset\mathcal{D}$ is the heart of a bounded t-structure, satisfying*

$$Z(\mathcal{A}\setminus\{0\})\in\{r\exp(i\pi\phi): r>0, 0<\phi\leq 1\} \tag{3.1}$$

together with the Harder-Narasimhan property: for any $E\in\mathcal{A}$, there exists a filtration $0=E_0\subset E_1\subset\cdots\subset E_N=E$ such that $F_i=E_i/E_{i-1}$ is Z-semistable with $\arg Z(F_i)>\arg Z(F_{i+1})$ for all i. Here $E\in\mathcal{A}$ is Z-semistable if for any subobject $0\neq F\subsetneq E$, we have $\arg Z(F)<(\leq)\arg Z(E)$.

Proof. The correspondence is as follows: given $(Z,\{\mathcal{P}(\phi)\}_{\phi\in\mathbb{R}})$, the corresponding heart $\mathcal{A}$ is the extension closure of $\mathcal{P}(\phi)$ for $0<\phi\leq 1$. Conversely given $(Z,\mathcal{A})$, the category $\mathcal{P}(\phi)$ is defined to be the category of Z-semistable objects $E\in\mathcal{A}$ with $Z(E)\in\mathbb{R}_{>0}\exp(i\pi\phi)$. Other $\mathcal{P}(\phi)$ are defined by the rule $\mathcal{P}(\phi+1)=\mathcal{P}(\phi)[1]$. □

Example 3.3. Let C be a smooth projective curve, $\mathcal{D}=D^b\mathrm{Coh}(C)$, $\Gamma=\mathbb{Z}^{\oplus 2}$ and $\mathrm{cl}=(\mathrm{rank},\deg)$. We set $Z\colon\Gamma\to\mathbb{C}$ to be $(r,d)\mapsto -d+ir$. Then $(Z,\mathrm{Coh}(C))$ is a stability condition, whose Z-semistable objects coincide with classical semistable sheaves on C.

3.2. The space of stability conditions. The space of stability conditions is defined as follows:

Definition 3.4. We define $\mathrm{Stab}_\Gamma(\mathcal{D})$ to be the set of stability conditions on $\mathcal{D}$ satisfying the *support property*, i.e. there is a constant $C > 0$ such that $\|\mathrm{cl}(E)\|/|Z(E)| < C$ holds for any $0 \neq E \in \cup_{\phi\in\mathbb{R}}\mathcal{P}(\phi)$.

The main result of Bridgeland [16] shows that the set $\mathrm{Stab}_\Gamma(\mathcal{D})$ has a structure of a complex manifold. If $\mathcal{D} = D^b\mathrm{Coh}(X)$ for a smooth projective variety X, $\Gamma = \mathrm{Im}(\mathrm{ch})$ and $\mathrm{cl} = \mathrm{ch}$, we set $\mathrm{Stab}(X) = \mathrm{Stab}_\Gamma(\mathcal{D})$. Let $\mathrm{Auteq}(X)$ be the group of exact autequivalences of $D^b\mathrm{Coh}(X)$. The space $\mathrm{Stab}(X)$ admits a left action of $\mathrm{Auteq}(X)$ and a right action of $\mathbb{C}$. The latter action is given by $(Z, \{\mathcal{P}(\phi)\}_{\phi\in\mathbb{R}}) \cdot \lambda = (e^{-i\pi\lambda}Z, \{\mathcal{P}(\phi + \mathrm{Re}\lambda)\}_{\phi\in\mathbb{R}})$ for $\lambda \in \mathbb{C}$. We are interested in the double quotient stack

$$[\mathrm{Auteq}(X)\backslash\mathrm{Stab}(X)/\mathbb{C}]\,. \tag{3.2}$$

The conjecture by Bridgeland [18] is that if X is a Calabi-Yau manifold, the above double quotient stack contains the stringy Kähler moduli space of X, that is the moduli space of complex structures of a mirror manifold of X.

Example 3.5.

1. If C is an elliptic curve, then (3.2) is shown in [16] to be isomorphic to the modular curve $\mathrm{SL}_2(\mathbb{Z})\backslash\mathbb{H}$. This is compatible with the fact that C is self mirror.
2. Let $\pi\colon X \to \mathbb{P}^2$ be the total space of $\omega_{\mathbb{P}^2}$, which is a non-compact Calabi-Yau 3-fold. In this case, $\mathrm{Stab}(X)$ is defined to be $\mathrm{Stab}_\Gamma(\mathcal{D})$ where $\mathcal{D}$ is the bounded derived category of compact supported coherent sheaves on X, Γ is the image of $\mathrm{ch}\circ\pi_*$ in $H^*(\mathbb{P}^2, \mathbb{Q})$, and $\mathrm{cl} = \mathrm{ch}\circ\pi_*$. Then the quotient stack (3.2) contains $[(\mathbb{C}\setminus\mu_3)/\mu_3]$ by [11]. The latter stack is the parameter space ψ^3 of the mirror family of X given by
$$\{y_0^3 + y_1^3 + y_2^3 - 3\psi y_1y_2y_3 = 0\} \subset \mathbb{P}^2.$$

The space (3.2) is most interesting for projective Calabi-Yau 3-folds, e.g. quintic hypersurfaces in $\mathbb{P}^4$. Even in the quintic 3-fold case, the space (3.2) is very difficult to study. In this case, Bridgeland's conjecture [18] is stated in the following way:

Conjecture 3.6. *Let $X \subset \mathbb{P}^4$ be a smooth quintic 3-fold, and set $\mathcal{M}_K = [(\mathbb{C}\setminus\mu_5)/\mu_5]$. Then there is an embedding*

$$\mathcal{M}_K \hookrightarrow [\mathrm{Auteq}(X)\backslash\mathrm{Stab}(X)/\mathbb{C}]\,.$$

The above embedding should be given by the solutions of the Picard-Fuchs equation which the period integrals of the mirror family of X satisfy. Its explicit description is available in [69]. However in the projective Calabi-Yau 3-fold case, it is even not known that whether $\mathrm{Stab}(X)$ is non-empty or not. The first issue in solving Conjecture 3.6 is to construct stability conditions, which we discuss in the next subsection.

3.3. Existence problem. It has been a serious issue to construct Bridgeland stability conditions on projective Calabi-Yau 3-folds. Contrary to the one dimensional case, it turns out that there is no stability condition $\sigma \in \mathrm{Stab}(X)$ of the form $\sigma = (Z, \mathrm{Coh}(X))$ if $\dim X \geq 2$. From the arguments in string theory, we expect the following conjecture:

Conjecture 3.7. *Let X be a smooth projective variety and take $B+i\omega \in H^2(X,\mathbb{C})$ with ω ample class. Then there exists the heart of a bounded t-structure $\mathcal{A}_{B,\omega}$ on $D^b\mathrm{Coh}(X)$ such that the pair $\sigma_{B,\omega}=(Z_{B,\omega},\mathcal{A}_{B,\omega})$ determines a point in $\mathrm{Stab}(X)$, where $Z_{B,\omega}$ is given by*

$$Z_{B,\omega}(E)=-\int_X e^{-i\omega}\mathrm{ch}^B(E).$$

Here $\mathrm{ch}^B(E)$ is defined to be $e^{-B}\mathrm{ch}(E)$.

The resulting stability conditions are expected to form a *neighborhood at the large volume limit* in terms of string theory. The above conjecture is known to hold if $\dim X\leq 2$. In the $\dim X=2$ case, the heart $\mathcal{A}_{B,\omega}$ is constructed to be a certain tilting of $\mathrm{Coh}(X)$, which we are going to review.

Let X be a d-dimensional smooth projective variety and take $B+i\omega\in H^2(X,\mathbb{C})$ with ω ample. The ω-slope function on $\mathrm{Coh}(X)$ is defined to be

$$\mu_\omega(E)=\frac{\mathrm{ch}_1(E)\cdot\omega^{d-1}}{\mathrm{rank}(E)}\in\mathbb{R}\cup\{\infty\}.$$

Here $\mu_\omega(E)=\infty$ if $\mathrm{rank}(E)=0$.

Definition 3.8. An object $E\in\mathrm{Coh}(X)$ is *μ_ω-(semi)stable* if for any non-zero subobject $0\neq F\subsetneq E$, we have $\mu_\omega(F)<(\leq)\mu_\omega(E/F)$.

We define the pair of subcategories $(\mathcal{T}_{B,\omega},\mathcal{F}_{B,\omega})$ of $\mathrm{Coh}(X)$ to be

$$\mathcal{T}_{B,\omega}=\langle E\in\mathrm{Coh}(X): E \text{ is } \mu_\omega\text{-semistable with } \mu_\omega(E)>B\omega^{d-1}\rangle$$
$$\mathcal{F}_{B,\omega}=\langle E\in\mathrm{Coh}(X): E \text{ is } \mu_\omega\text{-semistable with } \mu_\omega(E)\leq B\omega^{d-1}\rangle.$$

Here $\langle *\rangle$ means the extension closure. The existence of Harder-Narasimhan filtrations with respect to the μ_ω-stability implies that the pair $(\mathcal{T}_{B,\omega},\mathcal{F}_{B,\omega})$ is a torsion pair (cf. [33]) of $\mathrm{Coh}(X)$. Its tilting defines another heart

$$\mathcal{B}_{B,\omega}=\langle\mathcal{F}_{B,\omega}[1],\mathcal{T}_{B,\omega}\rangle\subset D^b\mathrm{Coh}(X).$$

The following result is due to [1, 17, 85].

Proposition 3.9. *If $\dim X=2$, then $(Z_{B,\omega},\mathcal{B}_{B,\omega})\in\mathrm{Stab}(X)$.*

Proof. Here is a rough sketch of the proof: if $\dim X=2$, then $Z_{B,\omega}(E)$ is written as

$$Z_{B,\omega}(E)=-\mathrm{ch}_2^B(E)+\mathrm{ch}_0^B(E)\omega^2/2+i\mathrm{ch}_1^B(E)\omega.$$

The construction of $\mathcal{B}_{B,\omega}$ immediately implies $\mathrm{Im}Z_{B,\omega}(E)\geq 0$ for any $0\neq E\in\mathcal{B}_{B,\omega}$. We need to check that $\mathrm{Im}Z_{B,\omega}(E)=0$ implies $\mathrm{Re}Z_{B,\omega}(E)<0$. This property can be easily deduced from the the classical Bogomolov-Gieseker (BG) inequality in Theorem 3.10 below. □

The following BG inequality played an important role:

Theorem 3.10 ([13, 29]). *Let X be a d-dimensional smooth projective variety, and E a torsion free μ_ω-semistable sheaf on X. Then we have the following inequality:*

$$\left(\mathrm{ch}_1^B(E)^2-2\mathrm{ch}_0^B(E)\mathrm{ch}_2^B(E)\right)\cdot\omega^{d-2}\geq 0.$$

3.4. Double tilting construction for 3-folds. Suppose that X is a smooth projective 3-fold, and B, ω are defined over $\mathbb{Q}$. In this case, the central charge $Z_{B,\omega}$ is written as

$$Z_{B,\omega}(E) = -\mathrm{ch}_3^B(E) + \mathrm{ch}_1^B(E)\omega^2/2 + i\left(\mathrm{ch}_2^B(E)\omega - \mathrm{ch}_0^B(E)\omega^3/6\right).$$

Contrary to the surface case, the heart $\mathcal{B}_{B,\omega}$ does not fit into a stability condition with central charge $Z_{B,\omega}$. In [12], Bayer, Macri and the author constructed a further tilting of $\mathcal{B}_{B,\omega}$ in order to give a candidate of $\mathcal{A}_{B,\omega}$ in Conjecture 3.7. The key observation is the following lemma, which also relies on Theorem 3.10:

Lemma 3.11 ([12]). *For any $0 \neq E \in \mathcal{B}_{B,\omega}$, one of the following conditions hold:*

(i) $\mathrm{ch}_1^B(E)\omega^2 > 0$.
(ii) $\mathrm{ch}_1^B(E)\omega^2 = 0$ *and* $\mathrm{Im}Z_{B,\omega}(E) > 0$.
(iii) $\mathrm{ch}_1^B(E)\omega^2 = \mathrm{Im}Z_{B,\omega}(E) = 0$ *and* $\mathrm{Re}Z_{B,\omega}(E) < 0$.

The above lemma indicates that the vector $(\mathrm{ch}_1^B(E)\omega^2, \mathrm{Im}Z_{B,\omega}(E), -\mathrm{Re}Z_{B,\omega}(E))$ behaves as if it were $(\mathrm{rank}, c_1, \mathrm{ch}_2)$ on coherent sheaves on surfaces. In [12], this observation led to the following slope function on $\mathcal{B}_{B,\omega}$:

$$\nu_{B,\omega}(E) = \frac{\mathrm{Im}Z_{B,\omega}(E)}{\mathrm{ch}_1^B(E)\omega^2} \in \mathbb{Q} \cup \{\infty\}.$$

Here $\nu_{B,\omega}(E) = \infty$ if $\mathrm{ch}_1^B(E)\omega^2 = 0$. The above lemma shows that $\nu_{B,\omega}$ satisfies the weak see-saw property, and it defines a slope stability condition on $\mathcal{B}_{B,\omega}$. In [12], it was called *tilt-stability*:

Definition 3.12. An object $E \in \mathcal{B}_{B,\omega}$ is tilt (semi)stable if for any subobject $0 \neq F \subsetneq E$, we have $\nu_{B,\omega}(F) < (\leq)\nu_{B,\omega}(E/F)$.

We can show the existence of Harder-Narasimhan filtrations with respect to the tilt stability. Similarly to the surface case, the pair of subcategories $(\mathcal{T}'_{B,\omega}, \mathcal{F}'_{B,\omega})$ of $\mathcal{B}_{B,\omega}$ defined to be

$$\mathcal{T}'_{B,\omega} = \langle E \in \mathcal{B}_{B,\omega} : E \text{ is tilt semistable with } \nu_{B,\omega}(E) > 0 \rangle$$
$$\mathcal{F}'_{B,\omega} = \langle E \in \mathcal{B}_{B,\omega} : E \text{ is tilt semistable with } \nu_{B,\omega}(E) \leq 0 \rangle$$

is a torsion pair. By tilting, we have another heart

$$\mathcal{A}_{B,\omega} = \langle \mathcal{F}'_{B,\omega}[1], \mathcal{T}'_{B,\omega} \rangle \subset D^b\mathrm{Coh}(X).$$

By the construction, we have $\mathrm{Im}Z_{B,\omega}(E) \geq 0$ for any $E \in \mathcal{A}_{B,\omega}$. In [12], we proposed the following conjecture:

Conjecture 3.13 ([12]). *If $\dim X = 3$, we have $(Z_{B,\omega}, \mathcal{A}_{B,\omega}) \in \mathrm{Stab}(X)$.*

3.5. Conjectural BG inequality for 3-folds. Our double tilting construction led to a BG type inequality conjecture evaluating the third Chern characters of tilt semistable objects.

Conjecture 3.14 ([12]). *Let X be a smooth projective 3-fold. Then for any tilt semistable object $E \in \mathcal{B}_{B,\omega}$ with $\nu_{B,\omega}(E) = 0$, i.e. $\mathrm{ch}_2^B(E)\omega = \mathrm{ch}_0^B(E)\omega^3/6$, we have the inequality*

$$\mathrm{ch}_3^B(E) \leq \frac{1}{18}\mathrm{ch}_1^B(E)\omega^2.$$

Remark 3.15. In order to show $(Z_{B,\omega}, \mathcal{A}_{B,\omega})$ satisfies the property (3.1), it is enough to show the weaker inequality $\mathrm{ch}_3^B(E) < \mathrm{ch}_1^B(E)\omega^2/2$. If this is true, the existence of HN filtrations is proved in [12], while the support property remains open. The stronger bound in Conjecture 3.14 was obtained by the requirement that the equality is achieved for tilt semistable objects with zero discriminant.

It seems to be a hard problem to show Conjecture 3.14 even in concrete examples. So far, it is proved when $X = \mathbb{P}^3$ by Macri [46], X is a quadric 3-fold by Schmidt [61], and X is a principally polarized abelian 3-fold with Picard rank one by Maciocia-Piyaratne [49, 50]. Another kind of evidence is that assuming Conjecture 3.14 implies some open problems in other research fields. In [4], it was proved that Conjecture 3.14 implies (almost) Fujita conjecture for 3-folds: for any polarized 3-fold (X, L), $K_X + 4L$ is free and $K_X + 6L$ is very ample. In [83], it was also proved that Conjecture 3.14 implies a conjectural relationship between two kinds of DT type invariants inspired by string theory. This result will be reviewed in Theorem 4.5. It may be worth pointing out that, in both of the above applications, assuming a weaker inequality, say $\mathrm{ch}_3^B(E) < \mathrm{ch}_1^B(E)\omega^2/2$, does not imply anything. The stronger evaluation in Conjecture 3.14 is crucial for the proofs of the applications.

3.6. The space of weak stability conditions. Although the existence of Bridgeland stability conditions on projective Calabi-Yau 3-folds remains open, we are able to modify the definition of Bridgeland stability conditions so that the story in Subsection 1.5 works. The notion of *weak stability conditions* in [77] is one of them. In the situation of Subsection 3.1, we further fix a filtration $0 \subsetneq \Gamma_0 \subsetneq \cdots \subsetneq \Gamma_N = \Gamma$ such that each subquotient Γ_j/Γ_{j-1} is a free abelian group. Instead of considering a group homomorphism $Z \colon \Gamma \to \mathbb{C}$, we consider an element

$$Z = \{Z_i\}_{j=0}^N \in \prod_{j=0}^N \mathrm{Hom}(\Gamma_j/\Gamma_{j-1}, \mathbb{C}). \tag{3.3}$$

Given an element (3.3), we set $Z(v) \in \mathbb{C}$ for $v \in \Gamma$ as follows: there is a unique $0 \leq m \leq N$ such that $v \in \Gamma_m \setminus \Gamma_{m-1}$, where $\Gamma_{-1} = \emptyset$. Then $Z(v)$ is defined to be $Z_m([v]) \in \mathbb{C}$ where $[v]$ is the class of v in Γ_m/Γ_{m-1}.

Definition 3.16. A weak stability condition on $\mathcal{D}$ with respect to the filtration $\Gamma_\bullet$ is data $(Z, \{\mathcal{P}(\phi)\}_{\phi \in \mathbb{R}})$, where Z is as in (3.3), $\mathcal{P}(\phi) \subset \mathcal{D}$ is a full subcategory, satisfying the same axiom in Definition 3.1.

Similarly to Lemma 3.2, giving a weak stability condition is equivalent to giving $(Z, \mathcal{A})$, where Z is as in (3.3), $\mathcal{A} \subset \mathcal{D}$ is the heart of a bounded t-structure, satisfying the same conditions in Lemma 3.2. We denote by $\mathrm{Stab}_{\Gamma_\bullet}(\mathcal{D})$ the set of weak stability conditions on $\mathcal{D}$ with respect to $\Gamma_\bullet$ with a support property. This set also has a structure of a complex

manifold, and coincides with $\mathrm{Stab}_\Gamma(\mathcal{D})$ if $N = 0$, i.e. the filtration $\Gamma_\bullet$ is trivial. In general, it is easier to show the non-emptiness for the space $\mathrm{Stab}_{\Gamma_\bullet}(\mathcal{D})$ with a non-trivial filtration $\Gamma_\bullet$. The result of Theorem 2.9 was obtained by the wall-crossing formula in the space of weak stability conditions on the following triangulated category

$$\mathcal{D}_X = \langle \mathcal{O}_X, \mathrm{Coh}_{\leq 1}(X)\rangle_{\mathrm{tr}} \subset D^b\mathrm{Coh}(X).$$

Here $\mathrm{Coh}_{\leq 1}(X)$ is the category of one or zero dimensional sheaves on X, and $\langle * \rangle_{\mathrm{tr}}$ is the triangulated closure. The relevant data is

$$\Gamma_0 = \mathbb{Z} \oplus H_2(X,\mathbb{Z}) \oplus \{0\} \subset \Gamma_1 = \Gamma = \mathbb{Z} \oplus H_2(X,\mathbb{Z}) \oplus \mathbb{Z}$$

with the map cl given by $\mathrm{cl}(E) = (\mathrm{ch}_3(E), \mathrm{ch}_2(E), \mathrm{ch}_0(E))$. Here $H_2(X,\mathbb{Q})$ is identified with $H^4(X,\mathbb{Q})$ via Poincaré duality. The result of Theorem 2.9 is proved along with the wall-crossing argument of Subsection 1.5 with respect to the one parameter family of weak stability conditions on $\mathcal{D}_X$

$$\sigma_\theta = (Z_{\omega,\theta}, \mathcal{A}_X) \in \mathrm{Stab}_{\Gamma_\bullet}(\mathcal{D}_X), \quad 1/2 \leq \theta < 1$$

from $\theta = 1/2$ to $\theta \to 0$. Here ω is an ample divisor on X, $Z_{\omega,\theta,j}$ are given by

$$Z_{\omega,\theta,0} \colon \Gamma_0 \ni (n,\beta) \mapsto n - (\omega\cdot\beta)i, \quad Z_{\omega,\theta,1} : \mathbb{Z} \ni r \mapsto r\exp(i\pi\theta).$$

The heart $\mathcal{A}_X \subset \mathcal{D}_X$ is obtained as the extension closure of objects $\mathcal{O}_X$ and $\mathrm{Coh}_{\leq 1}(X)[-1]$. We are able to construct DT type invariant

$$\mathrm{DT}_{\sigma_\theta}(1,0,-\beta,-n) \in \mathbb{Q}$$

which counts σ_θ-semistable objects $E \in \mathcal{A}_X$ with $\mathrm{ch}(E) = (1,0,-\beta,-n)$. It is shown that

$$\mathrm{DT}_{\theta\to 1}(1,0,-\beta,-n) = P_{n,\beta}, \quad \mathrm{DT}_{\theta=1/2}(1,0,-\beta,-n) = L_{n,\beta}$$

where $L_{n,\beta}$ is the invariant in Theorem 2.9. The wall-crossing formula describes the difference between $P_{n,\beta}$ and $L_{n,\beta}$. A similar wall-crossing phenomena also implies the relationship between $I_{n,\beta}$ and $P_{n,\beta}$ in Theorem 2.13. Combined them, we obtain the result of Theorem 2.9. Some more detail is also available in [81].

4. Further results and conjectures

4.1. Multiple cover formula conjecture. Although Conjecture 2.8 (i) is proved, a stronger version of the rationality conjecture remains open. It was proposed by Pandharipande-Thomas [59], and predicts the product expansion (called *Gopakumar-Vafa form*) of the generating series of PT invariants:

$$\begin{aligned} &1 + \sum_{n\in\mathbb{Z},\beta>0} P_{n,\beta} q^n t^\beta \\ &= \prod_{\beta>0}\left(\prod_{j=1}^{\infty}(1-(-q)^j t^\beta)^{jn_0^\beta} \prod_{g=1}^{\infty}\prod_{k=0}^{2g-2}(1-(-q)^{g-1}t^\beta)^{(-1)^{k+g}n_g^\beta\binom{2g-2}{k}}\right) \end{aligned}$$

for some $n_g^\beta \in \mathbb{Z}$. Using Theorem 2.9 and Theorem 2.13, the above strong rationality conjecture is proved in [81] to be equivalent to the following conjecture:

Conjecture 4.1 ([36, 81]). *We have the following identity:*

$$N_{n,\beta}=\sum_{k\in\mathbb{Z}_{\geq 1},k|(n,\beta)}\frac{1}{k^2}N_{1,\beta/k}.$$

The invariant $N_{1,\beta}$ is always integer, and the above conjecture is stronger then the integrality conjecture by Kontsevich-Soibelman [40].

4.2. Gepner type stability conditions. Let $W\in A=\mathbb{C}[x_1,\cdots,x_n]$ be a homogeneous polynomial of degree d. By definition, a graded matrix factorization consists of data

$$P^0\stackrel{p^0}{\to}P^1\stackrel{p^1}{\to}P^0(d)$$

where P^i are graded free A-modules of finite rank, p^i are homomorphisms of graded A-modules, $P^i\mapsto P^i(1)$ is the shift of the grading, satisfying $p^1\circ p^0=p^0\circ p^1=\cdot W$. The triangulated category $\mathrm{HMF}(W)$ is defined to be the homotopy category of graded matrix factorizations of W. It has a structure of a triangulated category, and related to $D^b\mathrm{Coh}(X)$ for the hypersurface $X=(W=0)\subset\mathbb{P}^{n-1}$. For instance if $d=n$, there is an equivalence [56]

$$\mathrm{HMF}(W)\stackrel{\sim}{\to}D^b\mathrm{Coh}(X). \tag{4.1}$$

As an analogy of Gieseker stability on $\mathrm{Coh}(X)$, we expect the existence of a natural stability condition on $\mathrm{HMF}(W)$. Based on the earlier works [41, 87], the following conjecture is proposed in [71]:

Conjecture 4.2. *There is a Bridgeland stability condition $\sigma_G=(Z_G,\{\mathcal{P}_G(\phi)\}_{\phi\in\mathbb{R}})$ on $\mathrm{HMF}(W)$ whose central charge Z_G is given by*

$$Z_G\left(\bigoplus_{i=1}^N A(m_i)\rightleftarrows\bigoplus_{i=1}^N A(n_i)\right)=\sum_{i=1}^N\left(e^{\frac{2\pi m_i\sqrt{-1}}{d}}-e^{\frac{2\pi n_i\sqrt{-1}}{d}}\right)$$

and the set of semistable objects satisfy $\tau\mathcal{P}_G(\phi)=\mathcal{P}_G(\phi+2/d)$, where τ is the graded shift functor $P^\bullet\mapsto P^\bullet(1)$.

If $n=d=5$, i.e. X is a quintic 3-fold, a stability condition above is expected to correspond to the orbifold point $0\in\mathcal{M}_K$ in Conjecture 3.6 called Gepner point. By this reason, a stability condition in Conjecture 4.2 is called *Gepner type*. Some evidence of Conjecture 4.2 is available in [41, 70, 71]. Suppose that Conjecture 4.2 is true for $n=d=5$. Then as an analogy of Fan-Jarvis-Ruan-Witten theory [26] in GW theory, we may define the DT type invariant

$$\mathrm{DT}_G(\gamma)\in\mathbb{Q},\ \gamma\in\mathrm{HH}_0(W) \tag{4.2}$$

which counts σ_G-semistable graded matrix factorizations $P^\bullet$ with $\mathrm{ch}(P^\bullet)=\gamma$. Here $\mathrm{HH}_0(W)$ is the zero-th Hochschild homology of $\mathrm{HMF}(W)$, and ch is the Chern character map on graded matrix factorizations (cf. [60]). Because of the property of σ_G, the invariant (4.2) should satisfy $\mathrm{DT}_G(\gamma)=\mathrm{DT}_G(\tau_*\gamma)$. Under the Orlov equivalence (4.1), the equivalence τ on the LHS corresponds to the equivalence $\mathrm{ST}_{\mathcal{O}_X}\circ\mathcal{O}_X(1)$ on the RHS, where $\mathrm{ST}_{\mathcal{O}_X}$ is the Seidel-Thomas twist [62] associated to $\mathcal{O}_X$. Along with the argument in Subsection 1.5, the existence of the invariant (4.2) should imply a hidden symmetry of the generating series of the original DT invariants on the quintic hypersurface $X=(W=0)$ with respect to the equivalence $\mathrm{ST}_{\mathcal{O}_X}\circ\mathcal{O}_X(1)$.

4.3. S-duality conjecture for DT invariants. Let us recall the original S-duality conjecture by Vafa-Witten [86]. It predicts the (at least almost) modularity of the generating series of Euler characteristics of moduli spaces of stable torsion free sheaves on algebraic surfaces with a fixed rank and a first Chern class. We refer to [28] for the developments on the S-duality conjecture so far. Instead of stable torsion free sheaves on algebraic surfaces, we consider semistable pure two dimensional torsion sheaves on Calabi-Yau 3-folds, and DT invariants counting them. Let X be a smooth projective Calabi-Yau 3-fold, H an ample divisor on X and fix a divisor class $P \in H^2(X, \mathbb{Z})$. We consider the following generating series

$$\mathrm{DT}_H(P) = \sum_{\beta \in H_2(X), n \in \mathbb{Q}} \mathrm{DT}_H(0, P, -\beta, -n - P \cdot c_2(X)/24) q^n t^\beta. \tag{4.3}$$

Here each coefficient counts H-semistable $E \in \mathrm{Coh}(X)$ whose Mukai vector (*not* Chern character) satisfies $\mathrm{ch}(E) \cdot \sqrt{\mathrm{td}_X} = (0, P, -\beta, -n)$. As a 3-fold version of the S-duality conjecture, we expect that the series (4.3) satisfies a modular transformation property of (almost) Jacobi forms. (We refer to [25] for a basic of Jacobi forms.) Some computations of the invariants $\mathrm{DT}_H(0, P, -\beta, -n)$ are available in [30, 31]. Also the transformation formula of the series (4.3) under a flop is obtained in [68]. Let us consider a flop diagram (2.2) with Y projective, and ω an ample divisor on Y. We assume that the exceptional locus C, $C^\dagger$ of f, $f^\dagger$ are isomorphic to $\mathbb{P}^1$ with $p = f(C) = f^\dagger(C^\dagger)$. Let l be the scheme theoretic length of $f^{-1}(p)$ at the generic point of C.

Theorem 4.3 ([68]). *There exist $n_j \in \mathbb{Z}_{\geq 1}$ for $1 \leq j \leq l$ such that we have the following formula:*

$$\begin{aligned}\mathrm{DT}_{f^{\dagger *}\omega}(\phi_* P) &= \phi_* \mathrm{DT}_{f^*\omega}(P) \\ &\quad \cdot \prod_{j=1}^{l} \left\{ i^{jP\cdot C - 1} \eta(q)^{-1} \vartheta_{1,1}(q, ((-1)^{\phi_* P} t)^{jC^\dagger}) \right\}^{j n_j P \cdot C}.\end{aligned}$$

Here ϕ_* is the variable change $(n, \beta) \mapsto (n, \phi_* \beta)$, $\eta(q)$ is the Dedekind eta function and $\vartheta_{1,1}(q, t)$ is the Jacobi theta function, given as follows:

$$\eta(q) = q^{\frac{1}{24}} \prod_{k \geq 1} (1 - q^k), \quad \vartheta_{1,1}(q, t) = \sum_{k \in \mathbb{Z}} q^{\frac{1}{2}\left(k + \frac{1}{2}\right)^2} (-t)^{k + \frac{1}{2}}. \tag{4.4}$$

Although $f^*\omega$ is not ample, it is shown that the invariants $\mathrm{DT}_{f^*\omega}(v)$ are well-defined. Recall that $\eta(q)$ is a modular form of weight $1/2$, $\vartheta_{1,1}(q, t)$ is a Jacobi form of weight $1/2$ and index $1/2$. The result of Theorem 4.3 shows that the series (4.3) transforms under a flop by a multiplication of a meromorphic Jacobi form, which gives evidence of the S-duality conjecture for DT invariants.

4.4. Mathematical approach toward OSV conjecture. In string theory, the OSV conjecture [57] predicts a certain approximation

$$\mathcal{Z}_{\mathrm{BH}} \sim |\mathcal{Z}_{\mathrm{top}}|^2 \tag{4.5}$$

where the LHS is the partition function of black hole entropy, and the RHS is the partition function of topological string. A version of the above conjecture is mathematically stated as

an approximation between the generating series of DT invariants counting torsion sheaves on Calabi-Yau 3-folds, and the generating series of GW invariants. In [23], Denef-Moore proposed a relationship among the series (4.3) and the generating series of $I_{n,\beta}$, $P_{n,\beta}$ in order to give a derivation of (4.5). A mathematical refinement of Denef-Moore conjecture is stated in [83]. For simplicity, suppose that $\mathrm{Pic}(X)$ is generated by an ample divisor H. For $m \in \mathbb{Z}_{>0}$, we define the following cut off series

$$I^m(q,t) = \sum_{(\beta,n)\in C(m)} I_{n,\beta} q^n t^\beta, \quad P^m(q,t) = \sum_{(\beta,n)\in C(m)} P_{n,\beta} q^n t^\beta.$$

Here $C(m) = \{(\beta,n) : \beta H < mH^3/2, |n| < m^2H^3/2\}$. Moreover, we define the cut off generating series of D6-anti-D6 brane counting

$$\mathcal{Z}_{\mathrm{D6}-\overline{\mathrm{D6}}}(q,t,w) = \sum_{m_2-m_1=m} q^{H^3(m_1^3-m_2^3)/6} t^{H^2(m_1^2-m_2^2)/2} w^{H^3m^3/6+Hc_2(X)m/12} I^m(qw^{-1}, q^{m_2H}tw^{-mH}) P^m(qw^{-1}, q^{-m_1H}t^{-1}w^{-mH}).$$

Conjecture 4.4 ([23, 83]). *For $m \gg 0$, we have the equality*

$$\mathrm{DT}_H(mH) = \frac{\partial}{\partial w} \mathcal{Z}_{\mathrm{D6}-\overline{\mathrm{D6}}}(q,t,w)|_{w=-1}$$

modulo terms of $q^n t^\beta$ with

$$-\frac{H^3}{24}m^3\left(1-\frac{1}{m}\right) \leq n + \frac{(\beta\cdot H)^2}{2mH^3}.$$

In [83], we proved the following:

Theorem 4.5 ([83]). *The unweighted version of Conjecture 4.4 is true if we assume Conjecture 3.14.*

Even if Conjecture 4.4 is proved, still the relationship (4.5) is not obvious. If we follow the arguments in [23], at least we need to prove S-duality conjecture for DT invariants in the previous subsection and MNOP conjecture. Moreover we need to make a mathematical understanding of the approximation $\sim$ in (4.5). Although the relationship (4.5) is motivated by string theory, it seems to involve deep and interesting mathematics.

Derived algebraic geometry and deformation quantization

Bertrand Toën

Abstract. This is a report on recent progress concerning the interactions between derived algebraic geometry and deformation quantization. We present the notion of derived algebraic stacks, of shifted symplectic and Poisson structures, as well as the construction of deformation quantization of shifted Poisson structures. As an application we propose a general construction of the quantization of the moduli space of G-bundles on an oriented space of arbitrary dimension.

Mathematics Subject Classification (2010). Primary 14A20; Secondary 16E35, 53D55.

Keywords. Derived algebraic geometry, deformation quantization, symplectic structures, Poisson structures, derived categories.

1. Introduction

Quantization is an extremely vast subject, particularly because it has a long-standing physical origin and history. Even from the more restrictive point of view of a pure mathematician, quantization possesses many facets and connects with a wide variety of modern mathematical domains. This variety of interactions explains the numerous mathematical incarnations that the expression *quantization* finds in the existing literature, though a common denominator seems to be a *perturbation of a commutative structure into a non-commutative structure*. For a commutative object X (typically a commutative algebra or a manifold), a quantization is most often realized as a family $X_\hbar$, of objects depending on a parameter $\hbar$, which recovers X when $\hbar = 0$ and which is non-commutative for general values of $\hbar$. The existence of the family $X_\hbar$ is in most cases related to the existence of certain additional geometric structures, such as symplectic or Poisson structures.

The purpose of this manuscript is to present a new approach to quantization, or more specifically to the construction and the study of interesting non-commutative deformations of commutative objects of geometrico-algebraic origins. This new approach is based on the *derived algebraic geometry*, a version of algebraic geometry that has emerged in the last decade (see [31, 32]), and which itself consists of a *homotopical perturbation of algebraic geometry*. Derived algebraic geometry not only leads to a unified geometric interpretation of most of the already existing quantum objects (e.g. it treats the quantum group and deformation quantization of a Poisson manifold on an equal footing), but also opens up a whole new world of quantum objects which, as far as we know, have not been identified in the past even though they seem to appear naturally in algebraic geometry, algebraic topology, or representation theory.

Proceedings of the International Congress of Mathematicians, Seoul, 2014

Convention. All varieties, algebras, schemes, stacks, algebraic groups etc ... will be over a ground field k of characteristic zero.

2. Quantization as deformed categories: three motivating examples

In this first section we briefly recall three well known important examples of "quantization in action" in different domains: quantum groups, skein algebras and Donaldson-Thomas invariants. We identify the natural moduli spaces behind each of these examples and explain how they all can be considered from the unified point of view of deformations of categories and monoidal categories of sheaves.

Quantum groups. Probably the most famous and most fundamental of quantum objects are quantum groups. For an algebraic group G, with lie algebra $\mathfrak{g}$, and a choice of a G-invariant element $p \in Sym^2(\mathfrak{g})$, Drinfeld constructs a quantum group (see [10]). Algebraically the quantum group is a deformation of the Hopf algebra $A = \mathcal{O}(G)$ of functions on G, into a non-commutative Hopf algebra $A_\hbar$.

Skein algebras. Skein algebras appear in low dimensional topology (see [38]). They are associated with a given Riemann surface Σ, and are explicitly defined in terms of generators and relations. The generators are given by simple curves traced on the surface Σ, and the relations are given by the so-called skein relations, which possess natural deformations by a parameter $q = e^{2i\pi\hbar}$. The skein algebra associated with Σ, $K_\hbar(\Sigma)$, is a non-commutative deformation of the ring of functions on the character variety of Σ for the group Sl_2 (i.e. the affine algebraic variety whose points describe Sl_2-representations of the fundamental group $\pi_1(\Sigma)$).

Donaldson-Thomas invariants. For X a Calabi-Yau algebraic variety of dimension 3, we denote by $\mathcal{M}_X$ the moduli space of stable vector bundles with fixed numerical invariants. It is a singular variety in general but with a very specific local structure. Indeed, it is known that locally around each point, X embeds into a smooth ambient variety Z as the critical points of a function $f : Z \to \mathbb{A}^1$. Each of these locally defined functions f define a (perverse) sheaf ν_f of vanishing cycles on X, which under an orientability assumption glue to a globally defined perverse sheaf $\mathcal{E}$ on X (see [2, 7, 8] for more on the subject). The sheaf $\mathcal{E}$ is a quantization of the space X, in the sense that it can be seen to be a deformation of the line bundle of *virtual half forms on* X (we refer here to the next section for more about virtual structures). This deformation is again a non-commutative deformation, but this time in a dramatic way as the multiplicative structure itself is lost and $\mathcal{E}$ only exists as a sheaf of (complexes of) vector spaces on X.

Despite their different origins and differences in appearance these three examples of quantization can be considered in a striking unified way: they all are deformations of categories of sheaves on natural moduli spaces, where the categories eventually come equipped with monoidal structures. More is true, these deformations are all induced by the same type of structures on the corresponding moduli spaces, at least when they are appropriately viewed as derived algebraic stacks as we will explain later. The moduli spaces related to these three examples are easy to guess: they are respectively the moduli space $Bun_G(*)$

of G-bundles on a point $*$, the moduli space $Bun_{Sl_2}(\Sigma)$ of Sl_2-bundles on the surface Σ, and the moduli space $\mathcal{M}_X$ of algebraic Gl_n-bundles on X, also denoted $Bun_{Gl_n}(X)$. In the case of the quantum group, there is no non-trivial G-bundles on a point, but the trivial G-bundle possesses many automorphisms. The moduli space $Bun_G(*)$ is thus trivial from the point of view of algebraic varieties but can be realized as a non-trivial algebraic stack BG. Quasi-coherent sheaves on BG are nothing else than linear representations of G, $QCoh(BG) = Rep(G)$. The quantum group $A_\hbar$ can then be realized as a deformation of $QCoh(BG)$ considered as a braided monoidal category. For the case of skein algebras, we already mentioned that $K_{\hbar=0}(\Sigma)$ is the ring of functions on the moduli space $\chi(\Sigma) = Bun_{Sl_2}(\Sigma)$. The moduli space $Bun_{Sl_2}(\Sigma)$ is an affine algebraic variety and thus its category of quasi-coherent sheaves is equivalent to modules over its ring of functions, $QCoh(Bun_{Sl_2}(\Sigma)) = K_{\hbar=0}(\Sigma) - Mod$. The deformation $K_\hbar(\Sigma)$ can thus be realized as a deformation of the category $QCoh(Bun_{Sl_2}(\Sigma))$, simply considered as a linear category. Finally, the perverse sheaf $\mathcal{E}$ on $\mathcal{M}_X$ can itself be considered as a deformation of a natural object $\omega_X^{1/2,virt}$, of *virtual half top forms on* X, which is almost a quasi-coherent sheaf on X (it is a complex of such). The quantized object $\mathcal{E}$ is thus not a deformation of $QCoh(X)$, but is rather a deformation of one of its objects.

To summarize, all of the three examples discussed above have an interpretation in terms of deformations of categories, possibly with monoidal structures, of quasi-coherent sheaves on certain moduli spaces. Monoidal categories can be organized in a hierarchy, corresponding to the degree of symmetry imposed on the monoidal structure. For instance, a monoidal category can come equipped with a braiding, or a symmetry constraint. Monoidal categories will be referred to as 1-fold monoidal categories, braided monoidal categories as 2-fold monoidal categories, and symmetric monoidal categories as ∞-fold monoidal categories. We will moreover see that when categories are replaced by ∞-categories there is a notion of n-fold monoidal ∞-categories for $2 < n < \infty$ (also called E_n-monoidal ∞-categories), interpolating between braided and symmetric monoidal categories. When $n = 0$, a 0-fold category can be defined to simply be a category, a (-1)-monoidal category can be declared to be an object in a category, and a (-2)-monoidal category can be defined as an endomorphism of an object in a category. This hierarchy is rather standard in the setting of higher category theory in which a monoidal category is often considered as a 2-category with a unique object, and a braided monoidal categories as a 3-category with unique object and unique 1-morphism (see for instance [26, §V-25]).

In our examples above, quantum groups are deformations of $QCoh(Bun_G(*))$ as a 2-fold monoidal category. Skein algebras are deformations of $QCoh(Bun_{Sl_2}(\Sigma))$ as 0-fold monoidal categories. Finally, the perverse sheaf $\mathcal{E}$ is a deformation of $QCoh(Bun_{Gl_n}(X))$ considered as (-1)-fold monoidal category. The purpose of the present paper is to explain that this is only a very small part of a bigger coherent picture, which we present here as a key principle.

Principle 2.1. *For any oriented manifold of dimension d (understood either in the topological or in the algebraic sense), and any reductive group G, the moduli space of G-bundles on X, $Bun_G(X)$, possesses a quantization which is a deformation of $QCoh(Bun_G(X))$ considered as an $(2-d)$-fold monoidal ∞-category.*

We will see how this principle can becomes a theorem, after a suitable interpretation of $Bun_G(X)$, $QCoh(Bun_G(X))$, and a suitable understanding of $(2-d)$-fold monoidal structures. We will also see how this principle follows from the general framework of symplectic

and poisson structures in derived algebraic geometry, and a general quantization procedure.

3. Moduli spaces as derived stacks

The concept of an algebraic variety is not quite enough to encompass all the aspects of the moduli problems appearing in algebraic geometry. Starting in the 50' and continuing until this day, several successive generalizations of algebraic varieties were introduced in order to understand more and more refined aspects of moduli spaces. As a first step nilpotent functions have been allowed as it is well known that many interesting moduli spaces are non-reduced and must be considered as schemes instead of algebraic varieties. Secondly algebraic stacks have been introduced in order to take into account the fact that in most examples, moduli spaces classify objects only up to isomorphisms, and in many situations non-trivial automorphisms prevent the existence of any reasonable moduli spaces. Unfortunately algebraic stacks are still not enough to capture all aspects of moduli problems, as even though they see non-trivial automorphisms the so-called *higher structures* remain invisible. We will explain in this section what the higher structures are and how the notion of *derived algebraic stacks* is needed in order to incorporate them as part of the refined moduli space.

3.1. Higher structures I: higher stacks. A first type of higher structure concerns *higher homotopies*, which appear naturally each time objects are classified not only up to isomorphism but up to a weaker notion of *equivalences*. A typical example is the extension of the moduli space of vector bundles on a given smooth and projective algebraic variety X, by also allowing complexes of vector bundles, now considered up to quasi-isomorphism[1]. The moduli space of vector bundles on X can be realized as an algebraic stack, but the moduli of complexes of vector bundles taken up to quasi-isomorphism can not be represented by an algebraic stack in the sense of [1]. The reason for this is the existence of higher homotopies between maps between complexes, which is reflected in the fact that a complex E on X can have non-trivial negative self extension groups $Ext^{-i}(E,E)$. The vector spaces $Ext^{-i}(E,E)$ for $i>0$ are higher analogues of automorphism groups of vector bundles and their existence prevent the representability by an algebraic stack for the exact same reason that the existence of non-trivial automorphisms of vector bundles prevent the representability of the moduli problem of vector bundles on X by a scheme. In his manuscript "Pursuing stacks", A. Grothendieck brought forward the idea of *higher stack*, which is an extension of the notion of stacks of groupoids usually considered in moduli theory to a higher categorical or higher homotopical setting. This idea has been made concrete in [27] by the introduction of a notion of *algebraic n-stacks* (see also [31]). These algebraic n-stacks behave in a very similar way to algebraic stacks, and most of the standard notions and techniques of algebraic geometry remain valid in this new setting (they have derived categories, cohomology, tangent spaces, dimensions ...). Fundamental examples of algebraic n-stacks include the Eilenberg-McLane stacks of the form $K(A,n)$, for A a commutative algebraic group, which are higher analogues of classifying stacks BG. Another important example for us are the so-called linear stacks: for a scheme X and a complex of vector bundles E_* on X concentrated in degrees $[-n,0]$, there is a linear stack $\mathbb{V}(E_*)\longrightarrow X$, which is a generalization of the total space of a vector bundle. Finally, for X a smooth and projective variety, there is an

[1] This appears typically in Donaldson-Thomas theory for which moduli spaces of objects in the bounded coherent derived category $D^b_{coh}(X)$ must be considered.

algebraic n-stack of complexes of vector bundles on X, which also possesses many possible non-commutative generalizations (see [31, 32] for more on the subject).

3.2. Higher structures II: derived algebraic stacks. A second type of higher structure attached to moduli problems is called the *derived structure*. These derived structures are somehow dual to the higher homotopies we have just mentioned and exist even in absence of any stacky phenomenon (i.e. even when there are no non-trivial automorphisms). They have been introduced through the eye of deformation theory and originally were only considered at the formal level of moduli spaces. The *derived deformation theory*, also referred to as DDT, is a collection of ideas going back to the 80's, stipulating that moduli spaces, formally around a given fixed point, can be described in terms of Mauer-Cartan elements in a suitable dg-Lie algebra associated to this point. The most famous example is the deformation theory of a given smooth projective variety X, for which the natural dg-Lie algebra is $C^*(X, \mathbb{T}_X)$, the cochain complex computing the cohomology of the tangent sheaf, endowed with its dg-Lie structure coming from the bracket of vector fields. This example is not special, and in fact all possible moduli problems come with natural dg-Lie algebras describing their formal completions.

A striking consequence of the DDT is the existence of *virtual sheaves* on moduli spaces. Indeed, according to the DDT, for a point $x \in \mathcal{M}$ in some moduli space $\mathcal{M}$, we can find a dg-Lie algebra $\mathfrak{g}_x$ controlling the formal local ring of $\mathcal{M}$ at x. There is moreover an explicit formula reconstructing formal functions at x:

$$\widehat{\mathcal{O}}_{\mathcal{M},x} \simeq H^0(C^*(\mathfrak{g}_x)) \simeq H^0(\mathfrak{g}_x, k),$$

where $C^*(\mathfrak{g}_x) = \widehat{Sym}_k(\mathfrak{g}_x^*[-1])$ is the (completed) Chevalley complex of $\mathfrak{g}_x$, which also computes the cohomology of k considered as a the trivial $\mathfrak{g}_x$-module. An important observation is that the Chevalley complex $C^*(\mathfrak{g}_x)$ is a commutative dg-algebra which can have non trivial cohomology in non-positive degrees. These cohomology groups, $H^i(C^*(\mathfrak{g}_x))$ for $i < 0$, provide non-trivial coherent sheaves over the formal neighborhood of x, which are by definition the *derived structures of $\mathcal{M}$ around x*. These local coherent sheaves are quite important, as they control for instance the smoothness defect of the moduli space $\mathcal{M}$, and lead to the so-called virtual fundamental class (see [16]). Incorporating these higher structures as an intrinsic part of the moduli space itself has lead to the theory of *derived algebraic geometry*, and to introduction of *derived schemes* and *derived algebraic $(n-)$stacks* as the correct geometrico-algebraic notion to fully represent moduli problems in algebraic geometry.

3.3. Derived schemes and derived algebraic stacks. The foundations of the theory of derived algebraic geometry can be found in [36, 37] and [18]. We will not give precise definitions here, as the details easily become technical, and will rather concentrate on some basic definitions and basic facts.

3.3.1. Derived schemes. As objects derived schemes are rather easy to define and understand. We display below one possible definition of derived schemes (specific to the characteristic zero case, recall that everything is over a base field k of zero characteristic).

Definition 3.1. *A* derived scheme *(over the field k) consists of a pair $(X, \mathcal{O}_X)$, where X is a topological space and $\mathcal{O}_X$ is a sheaf of commutative differential graded k-algebras on X, satisfying the following conditions.*

- *The sheaves $H^i(\mathcal{O}_X)$ vanish for $i > 0$.*
- *The ringed space $(X, H^0(\mathcal{O}_X))$ is a k-scheme.*
- *For all i, $H^i(\mathcal{O}_X)$, considered as a sheaf of $H^0(\mathcal{O}_X)$-modules, is a quasi-coherent sheaf.*

The above definition makes derived schemes look as rather simple objects, but things get more sophisticated when morphisms between derived schemes are introduced. The sheaf of dg-algebras $\mathcal{O}_X$ must only be considered up to quasi-isomorphisms, and quasi-isomorphic derived schemes have to be considered as equivalent. Therefore, there is a *derived category of derived schemes*, which is a non-linear analogue of the derived category of a ring, and for which quasi-isomorphic sheaves of dg-algebras define the same derived scheme. There are two possible constructions of the category of derived schemes, a first one relies on model category structures and includes the quasi-isomorphisms as the weak equivalences of a certain model category. A more modern approach, powerful in practice but more demanding in terms of foundations, is to use ∞-categories, and to define the category of derived schemes directly as an ∞-category (see for instance [26]). Concretely this means that morphisms between two given derived schemes do not form a set anymore but are topological spaces, or a simplicial sets. This allows to consider homotopies between morphisms of derived schemes, and thus to define equivalences between derived schemes as morphisms having inverses up to homotopy. The ∞-category $\mathbf{dSch}$ of derived schemes is then defined so that quasi-isomorphisms become homotopy equivalences in $\mathbf{dSch}$. We refer to [32, §2.1] for more details on these two approaches, and we will consider $\mathbf{dSch}$ as an ∞-category in what follows.

There have been a certain number of works on the notion of derived schemes, making many of the basic aspects of scheme theory available in the derived setting. Derived schemes behave in a very similar fashion to schemes, they have a notion of (quasi-coherent) sheaves, cohomology, smooth, flat and étale maps etc .... Special among the derived schemes are the affine derived schemes, which are completely characterized by their functions, which themselves form a non-positively graded cdga. There is a $\mathbf{Spec}$ construction, sending a cdga A to an affine derived scheme $\mathbf{Spec}\, A$, whose underlying space is $\mathbf{Spec}\, H^0(A)$ and whose structure sheaf is given by the various localizations $A[f^{-1}]$ in a very similar manner as for un-derived schemes. The $\mathbf{Spec}$ functor produces a full embedding of the (opposite) ∞-category of cdga into $\mathbf{dSch}$. Here the ∞-category of cdga can be presented concretely as the category whose objects are quasi-free cdga together with the standard simplicial sets of morphisms $Map(A, B)$[2]. A general derived scheme X is locally equivalent to $\mathbf{Spec}\, A$ for some cdga A, and many of the notions defined for cdga can be extended to arbitrary derived scheme by sheafification. This is for instance the case for the notions of smooth, flat and étale maps, as well as for the notion of cotangent complexes of derived schemes, etc.

3.3.2. Derived algebraic stacks. The reader should have already guessed that derived schemes are not quite enough for our purpose and that we will need the notion of derived algebraic stacks (including derived higher stacks in some cases). These are defined in a similar fashion as algebraic stacks and higher algebraic stacks (see [32, 37] for details). In a nutshell a derived algebraic stack is given by a quotient of a derived scheme X by an action of a smooth groupoid. Concretely a derived algebraic stack is associated to a simplicial object

[2]Whose set of n-simplicies is $Hom(A, B \otimes_k DR(\Delta^n))$, where $DR(\Delta^n)$ is the algebraic de Rham complex of the algebraic n-dimensional simplex $\{\sum x_i = 1\} \subset \mathbb{A}^{n+1}$.

X_* made of derived schemes satisfying some smooth Kan lifting conditions (see [24]). A typical example is the action of an algebraic group G on a derived scheme Y, for which the simplicial objects is the standard nerve of the action $([n] \in \Delta) \mapsto Y \times G^n$, where the face maps are defined by the action of G on Y and the multiplication on G, and the degeneracies are induced by the unit in G. The derived algebraic stack obtained this way will be denoted by $[Y/G]$, and it should be noted that already some interesting derived algebraic stacks are of this form (but these are not enough to represent all moduli problems).

Derived algebraic stacks are good objects to do algebraic geometry with, and many of the standard notions and results known for underived algebraic stacks can be extended to the derived setting. One construction of fundamental importance for us is the (dg-)category (see [15]) of quasi-coherent complexes on a given derived algebraic stack. For an affine derived scheme $X = \mathbf{Spec}\, A$, the quasi-coherent complexes over X are declared to be the A-dg-modules. The A-dg-modules form a nice k-linear dg-category $L(A)$, for which one explicit model consists of the dg-category of quasi-free A-dg-modules. For a general derived algebraic stack X the dg-category of quasi-coherent complexes is defined by approximating X by affine derived schemes

$$L(X) = L_{qcoh}(X) := \lim_{\mathbf{Spec}\, A \to X} L(A),$$

where the limit is taken inside a suitable ∞-category of dg-categories (see [34]), or equivalently is understood as a homotopy limit inside the homotopy theory of dg-categories of [29].

Another important notion we will use is the cotangent complex. Any derived algebraic stack possesses a canonically defined object $\mathbb{L}_X \in L(X)$, which is the derived version of the sheaf of Kalher 1-forms. When X is a smooth scheme then $\mathbb{L}_X$ is the vector bundle Ω^1_X considered as an object in the quasi-coherent derived category of X. When $X = \mathbf{Spec}\, A$ is an affine derived scheme, $\mathbb{L}_A$ is the A-dg-module representing the so-called André-Quillen homology, and can be defined as the left derived functor of $A \mapsto \Omega^1_A$. For a scheme X, $\mathbb{L}_X$ coincides with Illusie's cotangent complex. For a general derived algebraic stack X the cotangent complex $\mathbb{L}_X \in L_{qcoh}(X)$ is obtained by gluing the cotangent complexes of each stage in a simplicial presentation, but can also be characterized by a universal property involving square zero extensions (see [32, §3.1]). The dual object $\mathbb{T}_X := \underline{Hom}_{\mathcal{O}_X}(\mathbb{L}_X, \mathcal{O}_X) \in L_{qcoh}(X)$ is called the tangent complex of X and is a derived version of the sheaf of derivations.

To finish with general facts about derived algebraic stacks, we would like to mention a specific class of objects which are particularly simple to describe in algebraic terms, and which already contains several non-trivial examples. This class consists of derived algebraic stacks of the form $X = [Y/G]$, where Y is an affine derived scheme and G a linear algebraic group acting on Y. The derived affine scheme Y is the spectrum of a commutative dg-algebra A, which up to a quasi-isomorphism can be chosen to be a cdga inside the category $Rep(G)$ of linear representations of G (and A can even be assumed to be free as a commutative graded algebra). The cdga A, together with its strict G-action, can be used in order to describe $L_{qcoh}(X)$ as well as $\mathbb{L}_X \in L_{qcoh}(X)$. A model for the dg-category $L_{qcoh}(X)$ is the dg-category of cofibrant and fibrant A-dg-modules inside $Rep(G)$, where here fibrant refers to a model category structure on the category of complexes of representations of G (and fibrant means $\mathcal{K}$-injective complex of representations). In particular the homs in the dg-category $L_{qcoh}(X)$ compute G-equivariant ext-groups of A-dg-modules. The object $\mathbb{L}_X \in L_{qcoh}(X)$ can be described as follows. The G-action on A induces a morphism of A-dg-modules

$\mathbb{L}_A \longrightarrow \mathfrak{g}^\vee \otimes_k A$, where $\mathfrak{g}$ is the Lie algebra of G, which is a morphism of A-dg-modules inside $Rep(G)$. The cone of this morphism, or more precisely a cofibrant and fibrant model for this cone, is a model for $\mathbb{L}_X$ as an object in $L_{qcoh}(X)$.

3.4. Representability of derived mapping stacks. As for the case of derived schemes, derived algebraic stacks form an ∞-category denoted by $\mathbf{dArSt}$ (where "Ar" stands for "Artin"). This ∞-category is itself a full sub-∞-category of $\mathbf{dSt}$, the ∞-category of (possibly non-algebraic) derived stacks. The objects of $\mathbf{dSt}$ are ∞-functors $F : \mathbf{cdga} \longrightarrow \mathbb{S}$ satisfying étale descent conditions, and are also called *derived moduli problems*. The derived moduli problems can sometimes be represented by schemes, by derived schemes, or by derived algebraic stacks, in the sense that there exists a derived algebraic stack X together with functorial equivalences $F(A) \simeq Map_{\mathbf{dArSt}}(\mathbf{Spec}\, A, X)$. Proving that a given derived moduli problem is representable is in general not a trivial task, and the following theorem provides a way to construct new derived algebraic stacks.

Theorem 3.2 ([37, Thm. 2.2.6.11]). *Let X be a smooth and proper scheme and Y a derived algebraic stack which is locally of finite presentation over the base field k. Then, the derived moduli problem $A \mapsto Map_{\mathbf{dSt}}(X \times \mathbf{Spec}\, A, Y)$ is representable by a derived algebraic stack denoted by $\mathbf{Map}(X, Y)$.*

One important aspect of the theorem above lies in the fact that the (co-)tangent complexes of the derived mapping stacks $\mathbf{Map}(X, Y)$ are easy to compute: there is a diagram of derived algebraic stacks $Y \xleftarrow{ev} X \times \mathbf{Map}(X, Y) \xrightarrow{p} \mathbf{Map}(X, Y)$, where ev is the evaluation map and p is the natural projection, and we have

$$\mathbb{T}_{\mathbf{Map}(X,Y)} \simeq p_* ev^*(\mathbb{T}_Y) \in L_{qcoh}(\mathbf{Map}(X, Y)). \tag{3.1}$$

At a given point $f \in \mathbf{Map}(X, Y)$, corresponding to a morphism $f : X \longrightarrow Y$, the formula states that the tangent complex at f is $C^*(X, f^*(\mathbb{T}_Y))$, the cochain complex of cohomology of X with coefficients in the pull-back of $\mathbb{T}_Y$ by f. This last formula is moreover compatible with the dg-Lie structures: the formal completion of $\mathbf{Map}(X, Y)$ corresponds, via the DDT correspondence, to the dg-Lie algebra $C^*(X, f^*(\mathbb{T}_Y))[-1]$ (here $\mathbb{T}_Y[-1]$ is equipped with its natural dg-Lie structure, see [12]). This provides a nice and efficient way to understand the derived moduli space $\mathbf{Map}(X, Y)$ at the formal level.

The above theorem also possesses several possible variations, which often can be reduced to the statement 3.2 itself. For instance X can be replaced by a finite homotopy type (e.g. a compact smooth manifold), or by formal groupoids such as X_{DR} or X_{Dol} (see [28, §9]). This provides existence of derived moduli stacks for maps $X \longrightarrow Y$ understood within different settings (e.g. locally constant maps, maps endowed with flat connections or with a Higgs field etc ...). The formula for the tangent complex remains correct for these variants as well, with a suitable definition of the functors p_* and ev^* involved. Pointwise this is reflected in the fact that $C^*(X, f^*(\mathbb{T}_Y))$ is replaced with the appropriate cohomology theory (cohomology with local coefficients when X is a finite homotopy type, algebraic de Rham cohomology for X_{DR} etc ...).

The main examples of applications of theorem 3.2 will be for us when $Y = BG$, the classifying stack of G-bundles, in which case $\mathbf{Map}(X, BG)$ is by definition the derived moduli stack of G-bundles on X. Other interesting instances of applications arise when $Y = \mathbf{Perf}$ is the derived stack of perfect complexes (in which case $\mathbf{Map}(X, Y)$ is the

derived moduli stack of perfect complexes on X), or when Y is the total space of a shifted total cotangent bundle (see below).

4. Symplectic and Poisson structures in the derived setting

In the previous section we saw why and how moduli problems can be represented by derived schemes and derived algebraic stacks. In the sequel we will be further interested in the representability of derived mapping stacks provided by our theorem 3.2, as well as the formula for their tangent complexes. This formula is the key for the construction of symplectic structures on derived mapping stacks, by using cup products in cohomology in order to define pairing on tangent complexes. This brings us to the notions of *shifted symplectic structures*, and of *shifted poisson structures*, of major importance in order to achieve the goal proposed by our principle 2.1.

4.1. Algebraic de Rham theory of derived algebraic stacks. Let X be a derived algebraic stack locally of finite presentation over our ground field k. We have seen that X possesses a cotangent complex $\mathbb{L}_X$, which is a quasi-coherent complex on X. In our situation $\mathbb{L}_X$ is moreover a perfect $\mathcal{O}_X$-module (see [37, Def. 1.2.4.6]) because of the locally finite presentation condition, and is thus a dualizable object in $L_{qcoh}(X)$. Its dual (dual here as an $\mathcal{O}_X$-module), is the tangent complex $\mathbb{T}_X := \mathbb{L}_X^\vee$. A *p-form on* X is simply defined as an element in $H^0(X, \wedge^p_{\mathcal{O}_X}\mathbb{L}_X)$, or equivalently as a homotopy class of morphisms $w : \wedge^p_{\mathcal{O}_X}\mathbb{T}_X \longrightarrow \mathcal{O}_X$ in $L_{qcoh}(X)$. More generally, if $n \in \mathbb{Z}$, a *p-form of degree* n *on* X is an element in $H^n(X, \wedge^p_{\mathcal{O}_X}\mathbb{L}_X)$, or equivalently a homotopy class of morphisms $w : \wedge^p_{\mathcal{O}_X}\mathbb{T}_X \longrightarrow \mathcal{O}_X[n]$ in $L_{qcoh}(X)$. For p fixed, p-forms of various degrees form a complex of k-vector spaces $\mathcal{A}^p(X) = \Gamma(X, \wedge^p_{\mathcal{O}_X}\mathbb{L}_X)$[3], whose n-th cohomology space is the space of p-forms of degree n.

The total complex of differential forms on X is defined as an infinite product

$$\mathcal{A}(X) := \prod_{i\geq 0} \mathcal{A}^i(X)[-i],$$

and except in the very special case where X is a smooth scheme, this infinite product does not restrict to a finite product in general (i.e. $\mathcal{A}^p(X) \neq 0$ for arbitrary large p's in general). The complex $\mathcal{A}(X)$ can be shown to carry an extra differential called the *de Rham differential* and denoted by dR[4]. The differential dR commutes with the cohomological differential, and the complex $\mathcal{A}(X)$ will be always considered endowed with the corresponding total differential. When X is a smooth scheme $\mathcal{A}(X)$ is simply the algebraic de Rham complex of X. When X is a singular scheme $\mathcal{A}(X)$ is the derived de Rham complex of X, which is known to compute the algebraic de Rham cohomology of X (see [3]). When X is a derived algebraic stack the complex $\mathcal{A}(X)$ is by definition the (algebraic and derived) de Rham complex of X, and it can be shown to compute the algebraic de Rham cohomology of the underlying algebraic stack, and thus the Betti cohomology of its geometric realization when $k = \mathbb{C}$.

The de Rham complex comes equipped with a standard Hodge filtration, which is a decreasing sequence of sub-complexes $F^p\mathcal{A}(X) \subset F^{p-1}\mathcal{A}(X) \subset \mathcal{A}(X)$, where $F^p\mathcal{A}(X)$

[3]Here and in the sequel $\Gamma(X, -)$ stands for the ∞-functor of global sections, and thus computes hypercohomology on X.

[4]The existence of this differential is not a trivial fact because of the stackyness of X, see [22].

consists of the sub-complex $\prod_{i\geq p}\mathcal{A}^i(X)[-i]\subset\prod_{i\geq 0}\mathcal{A}^i(X)$. The complex $F^p\mathcal{A}(X)[p]$ is also denoted by $\mathcal{A}^{p,cl}(X)$ and is by definition the complex of closed p-forms on X. We note here that an n-cocycle in $\mathcal{A}^{p,cl}(X)$ consists of a formal series $\sum_{i\geq 0}\omega_i\cdot t^i$, where ω_i an element of degree $n-i$ in $\mathcal{A}^{p+i}(X)$, and satisfies the infinite number of equations

$$dR(\omega_{i-1})+d(\omega_i)=0 \qquad \forall\, i\geq 0,$$

where dR is the de Rham differential, d is the cohomological differential and ω_i is declared to be 0 when $i<0$. With this notation, ω_0 is the underlying p-form and the higher forms ω_i are the *closeness structures*, reflecting that ω_0 *is closed up to homotopy*.

By definition a closed p-form of degree n on X is an element in $H^n(\mathcal{A}^{p,cl}(X))$. Any closed p-form $\sum_{i\geq 0}\omega_i\cdot t^i$ of degree n has an underlying p-form ω_0 of degree n, and thus defines a morphism $\wedge^p_{\mathcal{O}_X}\mathbb{T}_X\longrightarrow\mathcal{O}_X[n]$ in $L_{qcoh}(X)$. We note here that a given p-form of degree n can come from many different closed p-forms of degree n, or in other words that the projection map $\mathcal{A}^{p,cl}(X)\longrightarrow\mathcal{A}^p(X)$, sending $\sum_{i\geq 0}\omega_i\cdot t^i$ to ω_0, needs not be injective in cohomology. This aspect presents a major difference with the setting of differential forms on smooth schemes, for which a given p-forms is either closed or not closed. This aspect can also be understood in the setting of cyclic homology, as differential forms on X can be interpreted as elements in Hochschild homology of X (suitably defined to encode the eventual stackyness of X), and closed forms as elements in negative cyclic homology.

4.2. Shifted symplectic structures.

Definition 4.1 ([22, Def. 1.18]). *An* n-shifted symplectic structure on X *consists of a closed* 2*-form of degree* n *whose underlying morphism*

$$\wedge^2_{\mathcal{O}_X}\mathbb{T}_X\longrightarrow\mathcal{O}_X[n]$$

is non-degenerate: the adjoint map $\mathbb{T}_X\longrightarrow\mathbb{L}_X[n]$ *is an equivalence of quasi-coherent complexes on* X.

There are some basic examples of n-shifted symplectic structures which are the building blocks of more evolved examples. A 0-shifted symplectic structure on a smooth scheme is simply a symplectic structure understood in the usual sense. For a reductive algebraic group G, the 2-shifted symplectic structures on the stack BG are in one-to-one correspondence with non-degenerate and G-invariant scalar products on the Lie algebra $\mathfrak{g}$ of G. Such a structure always exists and is even unique up to a constant when G is a simple reductive group. When $G=Gl_n$, there is a canonical choice for a 2-shifted symplectic structure on BG by considering the standard invariant scalar product on the space of matrices given by $(A,B)\mapsto Tr(A.B)$.

Another source of examples is provided by shifted cotangent bundles. For X a derived algebraic stack and n an arbitrary integer we define the n-shifted total cotangent derived stack of X by

$$T^*X[n]:=\mathbb{V}(\mathbb{L}_X[n])=\mathbf{Spec}\,(Sym_{\mathcal{O}_X}(\mathbb{T}_X[-n])),$$

as the linear derived algebraic stack over X determined by the perfect complex $\mathbb{L}_X[n]$. The derived algebraic stack $T^*X[n]$ comes equipped with a standard Liouville 1-form of degree n[5], whose de Rham differential provides an n-shifted symplectic structure on X. This is

[5]This form represents the universal 1-form of degree n on X.

already interesting for X a smooth scheme as it provides instances of n-shifted symplectic structures for arbitrary values of n. Note here that when X is a smooth scheme, then $T^*X[n]$ is either a smooth (and thus non-derived) algebraic n-stack if $n \geq 0$, or a derived scheme when $n < 0$. Another interesting and useful example is when $X = BG$ and $n = 1$, as $T^*X[1]$ is then identified with the quotient stack $[\mathfrak{g}^*/G]$, for the co-adjoint action of G. The quotient stack $[\mathfrak{g}^*/G]$ is thus equipped with a canonical 1-shifted symplectic structure, which sheds new light on symplectic reduction (we refer to [9, §2.2] for more on the subject). A third important example is the derived algebraic stack of perfect complexes $\mathbf{Perf}$ (see [22, §2.3]), which is a generalization of the stack BGl_n (BGl_n sits as an open in $\mathbf{Perf}$).

More evolved examples of shifted symplectic structures can be constructed by means of the following existence theorem. This result can be seen as a geometrico-algebraic counter part of the so-called AKSZ formalism.

Theorem 4.2 ([22, Thm. 2.5]). *Let X be either a connected compact oriented topological manifold of dimension d, or a connected smooth and proper scheme of dimension d equipped with a nowhere vanishing top form $s \in \Omega^d_X$. Let Y be a derived algebraic stack endowed with an n-shifted symplectic structure. Then the derived algebraic stack $\mathbf{Map}(X, Y)$ is equipped with a canonical $(n-d)$-shifted symplectic structure.*

An important special case is when $Y = BG$ for G a reductive algebraic group, equipped with the 2-shifted symplectic structure corresponding to a non-degenerate element in $Sym^2(\mathfrak{g}^*)^G$. We find this way that the derived moduli stack of G-bundles on X, $Bun_G(X) := \mathbf{Map}(X, BG)$ carries a canonical $(2-d)$-shifted symplectic structure, which is a first step towards a mathematical formulation of our principle 2.1.

Corollary 4.3. *With the above notations, $Bun_G(X)$ carries a canonical $(2-d)$-shifted symplectic structure.*

When $d = 2$ the above corollary recovers the well known symplectic structures on moduli spaces of G-local systems on a compact Riemann surface and of G-bundles on K3 and abelian surface. However, even in this case, the corollary is new and contains more as the 0-shifted symplectic structure exists on the whole derived moduli stack, not only on the nice part of this moduli stack which is a smooth scheme (see for instance our comments in §6.1).

In dimension 3 the corollary states that $Bun_G(X)$ is equipped with a natural (-1)-shifted symplectic structure. The underlying 2-form of degree -1 is an equivalence of perfect complexes $\mathbb{T}_{Bun_G(X)} \simeq \mathbb{L}_{Bun_G(X)}[-1]$. When restricted to the underived part of the moduli stack this equivalence recovers the symmetric obstruction theory used in Donaldson-Thomas theory (see [8, Def. 1.1]). However, here again the full data of the (-1)-shifted symplectic structure contains strictly more than the underlying symmetric obstruction theory, essentially because of the fact that a shifted symplectic structure is not uniquely determined by its underlying 2-form (see [21]).

Finally, when the dimension d is different from 2 and 3 the content of the corollary seems completely new, thought in dimension 1 it essentially states that $[G/G]$ is 1-shifted symplectic, which can be used in order to provide a new understanding of quasi-hamiltonian actions (see [9, §2.2]).

The idea of the proof of theorem 4.2 is rather simple, and at least the underlying 2-form can be described explicitly in terms of the formula for the tangent complexes (formula (3.1) of §3.4). We define a pairing of degree $(n-d)$ on this complex by the composition of the

natural maps and the pairing of degree n on $\mathbb{T}_Y$

$$\wedge^2 p_*(ev^*(\mathbb{T}_Y)) \longrightarrow p_*(ev^*(\wedge^2\mathbb{T}_Y)) \longrightarrow p_*(\mathcal{O})[n] \longrightarrow \mathcal{O}[n-d],$$

where the last map comes from the fundamental class in $H^d(X,\mathcal{O}_X) \simeq k$. This defines a non-degenerate 2-form on $\mathbf{Map}(X,Y)$, and the main content of the theorem 4.2 is that this 2-form comes from a canonically defined closed 2-form of degree $(n-d)$.

For variants and generalizations of theorem 4.2 we refer to [9, 22, 32] in which the reader will find non-commutative generalizations as well as versions with boundary conditions, but also several other possible admissible sources.

4.3. Derived critical loci. To finish the part on n-shifted symplectic structures let us mention critical loci and their possible generalizations. We have already seen that for a given derived algebraic stack X the shifted cotangent $T^*X[n]$ carries a canonical n-shifted symplectic structure. Moreover, the zero section $X \longrightarrow T^*X[n]$ has a natural Lagrangian structure (see [22, Def. 2.8]). More generally, if $f \in H^n(X,\mathcal{O}_X)$ is a function of degree n on X, its de Rham differential $dR(f)$ defines a morphism of derived algebraic stacks $dR(f) : X \longrightarrow T^*X[n]$ which is also equipped with a natural Lagrangian structure. Therefore, the intersection of the zero section with the section $dR(f)$ defines a natural $(n-1)$-shifted derived algebraic stack (see [22, Thm. 2.9]) denoted by $\mathbb{R}Crit(f)$ and called the derived critical locus of f. When $f = 0$ the derived critical locus $\mathbb{R}Crit(f)$ is simply $T^*X[n-1]$ together with its natural $(n-1)$-shifted symplectic structure. When X is a smooth scheme and f is a function of degree 0 (i.e. simply a function $X \longrightarrow \mathbb{A}^1$), then the symplectic geometry of $\mathbb{R}Crit(f)$ is closely related to the singularity theory of the function f. From a general point of view derived critical loci provide a nice source of examples of n-shifted symplectic derived algebraic stacks, which contain already examples of geometric interests. It is shown in [5, 6] that every (-1)-shifted symplectic derived scheme is locally the derived critical locus of a function defined on a smooth scheme.

Derived critical loci are important because they are easy to describe and their quantizations can be understood explicitly. Moreover, derived critical loci and their generalizations can be used to provide local models for n-shifted symplectic structures by means of a formal Darboux lemma we will not reproduce here (see for instance [2, 5, 6]).

4.4. Shifted polyvector fields and poisson structures. The notion of shifted Poisson structure is the dual notion of that of shifted symplectic structure we have discussed so far. The general theory of shifted Poisson structures has not been fully settled down yet and we will here present the basic definitions as well as its, still hypothetical, relations with shifted symplectic structures. They are however a key notion in the existence of quantization that will be presented in the next section.

4.4.1. Shifted polyvectors on derived algebraic stacks. A derived algebraic stack X (as usual assumed locally of finite presentation over the ground field k) has a tangent complex $\mathbb{T}_X$, which is the $\mathcal{O}_X$-linear dual to the cotangent complex. The complex of n-shifted polyvector fields on X is defined by

$$\mathcal{P}ol(X,n) := \bigoplus_i \Gamma(X, Sym^i_{\mathcal{O}_X}(\mathbb{T}_X[-1-n])).$$

The complex $\mathcal{P}ol(X,n)$ has a natural structure of a graded commutative dg-algebra, for which the piece of weight i is $\Gamma(X, Sym^i_{\mathcal{O}_X}(\mathbb{T}_X[-1-n]))$ and the multiplication is induced by the canonical multiplication on the symmetric algebra. We note here that depending of the parity of n we either have $Sym^i_{\mathcal{O}_X}(\mathbb{T}_X[-1-n]) \simeq (\wedge^i \mathbb{T}_X)[-i-ni]$ (if n is even), or $Sym^i_{\mathcal{O}_X}(\mathbb{T}_X[-1-n]) \simeq (Sym^i \mathbb{T}_X)[-i-ni]$ (if n is odd). When X is a smooth scheme and $n=0$, $\mathcal{P}ol(X,0) = \oplus_i \Gamma(X, \wedge^i \mathbb{T}_X)[-i]$ is the standard complex of polyvector fields of X. When $n=1$, and still X a smooth scheme, $\mathcal{P}ol(X,1)$ coincides with $\Gamma(T^*X, \mathcal{O}_{T^*X})$, the cohomology of the total cotangent space of X with coefficients in $\mathcal{O}$. In general, $\mathcal{P}ol(X,n)$ can be interpreted as the graded cdga of cohomology of the shifted cotangent derived stack $T^*X[n+1]$ with coefficients in $\mathcal{O}$ (that is "functions" on $T^*X[n+1]$).

When X is a smooth scheme, $\mathbb{T}_X$ is a sheaf (say on the small étale site of X) of k-linear Lie algebras with the bracket of vector fields. This extends easily to the case where X is a derived Deligne-Mumford stack, $\mathbb{T}_X$ can be made into a sheaf of k-linear dg-Lie algebras for the bracket of dg-derivations. Therefore, polyvector fields $\mathcal{P}ol(X,n)$ can also be endowed with a k-linear dg-Lie bracket of cohomological degree $-1-n$, making it into a graded Poisson dg-algebra where the bracket has cohomological degree $(-1-n)$ and weight (-1). In particular $\mathcal{P}ol(X,n)[n+1]$ always comes equipped with a structure of a graded dg-Lie algebra over k. It is expected that this fact remains valid for a general derived algebraic stack X, but there is no precise construction at the moment. One complication when considering general algebraic stacks comes from the fact that vector fields can not be pulled-back along smooth morphisms (as opposed to étale maps), making the construction of the Lie bracket on $\mathcal{P}ol(X,n)$ much more complicated than for the case of a scheme. For a derived algebraic stack of the form $[\mathbf{Spec}\, A/G]$, for G linear, there are however two possible constructions. A first very indirect construction uses natural operations on the derived moduli stacks of branes (see [33]). A more direct construction can be done as follows. We can take A to be a cofibrant and fibrant cgda inside the category of representations $Rep(G)$. We let $\mathbb{T}_A$ be the A-dg-module of dg-derivations from A to itself. The action of G on A induces a morphism of dg-Lie algebras $\mathfrak{g} \otimes_k A \longrightarrow \mathbb{T}_A$ representing the infinitesimal action of G on A. We consider the co-cône $\mathbb{T}$ of the morphism $\mathfrak{g} \otimes_k A \longrightarrow \mathbb{T}_A$. The complex $\mathbb{T}$ is obviously a k-linear Lie algebra for the bracket induced from the brackets on $\mathbb{T}_A$ and on $\mathfrak{g}$, but this lie structure is *not* compatible with the cohomological differential and thus is not a dg-Lie algebra. However, its fixed points by G (assume G reductive for simplicity) is a dg-Lie algebra over k, which is a model for $\Gamma(X, \mathbb{T}_X)$ where $X = [\mathbf{Spec}\, A/G]$. This construction can be also applied to the G-invariant of the various symmetric powers of shifts of $\mathbb{T}$ in order to get the desired dg-Lie structure on $\mathcal{P}ol(X,n)[n+1]$ in this special case.

4.4.2. Shifted Poisson structures. Let X be a derived algebraic stack and fix an integer $n \in \mathbb{Z}$. We can define n-shifted Poisson structures as follows. We let $\mathcal{P}ol(X,n)[n+1]$ be the shifted polyvector fields on X, endowed with the structure of a graded dg-Lie algebra just mentioned. We let $k(2)[-1]$ be the graded dg-Lie algebra which is k in cohomological degree 1, with zero bracket and k is pure of weight 2. An n-shifted Poisson structure on X is then defined to be a morphism of graded dg-Lie algebras

$$p : k(2)[-1] \longrightarrow \mathcal{P}ol(X,n)[n+1].$$

Here, a morphism of graded dg-Lie algebras truly means a morphism inside the ∞-category of graded dg-Lie algebras, or a morphism in an appropriate homotopy category. Using the dictionary between dg-Lie algebras and formal moduli problems (see [19]), such a morphism

p is determined by a Mauer-Cartan element in $\mathcal{P}ol(X,n)[n+1]\otimes tk[[t]]$, which is of weight 2 with respect to the grading on $\mathcal{P}ol(X,n)$. Such an element can be described explicitly as a formal power series $\sum_{i\geq 1} p_i\cdot t^i$, where p_i is an element of cohomological degree $n+2$ in $\Gamma(X, Sym^{i+1}(\mathbb{T}_X[-1-n]))$, and satisfies the equations

$$d(p_i)+\frac{1}{2}\cdot\sum_{a+b=i}[p_a,p_b]=0 \qquad \forall i\geq 1.$$

As we already mentioned, shifted Poisson structures can be developed along the same lines as shifted symplectic structures (e.g. there is a notion of co-isotropic structures on a map with an n-shifted Poisson target, and a Poisson version of the existence theorem 4.2), but at the moment this work has not been carried out in full details. It is believed that for a given X and $n\in\mathbb{Z}$, there is a one-to-one correspondence between n-shifted symplectic structures on X and n-shifted Poisson structures on X which are non-degenerate in an obvious sense. However, this correspondence has not been established yet, except in some special cases, and remains at the moment an open question for further research (see §6.2).

5. Deformation quantization of n-shifted Poisson structures

In this section we finally discuss the existence of quantization of n-shifted Poisson structures, a far reaching generalization of the existence of deformation quantization of Poisson manifolds due to Kontsevich. For this we first briefly discuss the output of the quantization, namely the notion of deformation of categories and iterated monoidal categories, which already contains some non-trivial aspects. We then present the formality conjecture, which is now a theorem except in some very particular cases, and whose main corollary is the fact that every n-shifted Poisson structure defines a canonical formal deformation of the E_n-monoidal category of quasi-coherent complexes. We also discuss the case $n<0$ by presenting the *red shift trick* consisting of working with a formal parameter $\hbar$ living in some non-trivial cohomological degree.

5.1. The deformation theory of monoidal dg-categories. As we have seen in §2, a derived algebraic stack X has a dg-category of quasi-coherent complexes $L(X)$. It is a k-linear dg-category which admits arbitrary colimits. We will assume in this section that $L(X)$ is a compactly generated dg-category, or equivalently that it can be realized as the category of dg-modules over a small dg-category. More generally we will assume that X is a *perfect* derived algebraic stack, in the sense that perfect complexes on X are compact generators of $L(X)$. This is known to be the case under the assumption that X can be written as a quotient $[\mathbf{Spec}\, A/G]$ for a linear algebraic G acting on a cdga A.

5.1.1. Deformations of dg-categories. We let $T_0:=L(X)$ and we would like to study the deformation theory of T_0. For this, we define a first naive deformation functor

$$Def^{naive}(T_0):\mathbf{dg}-\mathbf{art}^*\longrightarrow\mathbb{S},$$

from the ∞-category of augmented local artinian cdga to the ∞-category of spaces as follows. To $A\in\mathbf{dg}-\mathbf{art}^*$ we assign the ∞-category $\mathbb{D}g^c(A)$, of cocomplete and compactly generated A-linear dg-categories and A-linear colimit preserving dg-functors (see

[34, §3.1]). For a morphism of dg-artinian rings $A \to B$, we have a base change ∞-functor $-\widehat{\otimes}_A B : \mathbb{D}g^c(A) \longrightarrow \mathbb{D}g^c(B)$. We then set

$$Def^{naive}(T_0)(A) := \mathbb{D}g^c(A) \times_{\mathbb{D}g^c(k)} \{T_0\}.$$

Here $\mathbb{D}g^c(A) \times_{\mathbb{D}g^c(k)} \{T_0\}$ is the fiber taken at the point T_0 of the ∞-functor $-\widehat{\otimes}_A k$ induced by the augmentation $A \to k$. As is, $Def^{naive}(T_0)(A)$ is an ∞-category, from which we extract a space by taking the geometric realization of its sub-∞-category of equivalences (i.e. taking the nerve of the maximal sub-∞-groupoid). Intuitively, $Def^{naive}(T_0)(A)$ is the classifying space of pairs (T, u), with T a compactly generated A-linear dg-category and u a k-linear equivalence $u : T\widehat{\otimes}_A k \simeq T_0$.

As already observed in [14] the ∞-functor $Def^{naive}(T_0)$ is not a formal moduli problem, it does not satisfies the Schlessinger conditions of [19], and thus can not be equivalent to the functor of Mauer-Cartan elements in a dg-Lie algebra. This bad behavior of the ∞-functor $Def^{naive}(T_0)$ has been a longstanding major obstacle preventing the understanding of the deformation theory of dg-categories. There have been several tentative modifications of $Def^{naive}(T_0)$ attempting to overcome this problem, for instance by allowing curved dg-categories as possible deformations, however none of these were successful. We propose here a new solution to this problem which provides the only complete understanding of deformations of dg-categories that we are aware of. For this, we introduce $Def(T_0) : \mathbf{dg} - \mathbf{art}^* \longrightarrow \mathbb{S}$, which is the universal ∞-functor constructed out of $Def^{naive}(T_0)$ and satisfying the Schlessinger conditions of [19] (in other words it is the best possible approximation of $Def^{naive}(T_0)$ by an ∞-functor associated to a dg-Lie algebra). By construction there is a natural transformation $l : Def^{naive}(T_0) \longrightarrow Def(T_0)$, as well as a dg-Lie algebra L such that $Def(T_0)$ is given by $A \mapsto \underline{MC}_*(L \otimes m_A)$ (where as usual $m_A \subset A$ is the augmentation dg-ideal in A, and $\underline{MC}_*$ denotes the space of Mauer-Cartan elements). Moreover the natural transformation l is universal for these properties, and in particular the dg-Lie L is uniquely determined and only depends on $Def^{naive}(T_0)$.

The following theorem is folklore and known to experts. It appears for instance in a disguised form in [23].

Theorem 5.1. *Let T_0 be a compactly generated dg-category.*

(1) *The dg-Lie algebra associated to the formal moduli problem $Def(T_0)$ is $HH(T_0)[1]$, the Hochschild cochains on T_0 endowed with its usual Gerstenhaber bracket (see e.g. [15, §5.4]).*

(2) *The space $Def(T_0)(k[[t]])$ is naturally equivalent to the classifying space of $k[\beta]$-linear structures on T_0, where $k[\beta]$ is the polynomial dg-algebra over k with one generator β in degree 2.*

The above theorem subsumes the two main properties of the formal moduli problem $Def(T_0)$, but much more can be said. The formla for the $k[[t]]$-points of $Def(T_0)$ can be generalized to any (pro-)artinian augmented dg-algebra A, by using B_A-linear structures on T_0, where now B_A is the E_2-Koszul dual of A (see [19], and the E_2-Koszul dual of $k[[t]]$ is of course $k[\beta]$). By construction we have a map of spaces $Def^{naive}(T_0)(A) \longrightarrow Def(T_0)(A)$. This map is not an equivalence but can be shown to have 0-truncated fibers (so it induces isomorphisms on π_i for $i > 1$ and is injective on π_1). It is interesting to note here that not only $Def(T_0)$ contains more objects than $Def^{naive}(T_0)$ but also contains more morphisms. There are natural conditions one can impose on T_0 in order to make $Def^{naive}(T_0)$ closer to

$Def(T_0)$. It is for instance believed that they coincide when T_0 is a smooth and proper dg-category, as well as for dg-categories of complexes in Grothendieck abelian categories. In our situation, $T_0 = L(X)$, with X a derived algebraic stack which is not smooth in general, it is not reasonable to expect any nice assumptions on T_0, and the above theorem is probably the best available result in order to understand formal deformations of $L(X)$.

5.1.2. Deformations of monoidal dg-categories. Theorem 5.1 also possesses monoidal and iterated monoidal versions as follows. First of all the ∞-category $\mathbb{D}g^c(A)$ of compactly generated A-linear dg-categories is equipped with a tensor product $\widehat{\otimes}_A$, making it into a symmetric monoidal ∞-category. It is therefore possible to use the notion of an E_n-monoid in $\mathbb{D}g^c(A)$ of [20], in order to define E_n-monoidal A-linear dg-categories (also called n-fold monoidal A-linear dg-categories). In a nutshell, an E_n-monoidal A-linear dg-category consists of a compactly generated A-linear dg-category T together with morphisms

$$\mu_k : E_n(k) \otimes T^{\widehat{\otimes}_A k} \longrightarrow T,$$

where the tensor by the space $E_n(k)$ and the tensor products are taken in the symmetric monoidal ∞-category $\mathbb{D}g^c(A)$, and together with compatibilty conditions/structures. For our derived algebraic stack X, the dg-category $L(X)$ is equipped with a symmetric monoidal structure and thus is naturally an E_n-monoidal dg-category for all $n \geq 0$, where by convention an E_0-monoidal dg-category simply is a dg-category.

For a cdga A, we set $\mathbb{D}g^c_{E_n}(A)$ for the ∞-category of compactly generated E_n-monoidal A-linear dg-categories. Here compactly generated also means that the compact objects are stable by the monoidal structure, so objects in $\mathbb{D}g^c_{E_n}(A)$ can also be described as dg-categories of dg-modules over small A-linear E_n-monoidal dg-categories. Morphisms in $\mathbb{D}g^c_{E_n}(A)$ must be defined with some care as they involve higher dimensional versions of Morita morphisms between algebras. For two E_n-monoidal dg-categories T and T' in $\mathbb{D}g^c_{E_n}(A)$, the dg-category of A-linear colimit preserving dg-functors can be written as $T^\vee \widehat{\otimes}_A T'$, where $T^\vee$ is the dual of T (i.e. we take the opposite of the sub-dg-category of compact generators). The A-linear dg-category $T^\vee \widehat{\otimes}_A T'$ is a new object in $\mathbb{D}g^c_{E_n}(A)$, and in particular it makes sense to consider E_n-algebras inside the dg-category $T^\vee \widehat{\otimes}_A T'$. From the point of view of dg-functors these correspond to E_n-lax monoidal A-linear colimit preserving dg-functors $T \to T'$. For two E_n-algebras M and N inside $T^\vee \widehat{\otimes}_A T'$, we can form a new E_n-algebra $M^{op} \otimes N$. The A-linear dg-category of $M^{op} \otimes N$-modules inside $T^\vee \widehat{\otimes}_A T'$ is then E_{n-1}-monoidal, so the process can be iterated. We can consider two E_{n-1}-algebras inside $M^{op} \otimes N$-modules, say M' and N', as well as their tensor product $M'^{op} \otimes N'$ and the A-linear dg-category of $M'^{op} \otimes N'$-modules, which is itself E_{n-2}-monoidal ... and so on and so forth. We are describing here $\mathbb{D}g^c_{E_n}(A)$ as an $(\infty, n+1)$-category (see [26]), whose objects are E_n-monoidal compactly generated A-linear dg-categories, whose 1-morphism from T to T' are E_{n-1}-algebras inside $T^\vee \widehat{\otimes}_A T'$, whose 2-morphisms between M' and N' are E_{n-2}-algebras inside $M'^{op} \otimes N'$-modules, etc .... The $(\infty, n+1)$-category $\mathbb{D}g^c_{E_n}(A)$ produces a space by considering the geometric realization of its maximal sub-∞-groupoid (i.e. realizing the sub-∞-category of equivalences).

For $T_0 = L(X)$, assuming that $L(X)$ is compactly generated and that its compact objects are the perfect complexes, we define a naive deformation functor $Def^{naive}_{E_n}(T_0)$, of T_0 considered as an E_n-dg-category, by sending an augmented dg-artinian ring $A \in \mathbf{dg} - \mathbf{art}^*$

to the fiber at T_0 of the restriction map

$$-\widehat{\otimes}_A k : \mathbb{D}g^c_{E_n}(A) \longrightarrow \mathbb{D}g^c_{E_n}(k).$$

The space $Def^{naive}_{E_n}(T_0)$ is the space of pairs (T, u), where T is an E_n-monoidal compactly generated A-linear dg-category, and $u : T\widehat{\otimes}_A k \simeq T_0$ an equivalence in $\mathbb{D}g^c_{E_n}(k)$. Similar to the case $n = 0$ we already discussed, the ∞-functor $Def^{naive}_{E_n}(T_0)$ does not satisfy the Schlessinger's conditions, and the bigger n is, the more this fails. We denote by $Def_{E_n}(T_0)$ the formal moduli problem generated by $Def^{naive}_{E_n}(T_0)$. The following theorem is the generalization of 5.1 to the iterated monoidal setting.

Theorem 5.2. *Let T_0 be a compactly generated E_n-monoidal dg-category.*

(1) *The dg-Lie algebra associated to the formal moduli problem $Def_{E_n}(T_0)$ is $HH^{E_{n+1}}(T_0)\,[n+1]$, the E_{n+1}-Hochschild cochains on T_0 of [11].*

(2) *The space $Def_{E_n}(T_0)(k[[t]])$ is naturally equivalent to the classifying space of $k[\beta_n]$-linear structures on T_0, where $k[\beta_n]$ is the commutative polynomial dg-algebra over k with one generator β_n in degree $2 + n$.*

Theorems 5.1 and 5.2 provides a way to understand the relations between (higher) Hochschild cohomology and formal deformations of dg-categories and iterated monoidal dg-categories. They state in particular that the correct manner to define a formal deformation of a given dg-category T_0, parametrized by $k[[t]]$, is by considering $k[\beta]$-linear structures on T_0, and similarly for the iterated monoidal setting with $k[\beta_n]$-linear structures. In the sequel, we will freely use the expression "formal deformation of the dg-category $L(X)$ considered as an E_n-monoidal dg-category", by which we mean an element in $Def_{E_n}(L(X))(k[[t]])$, and thus a $k[\beta_n]$-linear structure on T_0. We however continue to think of these deformations as actual deformations of $L(X)$ over $k[[\hbar]]$ for a formal parameter $\hbar$, even thought they are not quite as naive objects.

5.2. The higher formality conjecture. We have just seen that formal deformations of a given E_n-monoidal compactly generated dg-category T_0 is controlled by its higher Hochschild cochain complex $HH^{E_{n+1}}(T_0)[n+1]$, endowed with its natural structure of a dg-Lie algebra. We now turn to the specific case where $T_0 = L(X)$, the quasi-coherent dg-category of a derived algebraic stack X. We continue to assume that X is nice enough (e.g. of the form $[\mathbf{Spec}\, A/G]$) so that $L(X)$ is compactly generated by the perfect complexes). The higher Hochschild cohomology of T_0 can then be described in geometric terms as follows. We let $n \geq 0$, and let $S^n = \partial B^{n+1}$ be the topological n-sphere considered as a constant derived stack. We consider the derived mapping stack $\mathcal{L}^{(n)}(X) := \mathbf{Map}(S^n, X)$, also called the *$n$-dimensional derived loop stack of X*. There is a constant map morphism $j : X \longrightarrow \mathcal{L}^{(n)}(X)$, and thus a quasi-coherent complex $j_*(\mathcal{O}_X) \in L(\mathcal{L}^{(n)}(X))$. The E_{n+1}-Hochschild cohomology of the dg-category $L(X)$ can be identified with

$$HH^{E_{n+1}}(X) \simeq End_{L(\mathcal{L}^{(n)}(X))}(j_*(\mathcal{O}_X)).$$

Note that when $n = 0$ and X is a scheme this recovers the description of the Hochschild complex of X as the self extension of the diagonal. Because of the stackyness of X this definition can be modified by replacing $\mathcal{L}^{(n)}(X)$ by its formal completion $\widehat{\mathcal{L}^{(n)}(X)}$ along the map $X \longrightarrow \mathcal{L}^{(n)}(X)$, which is called the formal n-dimensional derived loop space

(when X is a derived scheme the formal and non-formal versions of the derived loop stacks coincide). We then have the formal version of Hochschild complex

$$\widehat{HH}^{E_{n+1}}(X) \simeq End_{L(\widehat{\mathcal{L}^{(n)}(X)})}(j_*(\mathcal{O}_X)).$$

Note that we have a natural morphism $\widehat{HH}^{E_{n+1}}(X) \longrightarrow HH^{E_{n+1}}(X)$.

The complexe $\widehat{HH}^{E_{n+1}}(X)$ has a structure of an E_{n+2}-algebra, as predicted by the so-called Deligne's conjecture which is now a theorem (see [11, 20]). In particular $\widehat{HH}^{E_{n+1}}(X)[n+1]$ is a dg-Lie algebra. The formality conjecture asserts that the dg-Lie algebra $\widehat{HH}^{E_{n+1}}(X)[n+1]$ can be described in simple terms involving shifted polyvector fields.

Conjecture 5.3 (Higher formality). *For a nice enough derived algebraic stack X, and $n \geq 0$, the dg-Lie algebra $\widehat{HH}^{E_{n+1}}(X)[n+1]$ is quasi-isomorphic to $\mathcal{P}ol(X,n)[n+1]$. The quasi-isomorphism is canonical up to a universal choice of a Drinfeld associator.*

Note that when X is a smooth scheme and $n = 0$ the conjecture 5.3 is the so-called *Kontsevich's formality theorem*. The conjecture has been proven in already many cases.

Theorem 5.4 ([33, Cor. 5.4]). *The above higher formality conjecture is true for all $n > 0$ and for all derived algebraic stacks X of the form $[\mathbf{Spec}\, A/G]$ for G a linear algebraic group acting on the cdga A. When X is a derived Deligne-Mumford stack it is also true for $n = 0$.*

The theorem above provides many cases in which conjecture 5.3 is satified. We believe it is also true in the remaining case when $n = 0$ and for non Deligne-Mumford stacks. We also believe that the restriction for X being of the form $[\mathbf{Spec}\, A/G]$ in the theorem 5.4 is not necessary, and that the theorem should be true for a large class of derived higher algebraic stacks as well.

5.3. Existence of deformation quantization. We finally arrive at the existence of quantization of derived algebraic stacks X endowed with n-shifted Poisson structures, and its consequence: the mathematical incarnation of our principle 2.1. Let X be a derived algebraic stack, and $n \geq 0$ to start with (the case of negative values will be treated below). We assume that X is nice enough and that the conjecture 5.4 is satisfied (e.g. under the hypothesis of theorem 5.4). Let p be an n-shifted Poisson structure on X. By definition it provides a morphism of dg-Lie algebras $p : k[-1] \longrightarrow Pol(X,n)[n+1]$. Using the conjecture 5.4 we find a morphism of dg-Lie algebras $p : k[-1] \longrightarrow \widehat{HH}^{E_{n+1}}(X)[n+1]$, which composed with the natural morphism $\widehat{HH}^{E_{n+1}}(X) \longrightarrow HH^{E_{n+1}}(X)$ provides a morphism of dg-Lie algebras

$$p : k[-1] \longrightarrow HH^{E_{n+1}}(X)[n+1].$$

The derived deformation theory (see [19]) and theorem 5.2 tell us that the morphism p provides a formal deformation of $L(X)$ as an E_n-monoidal dg-category, denoted by $L(X,p)$. This is the deformation quantization of the pair (X,p).

Assume now that $n < 0$ and that X is equipped with an n-shifted Poisson structure p such that the conjecture 5.4 is satisfied for X and $-n$. The n-shifted Poisson structure p is a morphism of graded dg-Lie algebras $k(2)[-1] \longrightarrow \mathcal{P}ol(X,n)[n+1]$ where $k(2)[-1]$ is the

abelian dg-Lie algebra which is k in cohomological degree 1 and pure weight 2. The category of $\mathbb{Z}$-graded complexes has a tensor auto-equivalence, sending a complex E pure of weight i to $E[-2i]$ again pure of weight i. This auto-equivalence induces an auto-equivalence of the ∞-category of graded dg-Lie algebras, and sends $\mathcal{P}ol(X,n)[n+1]$ to $\mathcal{P}ol(X,n+2)[n+3]$ and $k(2)[-1]$ to $k(2)[-3]$. Iterated n times, the morphism p goes to a new morphism of dg-Lie algebras $p' : k(2)[-2n-1] \longrightarrow \mathcal{P}ol(X,-n)[-n+1]$, which by conjecture 5.3 induces a morphism of dg-Lie algebras

$$p' : k[-2n-1] \longrightarrow HH^{E_{-n+1}}(X)[-n+1].$$

The abelian dg-Lie algebra $k[-2n-1]$ corresponds to the formal derived scheme $\mathbf{Spec}\, k[[\hbar_{2n}]]$, where now $\hbar_{2n}$ has cohomological degree $2n$. By the general DDT and theorem 5.2 we do find a formal deformation of $L(X)$, considered as an E_{-n}-monoidal dg-category, over $k[[\hbar_{2n}]]$. This deformation will be denoted by $L(X,p)$. This trick to deal with cases where $n<0$ is called the *red shift trick*. It is not new, and already appears in the conjecture [13, Page 14] where $\mathbb{Z}/2$-graded derived categories are considered instead of $\mathbb{Z}$-graded derived categories, and canceling out the red shift.

Definition 5.5. *The formal deformation $L(X,p)$ constructed above is the* deformation quantization of (X,p). *It is a formal deformation of $L(X)$ considered as an E_n-monoidal dg-category if $n \geq 0$, and a formal deformation of $L(X)$ considered as an E_{-n}-dg-category over $k[[\hbar_{2n}]]$ if $n<0$.*

Definition 5.5 applies in particular to the case $X = Bun_G(Y)$, making our principle 2.1 into a mathematical statement.

6. Examples and open questions

We present here some examples as well as some further questions.

6.1. Three examples. We start by coming back to the three situations we mentioned in §2.

Quantum groups. We let $X = BG$, for G reductive. We have seen that X has a 2-shifted symplectic structure given by the choice of non-degenerate G-invariant scalar product on $\mathfrak{g}$. The dg-category $L(X)$ here is the dg-category of complexes of representations of G. Our quantization is then a formal deformation of $L(X)$ as an E_2-monoidal dg-category, and is simply realized by taking the dg-category of complexes of representations of the quantum group.

Skein dg-algebras. We now let $X = Bun_G(\Sigma)$ be the derived moduli stack of G-bundles on a compact oriented surface Σ. We know that X carries a natural 0-shifted symplectic structure (depending on a choice of a non-degenerate G-invariant scalar product on $\mathfrak{g}$), whose quantization $L(X,p)$ in our sense is a deformation of the dg-category $L(X)$[6]. The dg-category $L(X,p)$ is an interesting refinement of the skein algebra of Σ which, as far as the author is aware, has not been considered before. The structure sheaf $\mathcal{O}_X \in L(X)$

[6]Note however that here $n=0$ and the formality conjecture 5.3 is not established yet, so this situation is still conjectural at the moment.

deforms to a uniquely defined object $\widetilde{\mathcal{O}_X} \in L(X,p)$, whose endormophisms form a dg-algebra $B_\hbar = End(\widetilde{\mathcal{O}_X})$ over $k[[\hbar]]$, which is a deformation of $\mathcal{O}_X(X)$ the dg-algebra of functions on X. The skein algebra is recovered as $H^0(B_\hbar)$, but $B_\hbar$ is not cohomologically concentrated in degree 0 in general and contains strictly more than $K_\hbar(\Sigma)$. The higher cohomology groups of $B_\hbar$ are directly related to the non-trivial derived structure of X, which is concentrated around the singular points corresponding to G-bundles with many automorphisms. Outside these bad points the dg-category $L(X,p)$ is essentially given by complexes of $K_\hbar(\Sigma)$-modules. Formally around a given singular point $\rho \in X$, the dg-category $L(X,p)$ has a rather simple description as follows. The formal completion of X at ρ is controlled by the formal dg-Lie algebra $L_\rho := H^*(\Sigma, \mathfrak{g}_\rho)$, where $\mathfrak{g}_\rho$ is the local system of Lie algebras associated to the G-bundle ρ. The dg-Lie algebra L_ρ is endowed with a non-degenerate pairing of degree 2 induced by the choice of a G-invariant scalar product on $\mathfrak{g}$ which defines a non-degenerate pairing $p : L_\rho^\vee[-1] \wedge L_\rho^\vee[-1] \longrightarrow k$. The pairing p defines itself a Poisson structure on the completed Chevalley complex $\widehat{\mathcal{O}_{X,\rho}} \simeq \widehat{Sym}_k(L_\rho^\vee[-1])$, which is the cdga of formal functions on X around ρ. The quantization of this Poisson cdga, which can be described in simple terms as the Weyl dg-algebra associated to L_ρ with the pairing p, is the quantization of X around ρ and can be used to describe the full sub-dg-category of $L(X,p)$ generated by objects supported at ρ.

Donaldson-Thomas theory. We now turn to the case where $X = Bun_G(Y)$ for a Calabi-Yau 3-fold Y, which is endowed with a (-1)-shifted symplectic form. Our quantization $L(X,p)$ here is a formal deformation of $L(X)$ as a monoidal dg-category with a formal parameter $\hbar_{-2}$ of degree -2. To simplify a bit we can consider this as a formal deformation of $L^{\mathbb{Z}/2}(X)$, the 2-periodic dg-category of quasi-coherent complexes on X, considered as a monoidal dg-category and with a formal parameter $\hbar$ sitting now in degree 0. Locally, X is essentially given as the critical locus of a function f, whose category of matrix factorizations $MF(f)$ provides a natural $L(X,p)$-module (i.e. $MF(f)$ is enriched over the monoidal dg-category $L(X,p)$). In a precise sense, $MF(f)$ can be viewed as an object $\mathcal{M}$ in the quantization of X[7]. The object $\mathcal{M}$ only exists locally, but when X is endowed with orientation data we can expect more and maybe an existence globally on X (for instance, the class of $\mathcal{M}$ in a suitable Grothendieck group has been constructed in [17]). This suggests a possible relation with the perverse sheaf $\mathcal{E}$ we mentioned in §2, as $\mathcal{E}$ should be somehow the Betti realization of the sheaf of dg-categories $\mathcal{M}$. Our quantization should thus refine and reinterpret some already known constructions in Donaldson-Thomas theory.

6.2. Further questions. We finish by a sample of further possible research directions.

Symplectic to Poisson and formality for n=0. As already mentioned in the text the precise way to obtain an n-shifted Poisson structure out of an n-shifted symplectic structure is not clear at the moment, except in some special case (e.g. for derived scheme for which a version of the Darboux lemma holds and can be used, see [5, 6]). Also recall that our conjecture 5.3 remains open for non Deligne-Mumford derived algebraic stacks.

Quantization of Lagrangian morphisms. For a morphism between derived algebraic stacks, the correct analog of a shifted symplectic structure is that of a Lagrangian structure

[7]This is so when monoidal dg-categories are considered through their $(\infty,2)$-category of modules.

(see [22]). These are the maps that are candidates to survive after the deformation quantization. For this a version of the formality conjecture 5.3 must be stated and proved (if at all true). The basic idea here is that a Lagrangian morphim $f : X \longrightarrow Y$, with Y n-shifted symplectic ($n > 0$), should deform $L(X)$ as an E_{n-1}-monoidal dg-category enriched over the deformation quantization of $L(Y)$. According to [9], fully extended TQFT should be obtained this way, by quantization of fully extended TQFT with values in a certain category of n-shifted symplectic derived algebraic stacks and Lagrangian correspondences between them.

Quantization for $n = -1, -2$. When $n = -1$, and $n = -2$ the output of our quantization is respectively a monoidal dg-category and braided monoidal dg-category. There are other possible interpretations of the quantization in these two specific cases, as the expression "E_{-1}-monoidal dg-category" can be understood as "an object in a dg-category", and "E_{-2}-monoidal dg-category" as "an endomorphism of an object in a dg-category". In particular, the quantization of a derived algebraic stack X endowed with a (-1)-shifted (resp. (-2)-shifted) Poisson structure could also be interpreted as the construction of a deformation of an object in $L(X)$ (resp. the deformation of an endomorphism in $L(X)$). For $n = -1$ this is the point of view taken by Joyce and his coauthors (see [2, 7, 8]). Note that in this setting the existence of quantization is predicated on the existence of orientation data which may not exist. The precise relations with the quantization of 5.5 remains to be investigated, and at the moment there is no precise explanations of the construction of the constructible sheaf of [2, 7, 8] in term of derived deformation theory.

Motivic aspects. Deformation quantization possesses an interesing interaction with the motivic world. This is particularly clear when $n = -1$ (e.g. in the setting of Donaldson-Thomas theory): DT are made "motivic" in [17], and the constructible sheaf $\mathcal{E}$ we mentioned above is expected to be the Betti realization of a certain "motive" over $Bun_G(X)$. Because of deformation quantization these motives most probably are instances of "non-commutative motives" over non-commutative schemes ("E_2-schemes" in the setting of DT theory). For commutative base schemes non-commutative motives have been studied in [25], for which the constructions of [4] provides a possible Betti realization functor. From a general point of view, the specific example of Donaldson-Thomas theory suggests the notion of *E_n-motives*, related to our deformation quantization for arbitrary values of n, as well as E_n-motives over a base E_{n-1}-scheme (or stack), which is worth studying along the same lines as [25, 30]

Geometric quantization. Only deformation quantization has been considered in this text. However, derived algebraic geometry can also interact nicely with geometric quantization, a direction currently investigated in [39].

Acknowledgements. The content of this manuscript represents works still in progress in collaboration with T. Pantev, M. Vaquié and G. Vezzosi. The author is thankful to the three of them for numerous conversations that have helped a lot in the writting of this manuscript. An important part of the present text has been prepared during a, snowy but enjoyable, visit at Yale Mathematics department. A particular thanks to S. Goncharov and M. Kapranov for many enlightening conversations on related subjects.

Teichmüller spaces, ergodic theory and global Torelli theorem

Misha Verbitsky

Abstract. A Teichmüller space Teich is a quotient of the space of all complex structures on a given manifold M by the connected components of the group of diffeomorphisms. The mapping class group Γ of M is the group of connected components of the diffeomorphism group. The moduli problems can be understood as statements about the Γ-action on Teich. I will describe the mapping class group and the Teichmüller space for a hyperkähler manifold. It turns out that this action is ergodic. We use the ergodicity to show that a hyperkähler manifold is never Kobayashi hyperbolic.

Mathematics Subject Classification (2010). Primary 32G13; Secondary 53C26.

Keywords. Torelli theorem, hyperkähler manifold, moduli space, mapping class group, Teichmüller space, ergodicity.

This talk is based on two papers, [46] and [47]. In these papers one can find details, examples, and rigorous proofs omitted here.

1. Teichmüller spaces

1.1. Teichmüller spaces and period maps. The notion of Teichmüller spaces has a long history since its discovery by Teichmüller in 1944 ([38]) and further development by Ahlfors, Bers and others. However, it is rarely applied to complex manifolds of dimension > 1. It turns out that this notion is interesting and useful for many purposes of complex geometry in any dimension.

Definition 1.1. Let M be a smooth manifold. An **almost complex structure** is an operator $I:\ TM \longrightarrow TM$ which satisfies $I^2 = -\operatorname{Id}_{TM}$. An almost complex structure is **integrable** if $\forall X, Y \in T^{1,0}M$, one has $[X,Y] \in T^{1,0}M$. In this case I is called **a complex structure operator**. A manifold with an integrable almost complex structure is called **a complex manifold**.

Definition 1.2. The space of almost complex structures is an infinite-dimensional Fréchet manifold X_M of all tensors $I \in \operatorname{End}(TM)$ satisfying $I^2 = -\operatorname{Id}_{TM}$. Similarly, one considers **the group of diffeomorphisms** as a Fréchet Lie group.

Remark 1.3. Definition of Fréchet manifolds and Fréchet spaces and many results on the geometry of infinite-dimensional manifolds can be found in [18].

Proceedings of the International Congress of Mathematicians, Seoul, 2014

Definition 1.4. Let M be a compact complex manifold, and $\operatorname{Diff}_0(M)$ a connected component of its diffeomorphism group (**the group of isotopies**). Denote by Comp the space of complex structures on M, considered with the topology induced from a Fréchet manifold of almost complex structures, and let $\operatorname{Teich} := \operatorname{Comp} / \operatorname{Diff}_0(M)$ be the quotient space with the quotient topology. We call it **the Teichmüller space.**

Remark 1.5. When the complex manifold M admits a certain geometric structure, such as Kähler, or hyperkähler structure, it is natural to consider the Teichmüller space of complex structure compatible with (say) Kähler structure. Consider the open subset $\operatorname{Comp}_K \subset \operatorname{Comp}$ of all complex structures I such that (M, I) admits a Kähler structure. The corresponding Teichmüller space is $\operatorname{Teich}_K := \operatorname{Comp}_K / \operatorname{Diff}_0$. When working with the Teichmüller space of hyperkähler manifolds, or a torus, we shall always restrict ourselves to Comp_K and Teich_K.

Results of Kuranishi about local structure of deformation spaces can be summarized as a statement about local structure of Comp as follows ([14, 24, 25]).

Theorem 1.6. *Let M be a compact complex manifold and $I \in \operatorname{Comp}$. Then there exists an open neighbourhood $U \ni I$ in Comp and a neighbourhood R of unit in Diff_0 satisfying the following. Consider the quotient U/R of U by an equivalence relation generated by $x \sim wy$, for all $x, y \in U$ and $w \in R$. Then U/R is a complex analytic stack, equipped with a natural holomorphic embedding to the stacky quotient $H^1(TM)/\operatorname{Aut}(M)$. In particular, when $\operatorname{Aut}(M)$ is finite, the space U/R is a complex variety, embeddable to an orbifold $H^1(TM)/\operatorname{Aut}(M)$.*

Remark 1.7. The quotient space U/R obtained by Kuranishi is called **the Kuranishi space**. Let $\operatorname{Teich}(U)$ be an image of U in the Teichmüller space. Clearly, the Kuranishi space admits a surjective, continuous map to $\operatorname{Teich}(U)$. It is not entirely clear whether this map is always a homeomorphism. However, if it is always a homeomorphism, for a given M, the space Teich acquires a structure of a complex variety.

As shown by F. Catanese ([11, Proposition 15]), for Kähler manifolds with trivial canonical bundle, e.g. for the hyperkähler manifolds, the Teichmüller space is locally isomorphic to the Kuranishi moduli space, hence it is a complex variety. In this case it is actually a complex manifold, by Bogomolov-Tian-Todorov theorem ([7, 39, 42]).

It is not clear if this is true for a general complex manifold; in the present work we deal with hyperkähler manifolds, which are Calabi-Yau.

Question 1.8. *Consider a compact complex manifold M, and let Teich be its Teichmüller space. Can we equip Teich with a structure of a complex variety (possibly non-Hausdorff), in a way which is compatible with the local charts obtained from the Kuranishi theorem?*

When M is a torus, or a hyperkähler manifold, Teich is a complex manifold which can be described explicitly (Theorem 2.1, Theorem 4.5). However, even for a hyperkähler manifold, Teich is not Hausdorff.

Claim 1.9. *Assume that M is Kähler, and Teich the Teichmüller space of all complex structures of Kähler type on M. For a given $I \in \operatorname{Teich}$, choose a representative $\tilde{I} \in \operatorname{Comp}$. Then the Hodge decomposition $H^*(M) = \bigoplus H^{p,q}(M, \tilde{I})$ is independent from the choice of $\tilde{I}$.*

Proof. The ambiguity of a choice of $\tilde{I}$ lies in Diff_0. However, Diff_0 acts trivially on $H^*(M)$. □

This elementary claim allows one to define **the period map**.

Definition 1.10. Let M be a Kähler manifold, Teich its Teichmüller space, and Per the map associating to I the Hodge decomposition $H^*(M) = \bigoplus H^{p,q}(M, I)$. Then Per is called **the period map** of M.

Remark 1.11. Consider the product $\mathrm{Comp} \times M$ trivially fibered over Comp. The fibers of $\pi : M \times \mathrm{Comp} \longrightarrow \mathrm{Comp}$ can be considered as complex manifolds, with complex structure at $I \in \mathrm{Comp}$ given by I. This complex structure is clearly Diff_0-invariant, giving a complex structure on the fibers of the quotient fibration $(M \times \mathrm{Comp})/\mathrm{Diff}_0 \longrightarrow \mathrm{Teich}$. At each $I \in \mathrm{Teich}$, the fiber of this fibration (called **the universal fibration**) is isomorphic to (M, I).

1.2. Marked moduli spaces. A more conventional approach to the moduli problem goes as follows. Given a complex manifold M, one defines **the deformation functor** from marked complex spaces to sets as a functor mapping a complex space (B, x) to the set of equivalence classes of deformations $\pi : \mathcal{X} \longrightarrow B$ of M over B with M identified with the fiber of π at x.

If the deformation functor is representable by a complex space, this space is called **the fine moduli space** of deformations of M.

Usually, the fine moduli space does not exist. In this case, one considers the category of natural transformations from the deformation functor to representable functors. The initial object in this category is called **the coarse moduli space**. The points of coarse moduli are identified with equivalence classes of deformations of M.

In this setup, an analogue of Teichmüller space can be defined as follows. Fix an abelian group which is isomorphic to $H^*(M, \mathbb{Z})$, and define **a marked manifold** as a pair $(M, \varphi : V \tilde{\longrightarrow} H^*(M, \mathbb{Z}))$, where M is a complex manifold, and φ a group isomorphism. In the same way as above, one defines a coarse moduli space of deformations of marked manifolds. To compare this space with Teichmüller space, consider a subgroup group Γ_0 of mapping class group which acts trivially on cohomology. Clearly, the points of Teich/Γ_0 are in bijective correspondence with the equivalence classes of marked complex structures on M.

Given a coarse marked moduli space W, one obtains the tautological map $W \longrightarrow \mathrm{Teich}/\Gamma_0$, by construction continuous. For hyperkähler manifolds (or compact tori), this map is a diffeomorphism on each connected component ([46, Corollary 4.31]).

2. Torelli theorem

2.1. Torelli theorem: an introduction. Torelli theorems are a broad class of results which describe the Teichmüller spaces in terms of the period maps (Definition 1.10).

The name originates with Ruggiero Torelli, who has shown that it is possible to reconstruct a Riemann surface from its Jacobian [43]. The term "Torelli theorems" is due to André Weil [50], who gave a modern proof of this classical result, and explained its possible generalizations.

One may distinguish between the "local Torelli theorem", where a local structure of deformation space is described in terms of periods, and "global Torelli", where the Teichmüller space is described globally.

Weil, who was the first to define and study K3 surfaces, spent much time trying to prove

the Torelli theorem for K3 surfaces, but it was notoriously difficult. Its local version is due to Tjurina, Piatetski-Shapiro and Shafarevich [35, 40]. The local Torelli was generalized by Bogomolov to hyperkähler manifolds [6] and by Bogomolov-Tian-Todorov to Calabi-Yau manifolds [7, 39, 42], building foundation for the theory of Mirror Symmetry.

In dimension > 1, the global Torelli theorem was known only for compact tori (where it is essentially trivial) and the K3 surfaces, where it was proven by Kulikov in 1977 [23], and then improved many times during the 1980-ies [3, 15, 27, 41, 44].

2.2. Birational Teichmüller space. In what follows, **a hyperkähler manifold** is a compact complex manifold admitting a Kähler structure and a holomorphic symplectic form.

In generalizing global Torelli to more general hyperkähler manifolds, two problems were apparent. First of all, bimeromorphic hyperkähler manifolds have the same periods, hence the period map cannot distinguish between them. However, for $\dim_{\mathbb{C}} M > 0$, birational holomorphically symplectic manifolds can be non-isomorphic [12].

Another (mostly psychological) difficulty is based on attachment to moduli spaces, as opposed to marked moduli or Teichmüller spaces. For a K3, one can reconstruct a K3 from its Hodge structure, and this gives an identification between the moduli and the space of Hodge structures. In bigger dimension, one has to use the Teichmüller space. Indeed, for some classes of hyperkähler manifolds, the group $O(H^2(M, \mathbb{Z})$ of Hodge isometries of cohomology is strictly bigger than the image of the mapping class group. This gives elements $\gamma \in O(H^2(M, \mathbb{Z})$ acting non-trivially on the Teichmüller space in such a way that the complex manifolds (M, I) and $(M, \gamma(I))$ are not birationally equivalent ([30, 33]). However, their Hodge structures *are* equivalent, by construction. This example explains the necessity of using the Teichmüller spaces (or marked moduli) to state the Torelli theorem: its Hodge-theoretic version is often false.

For Teichmüller spaces, the Torelli theorem is a statement about the period map (Definition 1.10). Ideally, we want the period map to give a diffeomporphism between Teich and the corresponding space of Hodge structures. This is what happens for a compact torus.

Theorem 2.1. *Let M be a compact torus, $\dim_{\mathbb{R}} M = 2n$, and Teich the Teichmüller space of all complex structures of Kähler type on M. Denote by $\mathbb{P}\mathsf{er}$ the space $SL(2n, \mathbb{R})/SL(n, \mathbb{C})$ of all Hodge structures of weight one on $H^1(M, \mathbb{C})$, that is, the space of all complex operators on $H^1(M, \mathbb{R})$ compatible with the orientation. Then the period map $\mathsf{Per} : \operatorname{Teich} \longrightarrow \mathbb{P}\mathsf{er}$ is a diffeomorphism on each connected component of $\mathbb{P}\mathsf{er}$.*

Unfortunately, this ideal situation is almost never realized. Even in the simplest cases (such as for hyperkähler manifolds), the Teichmüller space is no longer Hausdorff. However, in some situations it is still possible to deal with non-Hausdorff points.

Remark 2.2. A non-Hausdorff manifold is a topological space locally diffeomorphic to $\mathbb{R}^n$ (but not necessarily Hausdorff).

Definition 2.3. Let X be a topological space, and $X \stackrel{\varphi}{\longrightarrow} X_0$ a continuous surjection. The space X_0 is called **a Hausdorff reduction** of X if any continuous map $X \longrightarrow X'$ to a Hausdorff space is factorized through φ.

Definition 2.4. Let M be a topological space. We say that $x, y \in M$ are **non-separable** (denoted by $x \sim y$) if for any open sets $V \ni x, U \ni y$, one has $U \cap V \neq \emptyset$.

Remark 2.5. Suppose that $\sim$ is an equivalence relation, and the quotient $M/\sim$ is Hausdorff. Then $M/\sim$ is a Hausdorff reduction of M.

Unfortunately, this notion cannot be applied universally. Firstly, $\sim$ is not always an equivalence relation; and secondly, even if $\sim$ is equivalence, the $M/\sim$ is not always Hausdorff. Fortunately, for Teichmüller space of a hyperkähler manifold, Hausdorff reduction can be defined, using the following theorem due to D. Huybrechts ([19]).

Theorem 2.6. *If I_1, $I_2 \in \operatorname{Teich}$ are non-separate points, then (M, I_1) is birationally equivalent to (M, I_2).*

Using this result and geometry of the period map (Bogomolov's local Torelli theorem), it is elementary to show that the quotient $\operatorname{Teich}_b := \operatorname{Teich} / \sim$ is a Hausdorff manifold. This quotient is called **the birational Teichmüller space** of a hyperkähler manifold.

Global Torelli theorem implies that for hyperkähler manifolds the period map induces a diffeomorphism between the Hausdorff reduction of the Teichmüller space and the appropriate period domain.

3. Hyperkähler manifolds and Bogomolov-Beauville-Fujiki form

3.1. Hyperkähler manifolds: definition and examples. The standard definition of hyperkähler manifolds is rather differential geometric. It is, indeed, synonymous with "holomorphic symplectic", but this synonymity follows from Calabi-Yau theorem. For more details about hyperkähler manifolds, please see [2] or [4].

Definition 3.1. A **hyperkähler structure** on a manifold M is a Riemannian structure g and a triple of complex structures I, J, K, satisfying quaternionic relations $I \circ J = -J \circ I = K$, such that g is Kähler for I, J, K.

Remark 3.2. This is equivalent to $\nabla I = \nabla J = \nabla K = 0$: the parallel translation along the connection preserves I, J, K.

Remark 3.3. A hyperkähler manifold has three symplectic forms: $\omega_I := g(I\cdot,\cdot)$, $\omega_J := g(J\cdot,\cdot)$, $\omega_K := g(K\cdot,\cdot)$.

Definition 3.4. Let M be a Riemannian manifold, $x \in M$ a point. The subgroup of $GL(T_xM)$ generated by parallel translations (along all paths) is called **the holonomy group** of M.

Remark 3.5. A hyperkähler manifold can be defined as a manifold which has holonomy in $Sp(n)$ (the group of all endomorphisms preserving I, J, K).

Definition 3.6. A holomorphically symplectic manifold is a complex manifold equipped with non-degenerate, holomorphic $(2,0)$-form.

Remark 3.7. Hyperkähler manifolds are holomorphically symplectic. Indeed, $\Omega := \omega_J + \sqrt{1}\omega_K$ is a holomorphic symplectic form on (M, I).

Theorem 3.8 (Calabi-Yau). *A compact, Kähler, holomorphically symplectic manifold admits a unique hyperkähler metric in any Kähler class.*

Remark 3.9. For the rest of this talk, a hyperkähler manifold means a compact complex manifold admitting a Kähler structure and a holomorphically symplectic structure.

Definition 3.10. A hyperkähler manifold M is called **simple**, or **IHS**, if $\pi_1(M) = 0$, $H^{2,0}(M) = \mathbb{C}$.

The rationale for this terminology comes from Bogomolov's decomposition theorem.

Theorem 3.11 (Bogomolov, [5]). *Any hyperkähler manifold admits a finite covering which is a product of a torus and several simple hyperkähler manifolds.*

Further on, all hyperkähler manifolds are assumed to be simple.

Remark 3.12. A hyperkähler manifold is simple if and only if its holonomy group is $Sp(n)$, and not a proper subgroup of $Sp(n)$ [4].

Example 3.13. Take a 2-dimensional complex torus T, then the singular locus of $T/\pm 1$ is 16 points locally of form $\mathbb{C}^2/\pm 1$. Its resolution by blow-up is called **a Kummer surface**. It is not hard to see that it is holomorphically symplectic.

Definition 3.14. A K3 surface is a hyperkähler manifold which is diffeomorphic to a Kummer surface.

In real dimension 4, the only compact hyperkähler manifolds are tori and K3 surfaces, as follows from the Kodaira-Enriques classification.

Definition 3.15. A **Hilbert scheme** $M^{[n]}$ of a complex surface M is a classifying space of all ideal sheaves $I \subset \mathcal{O}_M$ for which the quotient $\mathcal{O}_M/I$ has dimension n over $\mathbb{C}$.

Remark 3.16. A Hilbert scheme is obtained as a resolution of singularities of the symmetric power $\operatorname{Sym}^n M$.

Theorem 3.17 (Fujiki, Beauville). *A Hilbert scheme of a hyperkähler manifold of real dimension 2 is hyperkähler.*

Example 3.18. Let T be a torus. Then T acts on its Hilbert scheme freely and properly by translations. For $n = 2$, the quotient $T^{[n]}/T$ is a Kummer K3-surface. For $n > 2$, a universal covering of $T^{[n]}/T$ is called **a generalized Kummer variety**.

Remark 3.19. There are 2 more "sporadic" examples of compact hyperkähler manifolds, constructed by K. O'Grady ([34]). All known simple hyperkaehler manifolds are these 2 and the two series: Hilbert schemes of K3 and generalized Kummer.

3.2. Bogomolov-Beauville-Fujiki form and the mapping class group.

Theorem 3.20 (Fujiki, [16]). *Let $\eta \in H^2(M)$, and $\dim M = 2n$, where M is hyperkähler. Then $\int_M \eta^{2n} = cq(\eta,\eta)^n$, for some primitive integer quadratic form q on $H^2(M,\mathbb{Z})$, and $c > 0$ a positive rational number, called* **Fujiki constant**.

Definition 3.21. This form is called **Bogomolov-Beauville-Fujiki form**. It is defined by the Fujiki's relation uniquely, up to a sign. The sign is determined from the following formula (Bogomolov, Beauville)

$$\begin{aligned}\lambda q(\eta,\eta) = &\int_X \eta\wedge\eta\wedge\Omega^{n-1}\wedge\bar\Omega^{n-1} - \\ &- \frac{n-1}{n}\left(\int_X \eta\wedge\Omega^{n-1}\wedge\bar\Omega^n\right)\left(\int_X \eta\wedge\Omega^n\wedge\bar\Omega^{n-1}\right)\end{aligned}$$

where Ω is the holomorphic symplectic form, and $\lambda > 0$.

Remark 3.22. The BBF form q has signature $(b_2 - 3, 3)$. It is negative definite on primitive forms, and positive definite on $\langle \Omega, \bar{\Omega}, \omega \rangle$, where ω is a Kähler form.

Using the BBF form, it is possible to describe the automorphism group of cohomology in a very convenient way.

Theorem 3.23. *Let M be a simple hyperkähler manifold, and $G \subset GL(H^*(M))$ a group of automorphisms of its cohomology algebra preserving the Pontryagin classes. Then G acts on $H^2(M)$ preserving the BBF form. Moreover, the map $G \longrightarrow O(H^2(M, \mathbb{R}), q)$ is surjective on a connected component, and has compact kernel.*

Proof.

Step 1 : Fujiki formula $v^{2n} = q(v, v)^n$ implies that Γ_0 preserves the Bogomolov-Beauville-Fujiki up to a sign. The sign is fixed, if n is odd.

Step 2 : For even n, the sign is also fixed. Indeed, G preserves $p_1(M)$, and (as Fujiki has shown in [16]), $v^{2n-2} \wedge p_1(M) = q(v, v)^{n-1} c$, for some $c \in \mathbb{R}$. The constant c is positive, because the degree of $c_2(B)$ is positive for any non-trivial Yang-Mills bundle with $c_1(B) = 0$.

Step 3 : $\mathfrak{o}(H^2(M, \mathbb{R}), q)$ acts on $H^*(M, \mathbb{R})$ by derivations preserving Pontryagin classes ([45]). Therefore $\operatorname{Lie}(G)$ surjects to $\mathfrak{o}(H^2(M, \mathbb{R}), q)$.

Step 4 : The kernel K of the map $G \longrightarrow G\big|_{H^2(M,\mathbb{R})}$ is compact, because it commutes with the Hodge decomposition and Lefschetz $\mathfrak{sl}(2)$-action, hence preserves the Riemann-Hodge form, which is positive definite. □

Using this result, the mapping class group can also be computed. We use a theorem of D. Sullivan, who expressed the mapping group in terms of the rational homotopy theory, and expressed the rational homotopy in terms of the algebraic structure of the de Rham algebra.

Theorem 3.24 (Sullivan, [37, Theorem 10.3, Theorem 12.1, Theorem 13.3]). *Let M be a compact, simply connected Kähler manifold, $\dim_{\mathbb{C}} M \geqslant 3$. Denote by Γ_0 the group of automorphisms of an algebra $H^*(M, \mathbb{Z})$ preserving the Pontryagin classes $p_i(M)$. Then the natural map $\operatorname{Diff}(M)/\operatorname{Diff}_0 \longrightarrow \Gamma_0$ has finite kernel, and its image has finite index in Γ_0.*

As a corollary of this theorem, we obtain a similar result about hyperkähler manifolds.

Theorem 3.25. *Let M be a simple hyperkähler manifold, and Γ_0 the group of automorphisms of an algebra $H^*(M, \mathbb{Z})$ preserving the Pontryagin classes $p_i(M)$. Then*

(i) *$\Gamma_0\big|_{H^2(M,\mathbb{Z})}$ is a finite index subgroup of $O(H^2(M, \mathbb{Z}), q)$.*

(ii) *The map $\Gamma_0 \longrightarrow O(H^2(M, \mathbb{Z}), q)$ has finite kernel.*

We obtained that the mapping group is **arithmetic** (commensurable to a subgroup of integer points in a rational Lie group).

As follows from [20, Theorem 2.1], there are only finitely many connected components of Teich. Let Γ^I be the group of elements of mapping class group preserving a connected component of Teichmüller space containing $I \in \operatorname{Teich}$. Then Γ^I is also arithmetic. Indeed, it has finite index in Γ.

Definition 3.26. The image of Γ^I in $GL(H^2(M,\mathbb{Z}))$ is called **monodromy group of a manifold**.

Remark 3.27. The monodromy group can also be obtained as a group generated by monodromy of all Gauss-Manin local system for all deformations of M ([46, Theorem 7.2]). This explains the term. This notion was defined and computed in many special cases by E. Markman [29, 30].

4. Global Torelli theorem

4.1. Period map. To study the moduli problem, one should understand the mapping class group (described above) and the Teichmüller space. It turns out that the birational Teichmüller space has a very simple description in terms of the period map, inducing a diffeomorphism

$$\operatorname{Teich}_b \longrightarrow \frac{SO(b_2-3,3)}{SO(b_2-3,1)\times SO(2)}$$

on each connected component of Teich_b.

Definition 4.1. Let $\mathsf{Per}: \operatorname{Teich} \longrightarrow \mathbb{P}H^2(M,\mathbb{C})$ map J to a line $H^{2,0}(M,J) \in \mathbb{P}H^2(M,\mathbb{C})$. The map $\mathsf{Per}: \operatorname{Teich} \longrightarrow \mathbb{P}H^2(M,\mathbb{C})$ is called **the period map**.

Remark 4.2. Per maps Teich into an open subset of a quadric, defined by

$$\mathbb{P}\mathsf{er} := \{l \in \mathbb{P}H^2(M,\mathbb{C}) \mid q(l,l)=0, q(l,\bar{l})>0\}.$$

The manifold $\mathbb{P}\mathsf{er}$ is called **the period space** of M.

As follows from Proposition 4.8 below, $\mathbb{P}\mathsf{er} = \frac{SO(b_2-3,3)}{SO(b_2-3,1)\times SO(2)}$.

Theorem 4.3 (Bogomolov, [6]). *Let M be a simple hyperkähler manifold, and* Teich *its Teichmüller space. Then the period map* $\mathsf{Per}: \operatorname{Teich} \longrightarrow \mathsf{Per}$ *is etale (has invertible differential everywhere).*

Remark 4.4. Bogomolov's theorem implies that Teich is smooth. It is non-Hausdorff even in the simplest examples.

Now the global Torelli theorem can be stated as follows. Recall that the birational Teichmüller space Teich_b is a Hausdorff reduction of the Teichmüller space of the holomorphic symplectic manifolds of Kähler type.

Theorem 4.5. *Let M be a simple hyperkähler manifold, and* $\mathsf{Per}: Teich_b \longrightarrow \mathbb{P}\mathsf{er}$ *the period map. Then* Per *is a diffeomorphism on each connected component.*

The following proposition is proven in a straghtforward manner using 1950-ies style arguments of geometric topology.

Proposition 4.6 (The Covering Criterion). *Let $X \stackrel{\varphi}{\longrightarrow} Y$ be an etale map of smooth manifolds. Suppose that each $y \in Y$ has a neighbourhood $B \ni y$ diffeomorphic to a closed ball, such that for each connected component $B' \subset \varphi^{-1}(B)$, B' projects to B surjectively. Then φ is a covering.*

Now, the Global Torelli implied by the following result, which is proven in Subsection 4.2 using hyperkähler structures.

Proposition 4.7. *In assumptions of Theorem 4.5, the period map satisfies the conditions of the Covering Criterion.*

4.2. Moduli of hyperkähler structures and twistor curves.

Proposition 4.8. *The period space*

$$\mathbb{P}\mathsf{er} := \{l \in \mathbb{P}H^2(M,\mathbb{C}) \mid q(l,l)=0, q(l,\bar{l})>0\}$$

is identified with $\frac{SO(b_2-3,3)}{SO(2)\times SO(b_2-3,1)}$*, which is a Grassmannian of positive oriented 2-planes in* $H^2(M,\mathbb{R})$.

Proof.

Step 1 : Given $l \in \mathbb{P}H^2(M,\mathbb{C})$, the space generated by $\operatorname{Im} l, \operatorname{Re} l$ is 2-dimensional, because $q(l,l)=0, q(l,\bar{l})$ implies that $l \cap H^2(M,\mathbb{R})=0$.

Step 2 : This 2-dimensional plane is positive, because $q(\operatorname{Re} l, \operatorname{Re} l) = q(l+\bar{l}, l+\bar{l}) = 2q(l,\bar{l})>0$.

Step 3 : Conversely, for any 2-dimensional positive plane $V \in H^2(M,\mathbb{R})$, the quadric $\{l \in V\otimes_{\mathbb{R}}\mathbb{C} \mid q(l,l)=0\}$ consists of two lines; a choice of a line is determined by orientation. □

Remark 4.9. Two hyperkähler structures (M,I,J,K,g) and (M,I',J',K',g) are called **equivalent** if there exists a unitary quaternion h such that $I'=hIh^-1$, $J'=hJh^-1$, $K'=hKh^-1$. From the holonomy characterization of simple hyperkähler manifolds (Remark 3.12) it follows that two hyperkähler structures are isometric if and only if they are equivalent.

Definition 4.10. Let (M,I,J,K,g) be a hyperkähler manifold. **A hyperkähler 3-plane** in $H^2(M,\mathbb{R})$ is a positive oriented 3-dimensional subspace W, generated by three Kähler forms $\omega_I,\omega_J,\omega_K$.

Definition 4.11. Similarly to the Teichmüller space and period map of complex structures, one can define the period space of hyperkähler metrics. Denote it by Teich_H. The corresponding period map is

$$\mathsf{Per}: \operatorname{Teich}_H \longrightarrow \mathbb{P}\mathsf{er}_H,$$

where $\mathbb{P}\mathsf{er}_H = \frac{SO(b_2-3,3)}{SO(3)\times SO(b_2-3)}$ is the space of positive, oriented 3-planes, and Per maps a hyperkähler structure to the corresponding hyperkähler 3-plane.

Remark 4.12. There is one significant difference between Teich and the hyperkähler Teichmüller space Teich_H: the latter is Hausdorff, and, in fact, metrizable. Indeed, we could equip the space Teich_H of hyperkähler metrics with the Gromov-Hausdorff metric.

Let $I \in \operatorname{Teich}$ be a complex structure, and $\mathcal{K}(I)$ its Kähler cone. The set of hyperkähler metrics compatible with I is parametrized by $\mathcal{K}(I)$, by Calabi-Yau theorem. The corresponding 3-dimensional subspaces are generated by $\mathsf{Per}(I)+\omega$, where $\omega \in \mathcal{K}(I)$. The local Torelli

theorem implies that locally $I \in \mathrm{Teich}$ is uniquely determined by the 2-plane generated by ω_J and ω_K; Calabi-Yau theorem implies that the hyperkähler metric is uniquely determined by the complex structure and the Kähler structure. This gives the following hyperkähler version of the local Torelli theorem.

Theorem 4.13. *Let M be a simple hyperkähler manifold, and Teich_H its hyperkähler Teichmüller space. Then the period map $\mathsf{Per} : \mathrm{Teich} \longrightarrow \mathsf{Per}_H$ mapping an equivalence class of hyperkähler structures to is its 3-plane is etale (has invertible differential everywhere).*

Remark 4.14. Let $W \subset H^2(M, \mathbb{R})$ be a positive 3-dimensional plane. The set $S_W \subset \mathbb{P}\mathsf{er}$ of oriented 2-dimensional planes in W is identified with $S^2 = \mathbb{C}P^1$. When W is a hyperkähler 3-plane, S_W is called **the twistor family** of a hyperkähler structure. A point in the twistor family corresponds to a complex structure $aI + bJ + cK \in \mathbb{H}$, with $a^2 + b^2 + c^2 = 1$. We call the corresponding rational curves $\mathbb{C}P^1 \subset \mathrm{Teich}$ **the twistor lines**. It is not hard to see that the twistor lines are holomorphic.

Definition 4.15. Let $W \in \mathbb{P}\mathsf{er}_H$ be a positive 3-plane, $S_W \subset \mathbb{P}\mathsf{er}$ the corresponding rational curve, and $x \in S_W$ be a point. It is called **liftable** if for any point $y \in \mathsf{Per}^{-1}(x) \subset \mathrm{Teich}$ there exists $\mathcal{H} \in \mathrm{Teich}_H$ such that the corresponding twistor line contains y.

When W is generic, the corresponding line S_W is liftable, as indicated below.

Definition 4.16. The Neron-Severi lattice $NS(I)$ of a hyperkähler manifold (M, I) is

$$H^{1,1}(M, I) \cap H^2(M, \mathbb{Z}).$$

The following theorem, based on results of [13], was proven by D. Huybrechts.

Theorem 4.17 ([19]). *Let M be a hyperkaehler manifold with $\mathsf{NS}(M) = 0$. Then its Kaehler cone is one of two components of the set*

$$\{\nu \in H^{1,1}(M, \mathbb{R}) \mid q(\nu, \nu) \geqslant 0\}.$$

Definition 4.18. Let $S \subset \mathrm{Teich}$ be a $\mathbb{C}P^1$ associated with a twistor family. It is called **generic** if it passes through a point $I \in \mathrm{Teich}$ with $\mathsf{NS}(M, I) = 0$. Clearly, a hyperkähler 3-plane $W \subset H^2(M, \mathbb{R})$ corresponds to a generic twistor family if and only if its orthogonal complement $W^\perp \subset H^2(M, \mathbb{R})$ does not contain rational vectors. A 3-plane $W \in \mathbb{P}\mathsf{er}_H$ is called **generic** if $W^\perp \subset H^2(M, \mathbb{R})$ does not contain rational vectors. The corresponding rational curve $S_W \subset \mathbb{P}\mathsf{er}$ is called **a GHK line**. GHK lines are liftable, which is very useful for many purposes, including the proof of Torelli theorem (see also [1], where GHK lines were used to study Kähler cones of hyperkähler manifolds).

The following theorem immediately follows from the Calabi-Yau theorem and the description of the Kähler cone given in Theorem 4.17.

Theorem 4.19. *Let $W \in \mathbb{P}\mathsf{er}_H$ be a generic plane, $S_W \subset \mathbb{P}\mathsf{er}$ the corresponding rational curve, and $x \in S_W$ a generic point. Then (S_W, x) is liftable.*

Assumptions of the covering criterion (Proposition 4.7) immediately follow from Theorem 4.19. Indeed, it is not hard to see that any two points on a closed ball $B \subset \mathbb{P}\mathsf{er}$ can be connected inside B by a sequence of GHK curves intersecting in generic points of B. Since these curves are liftable, any connected component of $\mathsf{Per}^{-1}(B)$ is mapped to B surjectively.

5. Teichmüller spaces and ergodic theory

5.1. Ergodic complex structures. After the Teichmüller space and the mapping class group are understood, it is natural to consider the quotient space $\mathrm{Comp} / \mathrm{Diff} = \mathrm{Teich} / \Gamma$ of the Teichmüller space by the mapping class group $\Gamma := \mathrm{Diff} / \mathrm{Diff}_0$.

Claim 5.1. *Let M be a simple hyperkähler manifold, Γ its mapping class group, and Teich_b the birational Teichmüller space. Then the quotient $\mathrm{Teich}_b / \Gamma$ parametrizes the birational classes of deformations of M.*

One could call the quotient $\mathrm{Teich}_b / \Gamma$ "the moduli space", but, unfortunately, this is not a space in any reasonable sense. Indeed, as we shall see, non-trivial closed subsets of $\mathrm{Teich}_b / \Gamma$ are at most countable, making $\mathrm{Teich}_b / \Gamma$ terribly non-Hausdorff. This means that the concept of "moduli space" has no meaning, and all interesting information about moduli problems is hidden in dynamics of Γ-action on Teich.

Let $I \in \mathrm{Teich}$ be a point, and $\mathrm{Teich}^I \subset \mathrm{Teich}$ its connected component. Since Teich has finitely many components, a subgroup mapping class group fixing Teich has finite index. Its image in $\mathrm{Aut}(\mathrm{Teich}^I)$ is called **monodromy group** and denoted Γ^I (Definition 3.26). It is a finite index subgroup in $SO(H^2(M, \mathbb{Z}))$.

All that said, we find that the moduli problem for hyperkähler manifold is essentially reduced to the dynamics of the Γ^I-action on the space $\mathbb{P}\mathrm{er}$, which is understood as a Grassmannian of positive, oriented 2-planes in $H^2(M, \mathbb{R})$.

It is natural to study the dynamics of a group action from the point of view of ergodic theory, ignoring measure zero subsets. However, the quotient map $\mathrm{Teich} \longrightarrow \mathrm{Teich}_b$ is bijective outside of a union of countably many divisors, corresponding to complex structures I with $NS(M, I)$ non-zero. This set has measure 0. Therefore, the quotient map $\mathrm{Teich} \longrightarrow \mathrm{Teich}_b$ induces an equivalence of measured spaces. For the purposes of ergodic theory, we shall identify Teich^I with the corresponding homogeneous space $\mathbb{P}\mathrm{er}$.

Ths first observation, based on a theorem of C. Moore, implies that the monodromy action on $\mathbb{P}\mathrm{er}$ is ergodic.

Definition 5.2. Let (M, μ) be a space with measure, and G a group acting on M. This action is **ergodic** if all G-invariant measurable subsets $M' \subset M$ satisfy $\mu(M') = 0$ or $\mu(M \backslash M') = 0$.

Claim 5.3. *Let M be a manifold, μ a Lebesgue measure, and G a group acting on (M, μ) ergodically. Then the set of non-dense orbits has measure 0.*

Proof. Consider a non-empty open subset $U \subset M$. Then $\mu(U) > 0$, hence $M' := G \cdot U$ satisfies $\mu(M \backslash M') = 0$. For any orbit $G \cdot x$ not intersecting U, one has $x \in M \backslash M'$. Therefore, the set of such orbits has measure 0. □

Definition 5.4. Let $I \in \mathrm{Comp}$ be a complex structure on a manifold. It is called **ergodic** if its Diff-orbit is dense in its connected component of Comp.

Remark 5.5. This is equivalent to density of Γ-orbit of I in its Teichmüller component.

5.2. Ergodicity of the monodromy group action.

Definition 5.6. Let G be a Lie group, and $\Gamma \subset G$ a discrete subgroup. Consider the pushforward of the Haar measure to G/Γ. We say that Γ **has finite covolume** if the Haar measure of G/Γ is finite. In this case Γ is called **a lattice subgroup**.

Remark 5.7. Borel and Harish-Chandra proved that an arithmetic subgroup of a reductive group G is a lattice whenever G has no non-trivial characters over $\mathbb{Q}$ (see e.g. [48]). In particular, all arithmetic subgroups of a semi-simple group are lattices.

Theorem 5.8 (Calvin C. Moore, [31, Theorem 7]). *Let Γ be an arithmetic subgroup in a non-compact simple Lie group G with finite center, and $H \subset G$ a non-compact subgroup. Then the left action of Γ on G/H is ergodic.*

Theorem 5.9. *Let* Teich *be a connected component of a Teichmüller space, and Γ^I its monodromy group. Then the set of all non-ergodic points of* Teich *has measure 0.*

Proof. Global Torelli theorem identifies Teich (as a measured space) and G/H, where $G = SO(b_2 - 3, 3)$, $H = SO(2) \times SO(b_2 - 3, 1)$. Since Γ^I is an arithmetic lattice, Γ^I-action on G/H is ergodic, by Moore's theorem. □

Moore's theorem implies that outside of a measure zero set, all complex structures on Teich are ergodic. If we want to determine which exactly complex structures are ergodic, we have to use Ratner's theorem, giving precise description of a closure of a Γ^I-orbit in a homogeneous space.

Now I will state some basic results of Ratner theory. For more details, please see [22] and [32].

Definition 5.10. Let G be a Lie group, and $g \in G$ any element. We say that g is **unipotent** if $g = e^h$ for a nilpotent element h in its Lie algebra. A group G is **generated by unipotents** if G is multiplicatively generated by unipotent elements.

Theorem 5.11 ([32, 1.1.15 (2)]). *Let $H \subset G$ be a Lie subroup generated by unipotents, and $\Gamma \subset G$ a lattice. Then a closure of any H-orbit in G/Γ is an orbit of a closed, connected subgroup $S \subset G$, such that $S \cap \Gamma \subset S$ is a lattice.*

When this lattice is arithmetic, one could describe the group S very explicitly.

Claim 5.12 ([22, Proposition 3.3.7] or [36, Proposition 3.2]). *Let $x \in G/H$ be a point in a homogeneous space, and $\Gamma \cdot x$ its Γ-orbit, where Γ is an arithmetic lattice. Then its closure is an orbit of a group S containing stabilizer of x. Moreover, S is a smallest group defined over rationals and stabilizing x.*

For the present purposes, we are interested in a pair $SO(3, k) \supset SO(1, k) \times SO(2) \subset G$ (or, rather, their connected components $G = SO^+(3, k)$ and $H = SO(1, k) \times SO(2) \subset G$). In this case, there are no intermediate subgroups.

Claim 5.13. *Let $G = SO^+(3, k)$, and $H \cong SO^+(1, k) \times SO(2) \subset G$. Then any closed connected Lie subgroup $S \subset G$ containing H coincides with G or with H.*

Corollary 5.14. *Let $J \in \mathbb{P}\mathsf{er} = G/H$. Then either J is ergodic, or its Γ-orbit is closed in* $\mathbb{P}\mathsf{er}$.

By Ratner's theorem, in the latter case the H-orbit of J has finite volume in G/Γ. Therefore, its intersection with Γ is a lattice in H. This brings

Corollary 5.15. *Let $J \in \mathbb{P}\mathsf{er}$ be a point such that its Γ-orbit is closed in* $\mathbb{P}\mathsf{er}$. *Consider its stabilizer $\mathrm{St}(J) \cong H \subset G$. Then $\mathrm{St}(J) \cap \Gamma$ is a lattice in $\mathrm{St}(J)$.*

Corollary 5.16. *Let J be a non-ergodic complex structure on a hyperkähler manifold, and $W \subset H^2(M, \mathbb{R})$ be a plane generated by $\operatorname{Re}\Omega, \operatorname{Im}\Omega$. Then W is rational. Equivalently, this means that $Pic(M)$ has maximal possible dimension.*

Similar results are true for a torus of dimension > 1; we refer the reader to [47] for precise statements and details of the proof.

6. Applications of ergodicity

6.1. Ergodic complex structures, Gromov-Hausdorff closures, and semicontinuity. The ergodicity theorem (Subsection 5.2) has some striking and even paradoxical implications. For instance, consider a Kähler cone Kah of a hyperkähler manifold (or a torus of dimension > 1) equipped with an ergodic complex structure. By Calabi-Yau theorem, each point of Kah corresponds to a Ricci-flat metric on M. If we restrict ourselves to those metrics which satisfy $\mathsf{diam}(M, g) \leqslant d$ (with bounded diameter), then, by Gromov's compactness theorem ([17]), the set X_d of such metrics is precompact in the Gromov's space of all metric spaces, equipped with the Gromov-Hausdorff metric. It is instructive to see what kind of metric spaces occur on its boundary (that is, on $\bar{X}_d \backslash X_d$). To see this, let ν_i be a sequence of diffeomorphisms satisfying $\lim_i \nu_i(I) = I'$. By Kodaira stability theorem, the Kähler cone of (M, I) is lower continuous on I. Therefore, there exists a family of Kähler classes ω_i on $(M, \nu_i(I))$ which converge to a given Kähler class ω' on (M, I'). This implies convergence of the corresponding Ricci-flat metrics. We obtain that any Ricci-flat metric on (M, I') (for any I' in the same deformation class as I) is obtained as a limit of Ricci-flat metrics on (M, I).

This gives the following truly bizzarre theorem.

Theorem 6.1. *Let (M, I) be an ergodic complex structure on a hyperkähler manifold, $X \cong \mathrm{Kah}$ the set of all Ricci-flat Kähler metrics on (M, I), and g' another Ricci-flat metric on M in the same deformation class. Then g' lies in the closure of X with respect to the Gromov topology on the space of all metrics.*

This result is very strange, because Kah is a smooth manifold of dimension $b_2(M) - 2$. By Theorem 4.13, the space Teich_H of all hyperkähler metrics is a smooth manifold of dimension $\frac{b_2(b_2-1)(b_2-2)}{6}$, clearly much bigger than $\dim \mathrm{Kah}$. Obviously, the boundary of X is highly irregular and chaotic.

For another application, consider some numerical quantity $\mu(I)$ associated with an equivalence class of complex structures. Suppose that μ is continuous or semi-continuous on Teich. Then μ is constant on ergodic complex structures. To see this, suppose that μ is upper semicontinuous, giving

$$\mu(\lim_k I_k) \geqslant \lim_k (\mu(I_k)). \tag{6.1}$$

Given an ergodic complex structire I, find a sequence $I_k = \nu_k(I)$ converging to a complex structure I'. Then (6.1) gives $\mu(I) \leqslant \mu(I')$. This implies that any ergodic complex structure satisfies $\mu(I) = \inf_{I' \in \mathrm{Teich}} \mu(I')$.

This observation can be applied to Kobayashi pseudometric and Kobayashi hyperbolicity.

6.2. Kobayashi non-hyperbolicity of hyperkähler manifolds.

Definition 6.2. Pseudometric on M is a function $d: M \times M \longrightarrow \mathbb{R}^{\geqslant 0}$ which is symmetric: $d(x,y) = d(y,x)$ and satisfies the triangle inequality $d(x,y) + d(y,z) \geqslant d(x,z)$.

Remark 6.3. Let $\mathfrak{D}$ be a set of pseudometrics. Then $d_{\mathsf{max}}(x,y) := \sup_{d \in \mathfrak{D}} d(x,y)$ is also a pseudometric.

Definition 6.4. The Kobayashi pseudometric on a complex manifold M is d_{max} for the set $\mathfrak{D}$ of all pseudometrics such that any holomorphic map from the Poincaré disk to M is distance-non-increasing.

In other words, a Kobayashi pseudo-distance between two points x, y is an infimum of distance from x to y in Poincare metric for any sequence of holomorphic disks connecting x to y.

The following observation is not difficult to see.

Claim 6.5. *Let $\pi: \mathcal{M} \longrightarrow X$ be a smooth holomorphic family, which is trivialized as a smooth manifold: $\mathcal{M} = M \times X$, and d_x the Kobayashi metric on $\pi^{-1}(x)$. Then $d_x(m, m')$ is upper continuous on x.*

Corollary 6.6. *Denote the diameter of the Kobayashi pseudometric by*

$$\mathsf{diam}(d_x) := \sup_{m,m'} d_x(m, m').$$

Then the Kobayashi diameter of a fiber of π is an upper continuous function: $\mathsf{diam}: X \longrightarrow \mathbb{R}^{\geqslant 0}$.

For a projective K3 surface, the Kobayashi pseudometric vanishes ([49, Lemma 1.51]). However, all non-projective K3 surfaces are ergodic (Corollary 5.16). This proves the vanishing of Kobayashi pseudodistance for all K3 surfaces. A more general version of this result is due to due to Kamenova-Lu-Verbitsky.

Theorem 6.7 ([21]). *Let M be a Hilbert scheme of K3. Then the Kobayashi pseudometric on M vanishes.*

Definition 6.8. A complex manifold is called **Kobayashi hyperbolic** if the Kobayashi pseudometric is a metric.

Definition 6.9. An entire curve is a non-constant map $\mathbb{C} \longrightarrow M$.

Brody has shown that a compact manifold is Kobayashi hyperbolic if and only if it admits no entire curves. The same argument also proves semicontinuity.

Theorem 6.10 ([8]). *Let I_i be a sequence of complex structures on M which are not hyperbolic, and I its limit. Then (M, I) is also not hyperbolic.*

With ergodicity, this can be used to prove that all hyperkähler manifolds are non-hyperbolic. Recall that **a twistor family** of complex structures on a hyperkähler manifold (M, I, J, K) is a family of complex structures of form $S^2 \cong \{L := aI + bJ + cK, \quad a^2 + b^2 + c^2 = 1\}$. F. Campana has obtained a remarkable partial result towards non-hyperbolicity.

Theorem 6.11 ([10]). *Let M be a hyperkähler manifold, and $S \subset$ Teich a twistor family. Then there exists an entire curve in some $I \in S$.*

Claim 6.12. *There exists a twistor family which has only ergodic fibers.*

Proof. There are only countably many complex structures which are not ergodic; however, twistor curves move freely through the Teichmüller space of a hyperkähler manifold, as seen from Theorem 4.19. □

Applying Campana's theorem to the family constructed in Claim 6.12, we obtain an ergodic complex structure which is non-hyperbolic. Then the Brody's theorem implies that all complex structures in the same deformation class are non-hyperbolic.

Theorem 6.13. *All hyperkähler manifolds are non-hyperbolic.*

6.3. Symplectic packing and ergodicity. I will finish this talk with a list of open problems of hyperkähler and holomorphically symplectic geometry which might be solvable with ergodic methods.

Question 6.14. *Let M be a hyperkähler manifold, and* Teich *its Teichmüller space. Consider the universal fibration $\mathcal{X} \longrightarrow$ Teich (Remark 1.11). The mapping class group Γ acts on $\mathcal{X}$ in a natural way. Is this action ergodic?*

This question (suggested by Claire Voisin) seems to be related to the following conjecture.

Conjecture 6.15. *Let M be a K3 surface. Then for each $x \in M$ and $v \in T_xM$ there exists an entire curve $C \ni x$ with $T_xC \ni v$.*

The symplectic packing problem is a classical subject of symplectic geometry ([28]). However, its holomorphically symplectic version seems to be completely unexplored.

Definition 6.16. A holomorphic symplectic ball B_r of radius r is a complex holomorphically symplectic manifold admitting a holomorphic symplectomorphism to an open ball in $\mathbb{C}^{2n}$ of radius r with the standard holomorphic symplectic form $\sum_{i=1}^{n} dz_{2i-1} \wedge dz_{2i}$.

Notice that by a holomorphic symplectic version of Darboux theorem, any holomorphically symplectic manifold is locally symplectomorphic to a holomorphic symplectic ball.

Definition 6.17. Let M be a holomorphically symplectic manifold. **Symplectic packing** of radii $r_1, ..., r_k$ of M is a set of holomorphic symplectomorphisms $\varphi_i : \ B_{r_i} \hookrightarrow M$ with images of φ_i not intersecting.

Obviously, in these assumptions, $\sum \mathrm{Vol}(B_{r_i}) \leqslant \mathrm{Vol}_M$, where Vol denotes the symplectic volume of a holomorphic symplectic manifold (M, Ω_M):

$$\mathrm{Vol}(M) = \int_M (\Omega_M \wedge \bar{\Omega}_M), \ \ 2n = \dim_{\mathbb{C}} M.$$

The volume inequality puts certain restrictions on the possible symplectic packing. Are there any other restrictions?

For the usual (smooth) symplectic packing, some additional restrictions are obtained from the Gromov's symplectic capacity theorem and from the study of pseudoholomorphic

curves. However, it seems that in holomorphic symplectic situation these restrictions are also trivial. For a general compact torus of real dimension 4, volume is known to be the only restriction to existence of symplectic packing ([26]). It seems that a similar result about the smooth symplectic packings is true for K3 surfaces as well, and, possibly, for any hyperkähler manifold.

The arguments used to treat the usual (smooth) symplectic packings don't work for the holomorphic symplectic case. However, the set of possible radii for symplectic packing is obviously semicontinous, hence it can be studied by ergodic methods, in the same way as one studies the Kobayashi pseudometric.

The following classical question was treated Buzzard and Lu in [9].

Definition 6.18. A complex manifold M of dimension n is called **dominated by** $\mathbb{C}^n$ if there exists a holomorphic map $\varphi:\ \mathbb{C}^n \longrightarrow M$ which has non-degenerate differential in generic point.

Buzzard and Lu proved that Kummer K3 surfaces are dominated by $\mathbb{C}^2$. So far, there is not a single example of a hyperkähler manifold M for which it is proven that M is not dominated. This leads to the following conjecture

Conjecture 6.19. *Any compact hyperkähler manifold is dominated by* $\mathbb{C}^n$.

There is no semicontinuity in dominance, because Brody lemma fails to produce dominating maps $\mathbb{C}^n \longrightarrow M$ for $n > 1$ as limits of sequences of dominating maps. In the proof of Brody's lemma (showing that a limit of a sequence of entire curves contains an entire curve) one takes a reparametrizations of each of the curves in the sequence. Starting from a sequence of dominating maps, one could apply the same argument, but each subsequent reparametrization can lead to smaller Jacobian of the differential, and the differential of the limit could be zero.

It seems that more of the Brody's argument can be retained if we restrict ourselves to symplectomorphisms.

Question 6.20. *Consider a flat holomorphically symplectic structure on* $\mathbb{C}^2$. *Is there a holomorphic map* $\mathbb{C}^2 \longrightarrow M$ *to a K3 surface which is compatible with the holomorhic symplectic form?*

Probably not. However, a quantitative version of this question makes sense. Let M be a hyperkähler manifold, and $K(M)$ the supremum of all r such that there exists a symplectic immersion from a symplectic ball of radius r to M. It is not hard to see that $K(M)$ is semicontinuous in families, hence constant on ergodic complex structures.

Question 6.21. *For a given hyperkähler manifold, find* $K(M)$.

It is not clear if $K(M)$ is finite or infinite, even for a K3 surface (it is clearly infinite for a torus).

5. Geometry

Family Floer cohomology and mirror symmetry

Mohammed Abouzaid

Abstract. Ideas of Fukaya and Kontsevich-Soibelman suggest that one can use Strominger-Yau-Zaslow's geometric approach to mirror symmetry as a torus duality to construct the mirror of a symplectic manifold equipped with a Lagrangian torus fibration as a moduli space of those simple objects of the Fukaya category which are supported on the fibres. In the absence of singular fibres, the construction of the mirror is explained in this framework, and, given a Lagrangian submanifold, a (twisted) coherent sheaf on the mirror is constructed.

Mathematics Subject Classification (2010). Primary 53D40; Secondary 14J33.

Keywords. Lagrangian Floer cohomology, homological mirror symmetry.

1. Introduction

1.1. Overview. Mirror symmetry is a prediction from string theory identifying invariants associated to the complex geometry of a family of Calabi-Yau manifolds with invariants associated to the Kähler geometry of a possibly different Calabi-Yau manifold that is called the mirror. In our setting, we take as definition of a Calabi-Yau manifold a complex manifold equipped with a nowhere vanishing holomorphic volume form. The original focus in mathematics was on the dualities of Hodge diamonds which gave a straightforward though non-trivial check, and on the enumerative predictions for the number of curves of a given genus and degree that went beyond the computations which could be performed using rigourous methods. While it is not reasonable to expect the existence of a mirror partner to every Calabi-Yau manifold, there are large classes of examples (e.g. toric complete intersections [6, 17]) for which various original forms of the conjecture have been verified.

In [22], Kontsevich introduced a homological version of the conjecture: the invariants to be related would be the derived category of coherent sheaves on the complex side and the Fukaya category of Lagrangian submanifolds on the symplectic side. Strominger, Yau, and Zaslow [28] later introduced a geometric version of the conjecture: mirror pairs should arise as dual torus fibrations over the same base; these are often called SYZ fibrations. The degenerating family can then be understood as arising from rescaling the fibres.

It is easier to state precise versions of the SYZ conjecture (which still hold in a large class of examples) if one analyses the two sides of mirror symmetry separately, i.e. fixing a Kähler form on a Calabi-Yau manifold X whose symplectic topology will be related to the complex geometry of a Calabi-Yau variety Y over the ring of power series $\mathbb{C}[[T]]$ or the analogous rings appearing naturally in symplectic topology in which real exponents are

Proceedings of International Congress of Mathematicians, 2014, Seoul

allowed; weakening one side to a formal family is related to a convergence problem in Floer theory.

In this context, the starting point of a reformulation of the SYZ conjecture is the existence of a Lagrangian fibration $\pi\colon X \to Q$ with singularities (there is still no good approach to the class of allowable singularities). The space Y should then be constructed from the Fukaya category $\mathrm{Fuk}(X)$ as a moduli space of objects supported on fibres of this map [11]. While the moduli space of such objects can be described locally over the base as the dual torus fibration, the fact that we consider them as objects of the Fukaya category introduces non-trivial identifications of the local charts given by the sum of a classical term with *instanton corrections* that arise from the moduli space of holomorphic discs bounded by such fibres. These corrections are expected to be expressible in terms of the geometry of the base via *wall-crossing formulae* [23, 19].

In this setting, the homological mirror conjecture asserts the existence of a derived equivalence $D\,\mathrm{Fuk}(X) \cong D\,\mathrm{Coh}(Y)$, where both categories are linear over the appropriate version of power series rings. Much effort has gone in verifying this conjecture in certain examples [26, 1, 27], and extracting some of the classical statements of mirror symmetry from it [8, 20].

Unfortunately, all the current proofs of mirror symmetry rely on *ad hoc* methods to construct the mirror functor, neglecting the construction of the mirror as a moduli space of objects of the Fukaya category. To address this issue, Fukaya has introduced family Floer cohomology [10, 11, 12, 13] as a strategy for directly assigning a sheaf on Y to a Lagrangian L in X; as noted in [11], the main difficulty arises from the caustics of L, i.e. the singularities of its projection to the base. In Section 4, we use the invariance properties of Floer cohomology under continuation maps to bypass the difficulties arising from caustics (as in [10, Section 6]), and prove convergence in the rigid analytic sense.

1.2. A twisted example. Since the problem is sufficiently complicated in the absence of singular fibres, we shall henceforth only consider symplectic manifolds that admit smooth Lagrangian torus fibrations. This class includes, for example, a codimension $\frac{n(n-1)}{2}$ subspace of the $n(2n-1)$-dimensional space of linear symplectic structures on $\mathbb{R}^{2n}/\mathbb{Z}^{2n}$, corresponding to those structures that can be represented as the quotient of $\mathbb{R}^{2n}$ by a lattice which intersects some Lagrangian plane in a rank n subgroup. It also includes the following twisted example due to Thurston [30]:

Equip $\mathbb{R}^4$ with coordinates (x_1, x_2, x_3, x_4), and symplectic structure

$$dx_1 \wedge dx_2 + dx_3 \wedge dx_4. \tag{1.1}$$

This form is invariant under the transformation

$$(x_1, x_2, x_3, x_4) \to (x_1 + 1, x_2, x_3, x_4 + x_3) \tag{1.2}$$

as well as under translation by integral vectors of the form $(0, x_2, x_3, x_4)$. The Thurston manifold is the quotient of $\mathbb{R}^4$ by the group generated by these transformations.

Thurston considered the symplectic fibration obtained by forgetting the (x_3, x_4) coordinates, which gives a description of this space as a twisted (flat) torus bundle over the torus. In joint work with Auroux, Katzarkov, and Orlov [2] we noticed the existence of two (inequivalent) Lagrangian fibrations on this space:

(1) The fibration obtained by forgetting the x_2 and x_4 coordinates is a principal bundle on

which the (x_2, x_4)-torus acts. Since the total space is not trivial, this fibration admits no continuous section, and hence, in particular, no Lagrangian section.

(2) The fibration obtained by forgetting the x_1 and x_4 coordinates admits a Lagrangian section $(0, x_2, x_3, 0)$.

The above two examples show that one can have Lagrangian fibrations with completely different behaviour on the same symplectic manifold. The first fibration is mirror to a gerbe on an abelian variety, while the second is mirror to a Kodaira surface. To see this, write the first fibration as the quotient of $[0,1]^2 \times (\mathbb{R}/\mathbb{Z})^2$ by the equivalence relation

$$(0, x_3, x_2, x_4) \sim (1, x_3, x_2, x_4 + x_3) \tag{1.3}$$

$$(x_1, 0, x_2, x_4) \sim (x_1, 1, x_2, x_4). \tag{1.4}$$

Note that the gluing maps act trivially on the homology of the fibre, so the action on the space of local systems is trivial. Since the fibres bound no holomorphic disc, the mirror is the moduli space of such local systems; it agrees with the mirror of the symplectic manifold obtained via the trivial identifications. This symplectic manifold is simply the product of two tori of area 2π, hence the mirror is a product of two (families of) elliptic curves as is well-understood by now [1].

At this stage, it is clear that additional data are needed to implement mirror symmetry from this point of view. At the most basic level, the Lagrangian fibres are null-homologous, which implies that Floer cohomology has vanishing Euler characteristic whenever one of the two inputs is a fibre. Under mirror symmetry the fibres map to skyscraper sheaves of point, and there are therefore many coherent sheaves (e.g. vector bundles of non-vanishing rank) whose mirrors would be expected to have Floer cohomology groups with a fibre whose Euler characteristic does not vanish.

The additional data arise naturally on both sides: by obstruction theory, the failure of this torus fibration to be trivial is detected by a second cohomology group of the base as one can easily construct a Lagrangian section in the complement of a point. This obstruction class is constructed in Section 2.1 using a Čech cover, and a simple exponentiation procedure in Section 2.4 then yields an $\mathcal{O}^*$-valued second cohomology class on the mirror space; i.e. a gerbe. The correct statement of mirror symmetry involves sheaves twisted by this gerbe.

For completeness, we elaborate on the description of the mirror of the second fibration: a convenient starting point is the vector bundle $(\mathbb{R}/\mathbb{Z})^2 \times \mathbb{R}^2$ over the torus in the (x_2, x_3) coordinates whose fibre is the plane spanned by (x_1, x_4). The key observation is that the Thurston manifold is obtained by taking the quotient of the fibre over (x_2, x_3) by the lattice spanned by $(1, x_3)$ and $(0, 1)$. The corresponding family of lattices in $\mathbb{R}^2$ has non-trivial monodromy (given by an elementary transvection) around a loop in the x_3 direction. Constructing the mirror (complex) manifold by dualising the fibres, we conclude that the underlying smooth manifold is also a torus fibration over the torus with total Betti number 3, hence a primary Kodaira surface [21, p. 787-788]. With a bit more care, one can avoid appealing to the classification of surfaces and identify the (complex) mirror as the degenerating family of quotients of $\mathbb{C}^* \times \mathbb{C}^*$ by the groups of automorphisms

$$(z_1, z_2) \mapsto (z_1, T \cdot z_2) \tag{1.5}$$

$$(z_1, z_2) \mapsto (T \cdot z_1, z_1 z_2) \tag{1.6}$$

parametrised by a variable T. To obtain a precise statement of Homological mirror symmetry

in this setting, one then interprets the above as giving a rigid analytic primary Kodaira surface [33, p. 788].

One interesting outcome of this observation is that the two homological mirror symmetry statements imply the existence of a derived equivalence between twisted coherent sheaves on the mirror abelian variety and coherent sheaves on the mirror primary Kodaira surface. Such a result can be proved independently of mirror symmetry by exhibiting a Fourier-Mukai kernel [2].

1.3. Statement of the results. Let (X, ω) be a compact symplectic manifold, equipped with a fibration $\pi\colon X \to Q$ over a smooth manifold Q with Lagrangian fibres; the triple (X, ω, π) is called a *Lagrangian fibration*; write F_q for the fibre at a point q, and assume that $\pi_2(Q) = 0$.

Remark 1.1. The vanishing of the second homotopy group of Q implies that $\pi_2(X, F_q)$ vanishes, and hence that F_q bounds no holomorphic disc, which implies that there are no instanton corrections, i.e. that the mirror should be the space of rank-1 unitary local systems on the fibres. There seem to be no known examples where this condition fails (though this can be arranged if X is not assumed to be compact, or if singular fibres are allowed).

The symplectic topology of such fibrations is reviewed in Section 2.1, but for now, recall that the tangent space of Q at a point q is naturally isomorphic to $H^1(F_q, \mathbb{R}) \equiv H^1(F_q; \mathbb{Z}) \otimes \mathbb{R}$. Arnol'd's Liouville theorem implies that the corresponding lattice in TQ arises from an integral affine structure on Q. In particular, Q can be obtained by gluing polytopes in $\mathbb{R}^n$ by transformations whose differentials lie in $SL(n, \mathbb{Z})$.

To this integral affine structure, one associates a rigid analytic space (in the sense of Tate), which we denote Y (this is the same construction used in [23, 15, 32]): fix a field $\mathbf{k}$, and consider the Novikov field

$$\Lambda = \Big\{ \sum_{i=1}^{\infty} a_i t^{\lambda_i} | a_i \in \mathbf{k},\ \lambda_i \in \mathbb{R},\ \lambda_i \to +\infty \Big\}. \tag{1.7}$$

This is a non-archimedian field with valuation $\mathrm{val}\colon \Lambda - \{0\} \to \mathbb{R}$

$$\sum_{i=1}^{\infty} a_i t^{\lambda_i} \mapsto \min(\lambda_i | a_i \neq 0). \tag{1.8}$$

Denote by U_Λ the units of Λ, i.e. those elements with 0-valuation.

As a set, the space Y is the union $\coprod_{q \in Q} H^1(F_q; U_\Lambda)$. This description makes explicit the fact that Y parametrises Lagrangian fibres together with the datum of a *rank*-1 Λ-*local system* with monodromy in U_Λ. The analytic structure on Y arises from the natural identifications of the first cohomology groups of nearby fibres; the explicit construction appears in Section 2.2.

Given a Lagrangian $L \subset X$, satisfying the technical conditions required to make Floer cohomology well-defined, one obtains Floer cohomology groups $HF^k((F_q, b), L; \Lambda)$ for each $q \in Q$, and $b \in H^1(F_q; U_\Lambda)$.

These groups are locally the fibres of coherent sheaves on Y, as can be seen by adapting an argument of Fukaya [12] who studied the case of self-Floer cohomology. In order to encode the full data of the global Floer theory of X on the Y-side, an *analytic gerbe* α_X on Y is introduced in Section 2.4.

Theorem 1.2. *There is an α_X-twisted coherent sheaf on Y whose dual fibre at the point of Y corresponding to a pair (q, b) is $HF^k((F_q, b), L; \Lambda)$.*

Remark 1.3. One can interpret this theorem as an attempt to make rigourous the strategy introduced in Fukaya's announcement [10], which assigns to a Lagrangian a complex analytic sheaf *assuming convergence*. In the special case of Lagrangian surfaces constructed by Hyperkähler rotation, analytic continuation may provide an alternative approach for bypassing the problem arising from caustics, as noted in [11]. As part of an ongoing project to study mirror symmetry from the point of view of family Floer cohomology [31, 32], Junwu Tu has an independent argument to prove a similar result.

1.4. Difficulties lying ahead. While the above result points in the right direction, it is unfortunately not adequate for serious applications. The last section of this paper outlines the construction of an object $\mathcal{L}$ in a category of *α_X-twisted sheaves of perfect complexes* that is a differential graded enhancement of the derived category of α_X-twisted coherent sheaves on Y. The twisted sheaf in Theorem 1.2 is obtained from $\mathcal{L}$ by passing to cohomology.

The following conjecture makes clear why $\mathcal{L}$, rather than its cohomology sheaves, is the right object to study:

Conjecture 1.4. *If L_1 and L_2 are Lagrangians in X with corresponding twisted sheaves of perfect complexes $\mathcal{L}_1$ and $\mathcal{L}_2$, there is an isomorphism*

$$HF^*(L_1, L_2) \cong H^*(\mathrm{Hom}_*(\mathcal{L}_1, \mathcal{L}_2)). \tag{1.9}$$

There are two essential difficulties that arise in applying these techniques to the SYZ fibrations $X \to Q$ that are expected to exist, for example, on Calabi-Yau hypersurfaces in toric varieties:

(1) In general, some smooth fibres may bound non-constant holomorphic discs. Assuming such fibres are *unobstructed*, which essentially means that the counts of holomorphic discs with boundary on a single fibre algebraically vanish, Tu constructed the candidate (open subset) of the mirror in [31]. The basic idea, following Fukaya [11] and Kontsevich and Soibelman [23], is that we should obtain the mirror space by gluing affinoids as in the uncorrected case, but the gluing maps take into account moduli spaces of holomorphic discs. One can interpret part of the program of Gross and Siebert [19] as providing such a construction for fibrations arising from toric degenerations, though it is not yet known how to prove that their construction agrees with the one intrinsic to symplectic topology. Given the appropriate technical tools (i.e. a theory of virtual fundamental chains on moduli spaces of holomorphic discs, as in [14]), the extension of our results to this setting should be straightforward.

(2) The construction of the mirror space from an SYZ perspective also requires understanding the Floer theory of singular fibres. Whenever the fibre is *immersed*, this Floer theory is well-understood [4]. In the simplest situation, such a fibre is an immersed Lagrangian 2-sphere with a single double point in a 4-manifold, and the nearby Lagrangian (torus) fibres are obtained by Lagrangian surgery [24]. Using the relation between moduli spaces of holomorphic discs before and after surgery [14], Fukaya [13] has announced the construction of the mirror space in this setting. In particular, for a symplectic structure on a $K3$-surface admitting a Lagrangian torus fibration,

Fukaya's method provides a construction of the mirror space using family Floer cohomology. Unfortunately, in higher dimensions, SYZ fibrations are expected to have singular fibres which cannot be described as Lagrangian immersions, putting them beyond the reach of current techniques.

2. Background

2.1. Lagrangian torus fibrations. Let Q be the base of a Lagrangian fibration as in Section 1.3. The Arnol'd-Liouville theorem implies that we have canonical identifications

$$T_q Q = H^1(F_q; \mathbb{R}) \text{ and } T_q^* Q = H_1(F_q; \mathbb{R}). \tag{2.1}$$

Write $T_q^{\mathbb{Z}} Q$ for the image of $H^1(F_q; \mathbb{Z})$ in $T_q Q$ under the first isomorphism above, $T^{\mathbb{Z}} Q$ for the corresponding rank-n local system on Q, and $T_{\mathbb{Z}}^* Q$ for the dual. The key property satisfied by this sublattice of $T^* Q$ is that its (local) flat sections are closed, hence exact. On a subset P of Q, a choice of n functions whose differentials span $T_{\mathbb{Z}}^* P$ at every point defines an immersion into $\mathbb{R}^n$ mapping the fibres of $T^{\mathbb{Z}} P$ to the standard lattice $\mathbb{Z}^n$ in the tangent space of $\mathbb{R}^n$. By choosing P sufficiently small, we obtain a coordinate patch for the *integral affine structure* on Q induced by $T^{\mathbb{Z}} Q$.

The inverse image X_P of such a subset under π is fibrewise symplectomorphic to $T^* P / T_{\mathbb{Z}}^* P$. Given sets $P, P' \subset Q$ which intersect, the restrictions of the two symplectomorphisms induce a fibrewise symplectomorphism

$$T^*\left(P \cap P'\right) / T_{\mathbb{Z}}^*\left(P \cap P'\right) \to X_{P \cap P'} \to T^*\left(P \cap P'\right) / T_{\mathbb{Z}}^*\left(P \cap P'\right). \tag{2.2}$$

Such a symplectomorphism can be written as fibrewise addition by a closed 1-form which is uniquely defined up to an element of $T_{\mathbb{Z}}^*(P \cap P')$.

In order to classify symplectic fibrations which induce a given integral affine structure, choose a finite partially ordered set $\mathcal{A}$ labelling a simplicial triangulation of Q, i.e. there are vertices labelled by elements of $\mathcal{A}$, and every cell is the span of a unique ordered subset I of $\mathcal{A}$. Assume that this triangulation is sufficiently fine that there is a cover of Q by codimension 0 submanifolds with boundary $\{P_i\}_{i \in \mathcal{A}}$ so that P_i contains the open star of the vertex i and all iterated intersections are contractible. Let

$$P_I = \bigcap_{i \in I} P_i \tag{2.3}$$

and note that P_I contains the open star of the cell corresponding to I.

Choose a trivialisation τ_i of the inverse image X_{P_i}, i.e. a fibrewise symplectic identification with $T^* P_i / T_{\mathbb{Z}}^* P_i$. If $i < j$, the restrictions of τ_i and τ_j to $X_{P_{ij}}$ differ by fibrewise addition of a closed 1-form; choose a primitive for this 1-form

$$f_{ij} \colon P_{ij} \to \mathbb{R}. \tag{2.4}$$

If $i < j < k$, the cyclic sum

$$\alpha_X(ijk) = f_{ij} + f_{jk} - f_{ik} \tag{2.5}$$

is function on P_{ijk} whose differential lies in $T_{\mathbb{Z}}^* P_{ijk}$; i.e. an integral affine function. Such functions define a sheaf on Q that will be denoted Aff, and α_X yields a cocycle in $\check{C}^2(Q; \mathrm{Aff})$.

Write $[\alpha_X]$ for the corresponding cohomology class. Here, the Čech complex associated to a sheaf $\mathcal{F}$ on Q is given by

$$\check{C}^*_{\mathcal{A}}(Q;\mathcal{F}) = \bigoplus_{\substack{I=(i_0,\dots,i_r)\subset\mathcal{A}\\ i_0<\dots<i_r}} \mathcal{F}(P_I)[-r] \tag{2.6}$$

with differential given by restriction.

The importance of the sheaf Aff was noted by Gross and Siebert [18], who related it to classical invariants of affine structures. In that spirit, the following is a reformulation of a result of Duistermaat [9, Equation (2.6)]:

Proposition 2.1 (c.f. p. 476 of [5]). *X is determined up to fibrewise symplectomorphism by the triple $(Q, T^*_{\mathbb{Z}}Q, [\alpha_X])$.*

Proof. The fibrewise symplectic automorphisms of X_P are given by $\Omega^1_c(P)/T^*_{\mathbb{Z}}P$, where Ω^1_c is the sheaf of closed 1-forms. As noted by Duistermaat, this implies that Lagrangian fibrations which induce the integral affine structure $T^*_{\mathbb{Z}}Q$ are classified up to fibrewise symplectomorphism by $H^1(Q, \Omega^1_c/T^*_{\mathbb{Z}}Q)$.

To obtain the desired result, note that the identification of Ω^1_c with $C^\infty/\mathbb{R}$ induces an isomorphism of sheaves

$$C^\infty/\operatorname{Aff} \cong \Omega^1_c/T^*_{\mathbb{Z}}Q. \tag{2.7}$$

Since C^∞ is a soft sheaf, this implies the existence of a canonical isomorphism

$$H^1(Q, \Omega^1_c/T^*_{\mathbb{Z}}Q) \cong H^2(Q, \operatorname{Aff}). \tag{2.8}$$

□

Remark 2.2. The differentiable type of X is determined by a Chern class with values in $H^2(Q, T^*_{\mathbb{Z}}Q)$. The short exact sequence $\mathbb{R} \to \operatorname{Aff} \to T^*_{\mathbb{Z}}Q$ induces a long exact sequence

$$\cdots \to H^2(Q,\mathbb{R}) \to H^2(Q, \operatorname{Aff}) \to H^2(Q, T^*_{\mathbb{Z}}Q) \to \cdots \tag{2.9}$$

which has the following interpretation: once a smooth torus fibration over Q which is compatible with its affine structure is fixed, the set of symplectic structures on the total space for which this fibration is Lagrangian is either empty or an affine space over $H^2(Q,\mathbb{R})$, where the action is given by adding the pullback of a 2-form on Q.

2.2. Construction of the mirror space. The next step is to associate a rigid analytic space Y to the integral affine structure $T^{\mathbb{Z}}Q$ on Q. As a set, Y is simply the flat bundle over Q

$$Y = T^{\mathbb{Z}}Q \otimes_{\mathbb{Z}} U_\Lambda \tag{2.10}$$

where U_Λ is the multiplicative subgroup of the units in the Novikov ring as in Section 1.3. Write

$$\operatorname{val}\colon Y \to Q \tag{2.11}$$

for the projection. The fibre of val at a point $q \in Q$ is $H^1(F_q; U_\Lambda)$.

To construct an analytic structure on Y, start by considering the valuation

$$H^1(F_q;\Lambda^*) \to H^1(F_q;\mathbb{R}), \tag{2.12}$$

whose fibre is $H^1(F_q; U_\Lambda)$. Splitting the above map by taking a real number λ to T^λ, yields an isomorphism

$$H^1(F_q; U_\Lambda) \times H^1(F_q; \mathbb{R}) \cong H^1(F_q; \Lambda^*). \tag{2.13}$$

If P is a sufficiently small neighbourhood of $q \in Q$, it can be identified using parallel transport with respect to $T^{\mathbb{Z}}Q$ with a neighbourhood of the origin in T_qQ. This gives rise to a natural embedding

$$Y_P \equiv \mathrm{val}^{-1}(P) = \coprod_{p \in P} H^1(F_p; U_\Lambda) \subset H^1(F_q; \Lambda^*). \tag{2.14}$$

Assume now that $P \subset H^1(F_q; \mathbb{R})$ is a polytope defined by integral affine equations, i.e. that there exist integral homology classes $\{\alpha_i\}_{i=1}^d$, and real numbers $\{\lambda_i\}_{i=1}^d$ such that

$$P = \{v \in H^1(F_q; \mathbb{R}) | \langle v, \alpha_i \rangle \leq \lambda_i \text{ for } 1 \leq i \leq d\}. \tag{2.15}$$

If P is such a polytope, Y_P is a *special affine subset* in the sense of Tate [29, Definiton 7.1]; these are now usually studied as examples of the more general class of *affinoid domains* [7]. The affinoid ring $\mathcal{O}_P$ corresponding to Y_P in this case consists of formal series

$$\sum_{A \in H_1(F_q, \mathbb{Z})} f_A z_q^A, \quad f_A \in \Lambda \tag{2.16}$$

which T-adically converge at every point of Y_P, i.e. so that

$$\lim_{|A| \to +\infty} \mathrm{val}(f_A) + \langle v, A \rangle = +\infty \tag{2.17}$$

whenever v lies in P.

Remark 2.3. Despite the fact that Equation (2.16) refers to the basepoint q, the ring $\mathcal{O}_P$ does not depend on it. One way to see this is to construct a natural isomorphism of the rings associated to different choices of basepoints. Say that $p \in Q$ is obtained by exponentiating $v' \in H^1(F_q; \mathbb{R}) = T_qQ$. Using parallel transport to identify the tangent space of q with that of p, associate to P the polytope

$$P - v' \subset H^1(F_p; \mathbb{R}) = H^1(F_q; \mathbb{R}). \tag{2.18}$$

Note that the transformation

$$z_q^A \mapsto t^{\langle v', A \rangle} z_p^A \tag{2.19}$$

maps series in z_q coordinates which are convergent in P bijectively to series in z_p coordinates which are convergent in $P - v'$.

We now assume that the cover of Q chosen in Section 2.1 has the property that

$$\text{for each ordered subset } I \subset \mathcal{A}, P_I \text{ is an integral affine polytope.} \tag{2.20}$$

Covers satisfying this property exist for the following reason: every point in Q has a neighbourhood which is an integral affine polytope, and two such polytopes intersect along an integral affine polytope whenever they are sufficiently small. Using such a cover, we see that Y is obtained by gluing affinoid sets; it is therefore an affinoid variety.

2.3. Sheaves as functors. Consider the category $\mathcal{O}_{\mathcal{A}}$ whose objects are the ordered subsets of $\mathcal{A}$. The morphisms in $\mathcal{O}_{\mathcal{A}}$ are given by

$$\mathcal{O}(I,J) = \begin{cases} \mathcal{O}_J & \text{if } I \subset J \\ 0 & \text{otherwise.} \end{cases} \tag{2.21}$$

where $\mathcal{O}_I$ is the ring of functions on Y_I (and Y_I denotes Y_{P_I}). Composition is defined as

$$\mathcal{O}(J,K) \otimes \mathcal{O}(I,J) \cong \mathcal{O}_K \otimes \mathcal{O}_J \to \mathcal{O}_K \otimes \mathcal{O}_K \to \mathcal{O}_K \cong \mathcal{O}(I,K), \tag{2.22}$$

where the middle two arrows are respectively given by restriction (from Y_J to Y_K), and by multiplication (in $\mathcal{O}_K$).

Definition 2.4. A pre-sheaf of $\mathcal{O}$-modules on Y is a functor from $\mathcal{O}_{\mathcal{A}}$ to the category of Λ-vector spaces.

To see that this definition is reasonable, recall that a functor $\mathcal{F}$ assigns to each set I a Λ-vector space we denote $\mathcal{F}(I)$. Since the endomorphisms of the object I in $\mathcal{O}_{\mathcal{A}}$ is the ring of functions on Y_I, $\mathcal{F}(I)$ is equipped with an $\mathcal{O}_I$ module structure. Since $\mathcal{O}(I,J) = \mathcal{O}_J$ whenever $I \subset J$, we obtain a map

$$\mathcal{O}_J \otimes_\Lambda \mathcal{F}(I) \to \mathcal{F}(J). \tag{2.23}$$

The associativity equation implies that this is a map of $\mathcal{O}_J$ modules, and that it descends to a map

$$\mathcal{O}_J \otimes_{\mathcal{O}_I} \mathcal{F}(I) \to \mathcal{F}(J), \tag{2.24}$$

which exactly implies that we have pre-sheaf of $\mathcal{O}$-modules in the usual sense.

Definition 2.5. A *sheaf of* $\mathcal{O}$*-modules* on Y is a presheaf such that the structure maps in Equation (2.24) are isomorphisms.

The key point here is that the category of modules over the ring $\mathcal{O}_I$ is equivalent to the category of sheaves of $\mathcal{O}$-modules on the affinoid space Y_I (see, e.g. [7, Section 9.4.3]). The datum of a sheaf on Y_I can therefore be replaced by that of a single module $\mathcal{F}(I)$. As in the usual description, a sheaf is therefore a presheaf satisfying an additional property.

Remark 2.6. Since the ring of regular functions on an affinoid domain is Noetherian [7, p. 222], the notions of coherence and finite generation agree. So we may define a sheaf of coherent modules on Y to be a sheaf of $\mathcal{O}$-modules such that each module $\mathcal{F}(I)$ is finitely generated; i.e. admits a surjection from a finite rank free module. A standard argument implies that the cohomology modules of finite rank free cochain complexes over $\mathcal{O}_I$ are coherent modules; it is in this way that coherent sheaves on Y will arise from the mirror.

2.4. Rigid analytic gerbes and twisted sheaves. There is a natural map

$$\exp\colon \ \mathrm{Aff}(P) \to \mathcal{O}^*(Y_P) \tag{2.25}$$

$$F \mapsto t^{F(q)} z_q^{dF}, \tag{2.26}$$

which induces a map

$$H^2(Q, \mathrm{Aff}) \to H^2(Y, \mathcal{O}^*). \tag{2.27}$$

This map assigns to each Lagrangian fibration over Q an (analytic) gerbe on Y.

Remark 2.7. The above map is not surjective, but it is reasonably to expect surjectivity by considering deformations of Floer theory in X by the pullback of classes in $H^2(Q, U_\Lambda)$. For the subgroups $H^2(Q, \mathbb{Z}_2)$ and $H^2(Q, 1+\Lambda_+)$, such deformations were considered separately in [14] as *background class* and *bulk deformation*.

To define a twisted module over this gerbe, one needs a model for sheaf cohomology on Y: choose a cocycle α_X in $\check{C}^2_{\mathcal{A}}(Q, \mathrm{Aff})$ as in Equation (2.5); this consists of an assignment $\alpha_X(ijk) \in \mathrm{Aff}(P_{ijk})$ for every triple $i < j < k$, satisfying the cocycle condition. Given a triple $I \subset J \subset K$ of ordered subsets of $\mathcal{A}$ with final elements (i, j, k), define

$$\mathrm{Aff}(P_K) \ni \alpha_X(IJK) = \begin{cases} \alpha_X(ijk)|P_K & \text{if } i < j < k \\ 1 & \text{otherwise.} \end{cases} \tag{2.28}$$

Associated to this cocycle, we define a new category $\mathcal{O}^{\alpha_X}_{\mathcal{A}}$ with the same objects and morphisms as $\mathcal{O}_{\mathcal{A}}$. The composition is given by

$$\mathcal{O}(J, K) \otimes \mathcal{O}(I, J) \to \mathcal{O}(I, K) \tag{2.29}$$

$$f_K \otimes f_J \mapsto \exp(\alpha_X(ijk)) \cdot f_J|_{Y_K} \cdot f_K. \tag{2.30}$$

The cocycle property of α_X implies that composition is associative. As in the untwisted case, a functor $\mathcal{F}$ from $\mathcal{O}^{\alpha_X}_{\mathcal{A}}$ to Vect_Λ induces a map of $\mathcal{O}_J$ modules

$$\mathcal{O}_J \otimes_{\mathcal{O}_I} \mathcal{F}(I) \to \mathcal{F}(J). \tag{2.31}$$

Definition 2.8. An α_X-twisted $\mathcal{O}$-module is a functor from $\mathcal{O}^{\alpha_X}_{\mathcal{A}}$ to Λ-vector spaces such that the map in Equation (2.31) is an isomorphism for every pair $I \subset J$. □

The above definition unwinds into something more familiar: an α_X-twisted $\mathcal{O}$-module over Y is a collection $\mathcal{F}(I)$ of $\mathcal{O}_I$ modules, together with isomorphisms of $\mathcal{O}_J$ modules

$$\mathcal{F}_{IJ} \colon \mathcal{O}_J \otimes_{\mathcal{O}_I} \mathcal{F}(I) \to \mathcal{F}(J), \tag{2.32}$$

defined whenever $I \subset J$, such that

$$\mathcal{F}_{JK} \circ \mathcal{F}_{IJ}|_{Y_K} = \exp(\alpha_X(IJK)) \cdot \mathcal{F}_{IK} \tag{2.33}$$

for an ordered triple $I \subset J \subset K$. Here, $\mathcal{F}_{IJ}|_{Y_K}$ denotes the map induced by $\mathcal{F}_{IJ}$:

$$\mathcal{O}_K \otimes_{\mathcal{O}_I} \mathcal{F}(I) \xrightarrow{=} \mathcal{O}_K \otimes_{\mathcal{O}_J} \mathcal{O}_J \otimes_{\mathcal{O}_I} \mathcal{F}(I) \xrightarrow{\mathcal{F}_{IJ}} \mathcal{O}_K \otimes_{\mathcal{O}_I} \mathcal{F}(J). \tag{2.34}$$

3. Local constructions

3.1. Basics of Floer theory. Assume we are given a Lagrangian L so that

$$\begin{aligned} &L \text{ is } \textit{tautologically unobstructed,} \text{ i.e. there exists a tame almost complex structure } J_L \text{ on } X \text{ so that } L \\ &\text{bounds no } J_L\text{-holomorphic disc.} \end{aligned} \tag{3.1}$$

This is a technical condition, which will allow us to avoid discussing virtual fundamental chains, and should be replaced by the condition that L is unobstructed in the sense of [14].

Given a Hamiltonian diffeomorphism ϕ mapping L to a Lagrangian transverse to F_q, there is an ungraded Floer complex

$$CF^*(F_q, \phi(L)), \tag{3.2}$$

generated over $\Lambda_{\mathbb{F}_2}$ by the intersection points of $\phi(L)$ and F_q. To define the differential, choose a generic family of almost complex structures $\{J_t \in \mathcal{J}\}_{t\in[0,1]}$ so that $J_0 = \phi^*(J_L)$. For each pair (x, y) of intersection points between $\phi(L)$ and F_q, the space of J_t-holomorphic maps from the strip $B = \mathbb{R} \times [0, 1]$ to X satisfying the following boundary and asymptotic conditions

$$u(s, 1) \in \phi(L) \qquad u(s, 0) \in F_q \tag{3.3}$$

$$\lim_{s\to-\infty} u(s, t) = x \qquad \lim_{s\to+\infty} u(s, t) = y \tag{3.4}$$

admits a natural $\mathbb{R}$-action by translation in the s-coordinate. The quotient by this action of the space of such maps is the moduli space of strips $\mathcal{M}^q(x, y)$, and the matrix coefficient of x in dy is the count of rigid elements of this moduli space. The key point here is that this moduli space is regular for generic almost complex structures, so the count of such isolated elements gives a differential by standard methods.

In order for the mirror of L to be an object of the bounded derived category and to be defined away from fields of characteristic 2, this construction must be refined to a chain complex of free abelian groups which is $\mathbb{Z}$ graded. Combining the discussions of orientations in [14] and [25], assume that

$$w_2(L) = \pi^*(w_2(Q)). \tag{3.5}$$

Under this assumption, one could make an arbitrary choice of Pin^+ structure on the bundles $TF_q \oplus \pi^*(T^*Q \otimes |Q|^{\oplus 3})$ and $TL \oplus \pi^*(T^*Q \otimes |Q|^{\oplus 3})$ to define the Floer cohomology of L and F_q. It will be important to make a *global* choice, i.e. one obtained by restriction from X. To this end, identify the restriction of $\pi^*(T^*Q)$ to F_q with its tangent space via the Arnol'd-Liouville theorem. In particular, a Pin^+ structure on

$$T^*Q \oplus T^*Q \oplus |Q|^{\oplus 3} \tag{3.6}$$

will induce one by the pullback to all fibres. The above bundle has vanishing second Stiefel-Whitney class, which is the obstruction to such a structure.

Upon fixing Pin^+ structures on $TL \oplus \pi^*(T^*Q \otimes |Q|^{\oplus 3})$ and in Equation (3.6), index theory assigns a rank 1 free abelian group δ_x to each intersection point $x \in \phi(L) \cap F_q$, with the property that every rigid element of $\mathcal{M}^q(x, y)$ induces a canonical map

$$d_u \colon \delta_y \to \delta_x, \tag{3.7}$$

which should be thought of as the signed contribution of u to the differential.

It remains to lift the grading of the Floer complex to a $\mathbb{Z}$-grading. Equipped with any almost complex structure for which the fibres are totally real, there is a natural isomorphism of vector bundles $TX \cong \pi^*(TQ) \otimes_{\mathbb{R}} \mathbb{C}$. This implies that a density on Q induces an almost complex quadratic volume form on X. Evaluating such a form on a basis for the tangent space of a Lagrangian defines the phase function

$$\eta_\Omega \colon L \to S^1. \tag{3.8}$$

By assuming that the phase function on L is null homotopic and fixing a lift to $\mathbb{R}$, index theory assigns a degree $\deg(x) \in \mathbb{Z}$ to every intersection point $x \in \phi(L) \pitchfork F_q$ with the property that the moduli space $\mathcal{M}^q(x,y)$ has pure dimension

$$\dim(\mathcal{M}^q(x,y)) = \deg(x) - \deg(y) - 1. \tag{3.9}$$

The differential defined in Equation (3.7) then raises degree by 1 on the Floer complex

$$CF^d(F_q, \phi(L)) = \bigoplus_{\deg(x)=d} \delta_x \otimes \Lambda. \tag{3.10}$$

3.2. Convergence of the Floer differential and restriction. Let P be a polytope in Q containing q and $\mathcal{O}_P$ denote the affinoid ring of Y_P. This section adapts an argument of Fukaya showing that, whenever P is sufficiently small, the Floer complex in Equation (3.10) is the fibre of a complex of vector bundles on Y_P

$$\bigoplus_{x \in F_q \cap L} \mathcal{O}_P \otimes_{\mathbb{Z}} \delta_x. \tag{3.11}$$

More precisely, choosing P small enough, there is a differential on Equation (3.11) which specialises to the Floer complex

$$CF^*((F_p, b), \phi(L)) \tag{3.12}$$

for every point $(p,b) \in Y_P$.

In order to define the differential using this moduli space, it is useful to think of the intersection point $x \in F_q \cap \phi(L)$ as a sheet of $\phi(L)$ over P. Fixing a trivialisation

$$\tau_P \colon X_P \cong T^*P/T^*_{\mathbb{Z}}P, \tag{3.13}$$

this can be written as the differential of a function $g_x \colon P \to \mathbb{R}$ which is well-defined up to an integral affine function.

Definition 3.1. A collection of *Floer data* D_P consists of the choices $(\tau_P, \phi, J, \{g_x\})$. They *are tame in* P if there is a (smooth) map $\psi \colon P \to \mathrm{Diff}(X)$ which maps q to the identity, such that ψ_p maps F_q to F_p and preserves $\phi(L)$ and the tameness of the almost complex structures $\{J_t\}_{t\in[0,1]}$.

Choosing the functions $\{g_x\}$ yields for each strip u with sides mapping to L and F_q a class

$$[\partial u] \in H_1(F_q, \mathbb{Z}). \tag{3.14}$$

In order to define this class explicitly, note that the choice of trivialisation of X_P determines a 0-section of X_P, and hence a basepoint on F_q. The linear path tdg_x has endpoints the basepoint at $t=0$ and x at $t=1$. Define $[\partial u]$ to be the homology class of the loop obtained by concatenating the paths associated to dg_x, dg_y, and the restriction of u to the boundary.

Letting $z^{[\partial u]}$ be the exponential of the unique linear function on Q which vanishes at q and whose differential is given by $[\partial u]$ under the identification of Equation (2.1), define

$$d|\delta_y = \bigoplus_x \sum_{u \in \mathcal{M}^q(x,y)} T^{\mathcal{E}(u)} z^{[\partial u]} \otimes d_u, \tag{3.15}$$

where $\mathcal{M}^q(x,y)$ is the moduli space of strips defining the Floer differential, d_u is the map induced on determinant lines by u, and $\mathcal{E}(u)$ is the energy of u:

$$\mathcal{E}(u) = \int u^*\omega. \tag{3.16}$$

We shall presently use an idea of Fukaya to show that the infinite sum in the expression of the differential lies in $\mathcal{O}_P$.

Recall from Equation (2.14) that every element $z' \in Y_P$ can be written as a pair (p, b'), with $p \in P$ and $b' \in H^1(F_p; U_\Lambda)$. There is a natural isomorphism of Λ-modules

$$\bigoplus_x \mathcal{O}_P \underset{z=z'}{\otimes} \Lambda \otimes_{\mathbb{Z}} \delta_x = \bigoplus_x \Lambda \otimes_{\mathbb{Z}} \delta_x = CF^*((F_p, b'), \phi(L)). \tag{3.17}$$

If $q = p$, this map commutes with the differential defined using J, which in particular proves that the series in Equation (3.15) are convergent at such points. By defining the right hand side of Equation (3.17) using the almost complex structure $(\psi_p^{-1})^* J$ (c.f. [12]) so that composition with ψ_p gives a bijection between holomorphic strips with boundary on F_q and $\phi(L)$, and those with boundary on F_p and $\phi(L)$, convergence is achieved when $q \neq p$. This is where Definition 3.1 is used. To state the result, define $p - q$ as the point in T_qQ which exponentiates to p.

Lemma 3.2. *If u lies in $\mathcal{M}^q(x,y)$, the energy of $\psi_p \circ u$ is*

$$\mathcal{E}(\psi_p \circ u) = \mathcal{E}(u) + \langle p - q, [\partial u] \rangle + g_x(q) - g_y(q) + g_y(p) - g_x(p). \tag{3.18}$$

Proof. Consider the linear path in Q from q to p. The term $\langle p - q, [\partial u] \rangle$ is the area of a cylinder in X, lying over this path, and which intersects each fibre in a circle of homotopy class $[\partial u]$. The terms $g_x(p) - g_x(q)$ and $g_y(p) - g_y(q)$ are respectively the areas of strips over this path whose intersections with each fibre are the paths from the basepoint to the intersection of each fibre with the local sheets of $\phi(L)$ labelled x and y. The right hand side is therefore the sum of the area of u with that of a strip in X, which intersects each fibre along the segment from q to p in a path from the intersection with x to the intersection with y, lying in the homotopy class of $u|\mathbb{R} \times \{0\}$.

The result of gluing these two strips is homotopic to $\psi_p \circ u$, and Equation (3.18) follows from the invariance of the topological energy under homotopies with fixed Lagrangian boundary conditions. □

By the previous result, the contributions of a curve u to the differentials on the two sides of Equation (3.17) differ by multiplication by

$$T^{g_x(q) - g_y(q) + g_y(p) - g_x(p)}. \tag{3.19}$$

This readily implies that the pre-composition of the isomorphism in Equation (3.17) with multiplication by

$$T^{g_x(q) - g_x(p)} \tag{3.20}$$

on the $\Lambda \otimes_{\mathbb{Z}} \delta_x$ factor is a cochain isomorphism (the disappearance of $\langle p-q, [\partial u] \rangle$ is explained by Remark 2.3). Gromov compactness applied for all fibres F_p over the polygon P implies:

Proposition 3.3 (c.f. [12]). *For every pair of intersections (x, y) the series*

$$\sum_{u \in \mathcal{M}^q(x,y)} T^{\mathcal{E}(u)} z^{[\partial u]} \tag{3.21}$$

is convergent in Y_P. □

As a consequence, Equation (3.15) defines a differential on the complex

$$\mathcal{L}(Y_P; D_P) \equiv \bigoplus_{x \in F_q \cap \phi(L)} \mathcal{O}_P \otimes_{\mathbb{Z}} \delta_x. \tag{3.22}$$

It will be convenient to drop the Floer data from the notation whenever they are unambiguously given.

Given an inclusion of polytopes $P' \to P$, with basepoints q on P and q' on P', there are restricted data

$$D_P|_{P'} \equiv (\tau_P|_{X_{P'}}, \phi, (\psi_{q'}^{-1})^* J, \{g_x\}). \tag{3.23}$$

Multiplication of each summand by Equation (3.20) defines a cochain map

$$\mathcal{L}(Y_P; D_P) \to \mathcal{L}(Y_{P'}; D_P|_{P'}). \tag{3.24}$$

3.3. Change of trivialisation. Any pair of fibrewise identifications

$$\tau_i \colon X_P \cong T^*P / T^*_{\mathbb{Z}} P,\ i \in \{1, 2\}. \tag{3.25}$$

differ by the differential of a function $f \colon P \to \mathbb{R}$. With respect to two such trivialisations, choose functions g_x^1 and g_x^2 defining every local section of $\phi(L)$, and consider the two sets of data

$$D^i = (\tau_i, \phi, J, \{g_x^i\}),\ i \in \{1, 2\}. \tag{3.26}$$

Define the *change of trivialisation* cochain map

$$\mathcal{L}(Y_P; D^1) \to \mathcal{L}(Y_P; D^2) \tag{3.27}$$

as a diagonal map given on the factor δ_x by multiplication with $T^{f(q)} z_q^{df - dg_x^1 + dg_x^2}$.

Since this map does not entail counting any holomorphic curves, it is easy to check that given an inclusion $P' \subset P$, we have a commutative diagram

$$\begin{array}{ccc} \mathcal{L}(Y_P; D^1) & \longrightarrow & \mathcal{L}(Y_P; D^2) \\ \downarrow & & \downarrow \\ \mathcal{L}(Y_{P'}; D^1|_{P'}) & \longrightarrow & \mathcal{L}(Y_{P'}; D^2|_{P'}). \end{array} \tag{3.28}$$

3.4. Continuation maps. Let D^+ and D^- denote Floer data $(\tau, \phi^{\pm}, J^{\pm}, \{g_{x_\pm}\})$, which share a common trivialisation. This section recalls the construction of the continuation map

$$CF^*(F_q, \phi^+(L)) \to CF^*(F_q, \phi^-(L)) \tag{3.29}$$

as a count of pseudo-holomorphic sections of the projection $X \times B \to B$.

Pick a path of Hamiltonian diffeomorphisms ϕ^s such that

$$\phi^s = \begin{cases} \phi^+ \text{ if } 0 \ll s \\ \phi^- \text{ if } s \ll 0. \end{cases} \tag{3.30}$$

Recall that there is a unique function H on $X \times \mathbb{R}$ which generates this flow such that

$$\int_X H_s \omega^n = 0, \tag{3.31}$$

and pick a compactly supported function

$$G\colon\ X \times B \to \mathbb{R}, \tag{3.32}$$

which agrees with H on $X \times \mathbb{R} \times \{1\}$.

If α is a symplectic form on B of finite area, the 2-form

$$\omega_X - dG \wedge ds + C\alpha \tag{3.33}$$

defines a symplectic structure on $X \times B$ whenever C is a sufficiently large constant. We denote by $\tilde{\mathcal{J}}$ the space of almost complex structures $\tilde{J}$ on $B \times X$ which are of the form

$$\tilde{J} = \begin{pmatrix} J & K \\ 0 & j \end{pmatrix} \tag{3.34}$$

with $J \in \mathcal{J}$, and K vanishes outside a compact set in B. Any such almost complex structure will be tamed by the symplectic structure in Equation (3.33) whenever C is sufficiently large.

We choose an almost complex structure $\tilde{J} \in \tilde{\mathcal{J}}$ whose restrictions to $0 \ll s$ and $s \ll 0$ agree with

$$\tilde{J}^{\pm} = \begin{pmatrix} J^{\pm} & 0 \\ 0 & j \end{pmatrix}. \tag{3.35}$$

Definition 3.4. An *elementary continuation datum* D^{+-} from D^+ to D^- is a choice of the pair of data $(\{\phi^s\}, \tilde{J})$ above.

For each pair (x_-, x_+) of intersections points, we then define $\mathcal{M}^q_\kappa(x_-, x_+)$ with respect to the data D^{+-} to be the moduli space of maps $v\colon\ B \to X$ with $\tilde{J}$-holomorphic graph $\tilde{v}\colon\ B \to B \times X$ such that

$$v(s,0) \in F_q \tag{3.36}$$

$$v(s,1) \in \phi^s L \tag{3.37}$$

$$\lim_{s \to \pm\infty} v(s,t) = x_\pm. \tag{3.38}$$

For a generic almost complex structure $\tilde{J}$, these moduli spaces are regular. Computing the linearisation of the index of a solution shows that

$$\dim(\mathcal{M}^q_\kappa(x_-, x_+)) = \deg(x_-) - \deg(x_+). \tag{3.39}$$

The (topological) energy of a solution to the continuation equation is

$$\mathcal{E}(v) = \int_B v^*(\omega) - \int_{\mathbb{R}} H_s(v(s,1))ds = \int_B \tilde{v}^* \left(\omega - dG \wedge ds\right) \tag{3.40}$$

Lemma 3.5. *If* $\deg(x_-) = \deg(x_+)$*, then for any real number* E*, there are only finitely many elements* v *of* $\mathcal{M}_\kappa^q(x_-, x_+)$ *such that*

$$\mathcal{E}(v) \leq E. \tag{3.41}$$

Proof. By adding to $\mathcal{E}$ the total area of the form $C\alpha$ in Equation (3.33), we obtain the area of $\tilde{v}$ with respect to a symplectic structure on $X \times B$ for which $\tilde{J}$ is tame. A standard application of Gromov compactness therefore implies that the energy is proper on the Gromov-Floer compactification.

Having excluded bubbling via Assumption (3.1), the only broken curves in the limit arise when some energy escapes along the ends, which gives rise to components of hypothetical broken curves that are graphs of Floer trajectories. Since the moduli space of Floer trajectories is assumed to be regular, this is impossible whenever the moduli space we are considering has vanishing virtual dimension. □

As in the setting of Floer trajectories, an element $v \in \mathcal{M}_\kappa^q(x_-, x_+)$ induces a canonical map

$$\kappa_v \colon \delta_{x_+} \to \delta_{x_-} \tag{3.42}$$

whenever $\deg(x_+) = \deg(x_-)$. Taking the sum over all elements of such rigid moduli spaces defines the continuation map

$$\kappa \colon CF^*(F_q, \phi^+(L)) \to CF^*(F_q, \phi^-(L)) \tag{3.43}$$

$$\kappa|\delta_{x_+} = \sum_{\substack{\deg(x_+)=\deg(x_-) \\ v \in \mathcal{M}_\kappa^q(x_-, x_+)}} T^{\mathcal{E}(v)} \kappa_v. \tag{3.44}$$

3.5. Convergence of continuation maps. Let P be a polytope based at q, with the property that $\mathcal{L}(Y_P; D^\pm)$ are well defined. Pick diffeomorphisms $\psi^\pm$ as in Definition 3.1, and extend them to a family

$$\Psi \colon P \times B \to \mathrm{Diff}(X) \tag{3.45}$$

$$\{q\} \times B \mapsto \mathrm{Id} \tag{3.46}$$

such that the following properties hold for all $p \in P$ (see Figure 3.1):

$$\Psi_{p,s,t} = \psi_p^+ \text{ if } 0 \ll s \tag{3.47}$$

$$\Psi_{p,s,t} = \psi_p^- \text{ if } s \ll 0 \tag{3.48}$$

$$\Psi_{p,s,0}(F_q) = F_p \tag{3.49}$$

$$\Psi_{p,s,1} = \mathrm{Id} \text{ if } H_s \not\equiv 0. \tag{3.50}$$

For each $p \in P$, denote by $\tilde{\Psi}_p$ the fibrewise diffeomorphism of $B \times X$

$$(s, t, x) \mapsto (s, t, \Psi_{p,s,t}(x)). \tag{3.51}$$

Define $\tilde{J}_p = \left(\tilde{\Psi}_p^{-1}\right)^* \tilde{J}$. This is an almost complex structure on $B \times X$ which has the upper triangular form required in Equation (3.35).

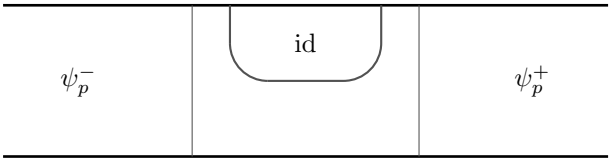

Figure 3.1.

Definition 3.6. The continuation data D^{+-} *are tame in* P if $\tilde{J}_p$ lies in $\tilde{\mathcal{J}}$ for all $p \in P$.

Of course, tameness depends on the choice of the fibrewise diffeomorphism Ψ of $B \times X$, but as this will be clear from the context, it is omitted. Condition (3.50) ensures that the off-diagonal term in $\tilde{J}_p$ vanishes outside a compact set. Openness of the taming condition implies:

Lemma 3.7. *If* P *is sufficiently small the data* D^{+-} *are tame in* P. □

Define $\mathcal{M}_\kappa^p(x_-, x_+)$ to be the space of maps from a strip to X, with boundary conditions F_p and $\phi^s(L)$, converging to $x_\pm$ at the respective ends, whose graphs are $\tilde{J}_p$-holomorphic.

Lemma 3.8. *Composition with* $\tilde{\Psi}_p$ *defines a bijection*

$$\mathcal{M}_\kappa^q(x_-, x_+) \cong \mathcal{M}_\kappa^p(x_-, x_+). \tag{3.52}$$

Proof. The key point is that the diffeomorphism $\tilde{\Psi}_p$ is compatible with the Lagrangian boundary conditions. In particular, given $v \in \mathcal{M}_\kappa^q(x_-, x_+)$, Equation (3.50) ensures that the boundary condition of $\tilde{\Psi}_p \circ \tilde{v}$ along $\mathbb{R} \times \{1\}$ is the path $\phi^s(L)$, and Equation (3.49) ensures that the boundary condition along $\mathbb{R} \times \{0\}$ is F_p. □

The advantage of introducing both moduli spaces is that we have independent energy estimates:

Lemma 3.9. *If* $\deg(x_-) = \deg(x_+)$, *the topological energy defines a proper map on* $\mathcal{M}_\kappa^p(x_-, x_+)$.

Proof. Condition (3.50) ensures that the off-diagonal term in $\tilde{J}_p$ vanishes outside a compact set, so escape of energy along the ends gives rise to Floer trajectories as in the proof of Lemma 3.5. The remainder of that proof applies mutatis mutandis. □

These results imply the existence of a cochain map

$$\kappa\colon\ \mathcal{L}(Y_P; D^+) \to \mathcal{L}(Y_P; D^-) \tag{3.53}$$

by counting solutions to continuation maps as follows: recall that the construction of the differential on the two $\mathcal{O}_P$ modules relied on choosing primitives defining the sheets of $\phi^+(L)$ and $\phi^-(L)$ over P. These primitives define a class $[\partial v] \in H_1(F_q, \mathbb{Z})$ associated to the boundary of $v \in \mathcal{M}_\kappa^q(x_-, x_+)$.

The continuation map is defined on each factor by the formula

$$\kappa|\delta_{x_+} = \bigoplus_{x_-} \sum_{v \in \mathcal{M}_\kappa(x_-, x_+)} T^{\mathcal{E}(v)} z^{[\partial v]} \otimes \kappa_v \tag{3.54}$$

The argument proving the convergence of the differential applies verbatim in this case.

Remark 3.10. It is important to note that κ is not defined over Λ_0 since the energy $\mathcal{E}(v)$ for a solution to the continuation equation is not necessarily positive. This raises obstacles to using the methods developed here to detect quantitative information about Lagrangians in X, e.g. displacement energy as in [16].

3.6. Families of continuation maps. Let Δ be a compact manifold with boundary parametrising a family $\{(\{\phi_\delta^s\}, \tilde{J}_\delta)\}_{\delta \in \Delta}$ of continuation data as in Definition 3.4.

For each pair (x_-, x_+) of intersections points, let $\mathcal{M}^q_{\kappa^\delta}(x_-, x_+)$ denote the moduli space of continuation maps corresponding to $\delta \in \Delta$, and consider the parametrised space

$$\mathcal{M}^q_{\kappa^\Delta}(x_-, x_+) \equiv \coprod_{\delta \in \Delta} \mathcal{M}^q_{\kappa^\delta}(x_-, x_+). \tag{3.55}$$

Assuming the data are chosen generically, this is a manifold with boundary of dimension

$$\deg(x_-) - \deg(x_+) + \dim(\Delta). \tag{3.56}$$

In particular, if this moduli space is rigid, we may consider the series:

$$\sum_{v \in \mathcal{M}^q_{\kappa^\Delta}(x_-, x_+)} T^{\mathcal{E}(v)} z^{[\partial v]}, \tag{3.57}$$

where the class $[\partial v] \in H_1(F_q, \mathbb{Z})$ is defined as in Equation (3.14).

Proposition 3.11. *There is a polytope $P_\Delta \subset Q$ so that Equation* (3.57) *defines an element of $\mathcal{O}_{P_\Delta}$.*

Proof. Condition (3.30) and the compactness of Δ imply that there is a constant S_Δ so that for all $\delta \in \Delta$, H^s_δ agrees with H^+ if $S_\Delta \leq s$, and with H^- if $s \leq -S_\Delta$. Consider a smooth family $\Psi_{\delta,p,s,t}$ of diffeomorphisms of X parametrised by $(\delta, p, s, t) \in \Delta \times P \times B$ satisfying, for fixed $\delta \in \Delta$, Conditions (3.46)-(3.50). The assumption that these diffeomorphisms are the identity for $p = q$ and the compactness of Δ imply that the corresponding fibrewise diffeomorphisms $\tilde{\Psi}_{\delta,p}$ of $B \times X$ preserve the tameness of the almost complex structure whenever p lies in a sufficiently small neighbourhood of q. This yields the analogue of Lemma 3.9, and hence convergence in this neighbourhood. □

3.7. Composition of continuation map. Let (ϕ^+, J^+), (ϕ^0, J^0) and (ϕ^-, J^-) denote three choices of Hamiltonian diffeomorphisms and almost complex structures, and pick (regular) continuation data D^{+0}, D^{0-} and D^{+-} which define cochain maps

$$\begin{array}{ccc} \mathcal{L}(Y_P; D^+) & \xrightarrow{\kappa_{+-}} & \mathcal{L}(Y_P; D^-) \\ & {\scriptstyle \kappa_{+0}} \searrow \quad \nearrow {\scriptstyle \kappa_{0-}} & \\ & \mathcal{L}(Y_P; D^0), & \end{array} \tag{3.58}$$

whenever P is sufficiently small.

Gluing the data D^{+0} and D^{0-}, defines a continuation map from $\mathcal{L}(Y_P; D^+)$ to $\mathcal{L}(Y_P; D^-)$ which agrees with the composition $\kappa_{0-} \circ \kappa_{+0}$. Choosing a homotopy between D^{+-} and the

glued data yields a family parametrised by an interval. Possibly upon shrinking P, Equation (3.57) and Proposition 3.11 produce a map

$$\kappa^1 \colon \mathcal{L}(Y_P; D^+) \to \mathcal{L}(Y_P; D^-)[1]. \tag{3.59}$$

For each pair of intersections (x_-, x_+) between $\phi^{\pm}(L)$ and F so that $\deg(x_+) = \deg(x_-)$, the moduli space $\mathcal{M}^q_{\kappa^1}(x_-, x_+)$ had dimension 1, and its boundary consists of the strata

$$\mathcal{M}^q_{\kappa}(x_-, x_+) \tag{3.60}$$

$$\coprod_{x_0 \in \phi^0(L) \cap F} \mathcal{M}^q_{\kappa}(x_-, x_0) \times \mathcal{M}^q_{\kappa}(x_0, x_+) \tag{3.61}$$

$$\coprod_{x'_+ \in \phi^+(L) \cap F} \mathcal{M}^q_{\kappa}(x_-, x'_+) \times \mathcal{M}^q(x'_+, x_+) \tag{3.62}$$

$$\coprod_{x'_- \in \phi^-(L) \cap F} \mathcal{M}^q(x_-, x'_-) \times \mathcal{M}^q_{\kappa}(x'_-, x_+). \tag{3.63}$$

Counting elements of the first two moduli spaces corresponds to the two compositions in Diagram (3.58). The second two moduli spaces respectively define the composition of κ^1 with the differentials in $\mathcal{L}(Y_P; D^+)$ and $\mathcal{L}(Y_P; D^-)$.

Proposition 3.12. *If P is sufficiently small, κ^1 defines a homotopy between the two compositions in Diagram* (3.58). □

Applying the above construction to the null-homotopy for the concatenation of a path and its inverse implies:

Corollary 3.13. *If P is sufficiently small, κ is a chain equivalence.* □

3.8. Compatibility of restriction, continuation, and change of trivilisations. Choose data $(\phi^{\pm}, J^{\pm})$ as in Section 3.4, and trivalisations $\{\tau_i\}_{i=1,2}$. These yield four sets of Floer data

$$D_i^{\pm} \equiv (\tau_i, \phi^{\pm}, J^{\pm}, \{g^i_{x_{\pm}}\}). \tag{3.64}$$

Using the same continuation equation to map the Floer complexes defined from the data D_i^+ to those defined from the data D_i^-, we have:

Lemma 3.14. *The following diagram, in which the vertical arrows are continuation maps and the horizontal ones are changes of coordinates, commutes*

$$\begin{array}{ccc} \mathcal{L}(Y_P; D_1^+) & \longrightarrow & \mathcal{L}(Y_P; D_2^+) \\ \downarrow & & \downarrow \\ \mathcal{L}(Y_P; D_1^-) & \longrightarrow & \mathcal{L}(Y_P; D_2^-). \end{array} \tag{3.65}$$

Proof. The class in $H_1(F_q, \mathbb{Z})$ associated to a continuation map v depends on the choices of local primitives. We write $[\partial v]^i$ for the choice associated to i. With this in mind, the commutativity of the diagram reduces to the equality

$$[\partial v]^1 + dg^1_{x_+} - dg^1_{x_-} - df = [\partial v]^2 + dg^2_{x_+} - dg^2_{x_-} - df \in H_1(F_q, \mathbb{Z}) \subset T^*_q P. \tag{3.66}$$

□

Similarly, given a subpolytope $P' \subset P$ with basepoint q', define $\kappa|P'$ to be the continuation map associated to the data

$$(\{\phi^s\}, \tilde{J}_{q'}). \tag{3.67}$$

As in Lemma 3.14, there is a commutative diagram

$$\begin{array}{ccc} \mathcal{L}(Y_P; D^+) & \xrightarrow{\kappa} & \mathcal{L}(Y_P; D^-) \\ \downarrow & & \downarrow \\ \mathcal{L}(Y_{P'}; D^+|_{P'}) & \xrightarrow{\kappa|P'} & \mathcal{L}(Y_{P'}; D^-|_{P'}). \end{array} \tag{3.68}$$

4. From Lagrangians to twisted sheaves

4.1. Homological patching. In this section, Floer cohomology groups are used to define an α_X-twisted sheaf $H^*\mathcal{L}$ associated to a Lagrangian L.

Start by choosing a simplicial triangulation as in Section 2.1, with associated cover P_i satisfying Condition (2.20). Denoting by $\mathcal{O}_I$ the ring of functions on the inverse image Y_I of P_I, this cover should be sufficiently fine that:

1. for each vertex $i \in \mathcal{A}$, there are Floer data D_i defining complexes of $\mathcal{O}_i$ modules $\mathcal{L}(i) \equiv \mathcal{L}(Y_i; D_i)$.
2. for each pair of vertices $i < j$, there are continuation data D_{ij} defining chain equivalences
$$\mathcal{L}_{ij} \colon \mathcal{L}(Y_{ij}; D_i|P_{ij}) \to \mathcal{L}(Y_{ij}; D_j|P_{ij}). \tag{4.1}$$
3. for each triple of vertices $i < j < k$, there are homotopies D_{ijk} of continuation data between D_{ik} and the gluing of D_{ij} and D_{jk} defining a chain homotopy $\mathcal{L}_{ijk}$ in the diagram
$$\begin{array}{ccc} \mathcal{L}(Y_{ijk}; D_i|P_{ijk}) & \longrightarrow & \mathcal{L}(Y_{ijk}; D_k|P_{ijk}) \\ & \searrow \quad \nearrow & \\ & \mathcal{L}(Y_{ijk}; D_j|P_{ijk}). & \end{array} \tag{4.2}$$

Lemma 4.1. *If the triangulation of Q is sufficiently fine, there are choices of data satisfying the above properties.*

Proof. Start with a finite cover $\mathcal{U}_1$ by polytopes equipped with tame Floer data. Then choose a second cover $\mathcal{U}_2$, subordinate to $\mathcal{U}_1$, so that, for each element of $\mathcal{U}_2$ contained in a pair of elements of $\mathcal{U}_1$, there are convergent continuation data between the two Floer data obtained by restriction, and fix a choice of such data for pairs. Finally, we pick a cover $\mathcal{U}_3$, subordinate to $\mathcal{U}_2$, so that there are convergent chain homotopies between all compositions of the continuation data chosen for $\mathcal{U}_2$.

Now, assume that the triangulation of Q labelled by $\mathcal{A}$ is subordinate to $\mathcal{U}_3$ (i.e. so that all open stars of all vertices are contained in an element of the cover), and choose the polytope P_i for each element $i \in \mathcal{A}$ to also be subordinate to this cover and contain the open star of i.

Pick the data D_i arbitrarily among the Floer data associated to elements of $\mathfrak{U}_3$ which contain P_i. The above choices determine continuation maps and homotopies satisfying the desired properties. □

Lemma 4.2. *The modules $H^*\mathcal{L}(i)$ and the structure maps $\mathcal{L}_{ij}$ define an α_X-twisted sheaf on Y.*

Proof. It suffices to show that the restriction maps commute up to multiplication by $\exp(\alpha_X(ijk))$. Lemma 3.14 reduces the proof to the case in which the Floer data (ϕ_j, J_j) and (ϕ_k, J_k) are obtained by restricting common data (ϕ_i, J_i). Let (f_{ij}, f_{jk}, f_{ik}) denote the transition functions between the three different trivialisations fixed on P_i, P_j and P_k. The composition $\mathcal{L}_{jk} \circ \mathcal{L}_{ij}$ is given on δ_x by multiplication with

$$T^{f_{jk}+f_{ij}} z^{df_{jk}+df_{ij}-dg_x^k+dg_x^i} = \exp(f_{jk}+f_{ij}) T^{dg_x^i-dg_x^k}, \tag{4.3}$$

while the restriction of $\mathcal{L}_{ik}$ to δ_x agrees with

$$T^{f_{ik}} z^{df_{ik}-dg_x^k+dg_x^i} = \exp(f_{ik}) T^{dg_x^i-dg_x^k}. \tag{4.4}$$

The result now follows immediately from Equation (2.5). □

4.2. Towards the mirror functor. To each ordered subset $I = (i_0, \ldots, i_r) \subset \mathcal{A}$ corresponding to an r-dimensional simplex in Q, Adams' construction [3] associates an $r-1$-dimensional cube σ_I of paths in Q from the initial to the final vertex. Paths parametrised by the boundary of this cube are given by (i) the family of paths associated to codimension 1 subsimplices, and (ii) the product of the cubes associated to a pair of complementary simplices in I. The homotopy constructed in Section 3.7 for a triple arose from a family of continuation maps associated to such a 1-dimensional cube in the case $r = 2$.

By gluing and induction on dimension, one obtains a family D_I of continuation maps from D_{i_0} to D_{i_r} parametrised by σ_I, whose restriction to the boundary strata of σ_I are given either by the continuation maps associated to a subsimplex, or the concatenation of continuation maps associated to complementary simplices. We are in the setting of Section 3.6 so, assuming the parametrised data are chosen generically and the triangulation is sufficiently fine, the count of rigid elements of such a moduli space defines a map

$$\mathcal{L}_I \colon \mathcal{L}(Y_{i_0}; D_{i_0}) \to \mathcal{L}(Y_I; D_{i_r}|P_I) \tag{4.5}$$

of degree $-r$. Adopting the convention that

$$\mathcal{L}(I) \equiv \mathcal{L}(Y_I; D_{i_r}|P_I), \tag{4.6}$$

the maps in Equation (4.5) naturally extend to an A_∞ module over $\mathcal{O}_{\mathcal{A}}^{\alpha_X}$, i.e an A_∞ functor

$$\mathcal{L} \colon \mathcal{O}_{\mathcal{A}}^{\alpha_X} \to \mathrm{Vect}_\Lambda\,. \tag{4.7}$$

This data is exactly that of an α_X-twisted A_∞-presheaf of $\mathcal{O}$-complexes on Y. Keeping in mind the fact that $\mathcal{L}(I)$ is a finite rank free $\mathcal{O}_I$ module, and that the map associated to an inclusion is a quasi-isomorphism (after restriction), $\mathcal{L}$ in fact defines an object of the A_∞-category of α_X-twisted sheaves of perfect complexes on Y, with respect to the cover $\mathcal{A}$. In this sense, the assignment $L \to \mathcal{L}$ gives, at the level of objects, the mirror functor between the derived Fukaya category of X and the derived category of α_X-twisted coherent sheaves on Y.

Remark 4.3. It is easy in this setting to implement one of the standard equivalences between A_∞ and dg-modules, and replace $\mathcal{L}$ by a quasi-equivalent dg-module over $\mathcal{O}^{\alpha x}_{\mathcal{A}}$, see e.g. [10, Theorem 6.15]. Since the Fukaya category is an A_∞ category, such a replacement does not seem to particularly simplify this approach to Homological mirror symmetry.

Acknowledgments. The author was supported by NSF grant DMS-1308179. It is my pleasure to thank my collaborators, on past and ongoing projects, for teaching me much of what I know about mirror symmetry and symplectic topology. Comments from Ivan Smith and Nick Sheridan were useful in clarifying the exposition and removing confusing conventions. In addition, I am grateful to Kenji Fukaya for explaining to me Tate's acyclicity theorem and its relevance to mirror symmetry, and to Paul Seidel for having instilled in me the lesson that constructions involving the Fukaya category should first be explained at the cohomological level.

Hyperbolic orbifolds of small volume

Mikhail Belolipetsky

Abstract. Volume is a natural measure of complexity of a Riemannian manifold. In this survey, we discuss the results and conjectures concerning n-dimensional hyperbolic manifolds and orbifolds of small volume.

Mathematics Subject Classification (2010). Primary 22E40; Secondary 11E57, 20G30, 51M25.

Keywords. Volume, Euler characteristic, hyperbolic manifold, hyperbolic orbifold, arithmetic group.

1. Volume in hyperbolic geometry

A hyperbolic manifold is an n-dimensional manifold equipped with a complete Riemannian metric of constant sectional curvature -1. Any such manifold $\mathcal{M}$ can be obtained as the quotient of the hyperbolic n-space $\mathbf{H}^n$ by a torsion-free discrete group Γ of isometries of $\mathbf{H}^n$:

$$\mathcal{M} = \mathbf{H}^n/\Gamma.$$

If we allow more generally the discrete group to have elements of finite order, then the resulting quotient space $\mathcal{O} = \mathbf{H}^n/\Gamma$ is called a *hyperbolic n-orbifold*.

We can descend the volume form from $\mathbf{H}^n$ to $\mathcal{O}$ and integrate it over the quotient space. This defines the hyperbolic volume of $\mathcal{O}$. The generalization of the Gauss-Bonnet theorem says that in even dimensions the volume is proportional to the Euler characteristic. More precisely, we have for n even:

$$\mathrm{Vol}(\mathcal{M}) = \frac{\mathrm{Vol}(\mathbf{S}^n)}{2} \cdot (-1)^{n/2}\chi(\mathcal{M}), \tag{1.1}$$

where $\mathrm{Vol}(\mathbf{S}^n)$ is the Euclidean volume of the n-dimensional unit sphere and $\chi(\mathcal{M})$ denotes the Euler characteristic. This formula generalizes to hyperbolic n-orbifolds with the orbifold Euler characteristic in place of χ. Conceptually it says that the hyperbolic volume is a topological invariant and, like for the Euler characteristic, its value is a measure of complexity of the space. In odd dimensions the Euler characteristic vanishes but the volume is still a non-trivial topological invariant that measures the complexity of $\mathcal{M}$. Indeed, the Mostow–Prasad rigidity theorem implies that every geometric invariant of a finite volume hyperbolic n-manifold (or orbifold) of dimension $n \geq 3$ is a topological invariant. One particular example of an application of the volume of the hyperbolic 3-manifolds as a measure of complexity appears in knot theory — see [15] and [16] where all knots up to a certain complexity are enumerated. Note that although many knots in the tables of Callahan–Dean–Weeks and

Proceedings of the International Congress of Mathematicians, Seoul, 2014

Champanerkar–Kofman–Patterson have the same number of simplexes in the minimal triangulations, only very few of them share the same volume. For large volume the picture is different (see [41] for the recent results in dimension 3 and [21] for higher dimensions and other symmetric spaces), but nevertheless, in practice, hyperbolic volume has proven to be very effective in distinguishing manifolds.

The main purpose of this report is to discuss what is currently known about the simplest (i.e. *minimal volume*) hyperbolic n-manifolds and orbifolds. More information about this topic with a particular emphasis on a connection with hyperbolic reflection groups can be found in a recent survey paper by Kellerhals [32].

The minimal volume problem for hyperbolic n-orbifolds goes back to the paper of Siegel [50] where the general setup is described and the solution to the problem for $n = 2$ is given. In fact, the solution of the 2-dimensional problem can be traced back to the earlier work of Hurwitz [29], which is briefly mentioned in Siegel's paper. The qualitative solution to Siegel's problem in general was obtained by Kazhdan and Margulis in [31] (the title of [31] refers to a conjecture of Selberg about the existence of unipotent elements in non-uniform lattices which was also resolved in the same 5-page paper). We are going to come back to the discussion of the Kazhdan–Margulis theorem in Section 5, but before that we shall consider the sharp lower bounds for the volumes of *arithmetic orbifolds*.

2. Arithmeticity and volume

The group of isometries of the hyperbolic n-space is isomorphic to the real Lie group $\mathrm{PO}(n,1)$. Its subgroup of orientation preserving isometries corresponds to the identity component $H = \mathrm{PO}(n,1)^\circ$, which can be further identified with the matrix group $\mathrm{SO}_0(n,1)$ – the subgroup of $\mathrm{SO}(n,1)$ that preserves the upper half space. We shall mainly consider *orientable finite volume hyperbolic n-orbifolds*

$$\mathcal{O} = \mathbf{H}^n/\Gamma, \quad \Gamma \text{ is a lattice in } H.$$

Let $\mathbf{G}$ be an algebraic group defined over a number field k which admits an epimorphism $\phi : \mathbf{G}(k \otimes_{\mathbb{Q}} \mathbb{R})^\circ \to H$ whose kernel is compact. Then, by the Borel–Harish-Chandra theorem [13], $\phi(\mathbf{G}(\mathcal{O}_k))$ is a finite covolume discrete subgroup of H (here and further on $\mathcal{O}_k$ denotes the ring of integers of k). Such subgroups and all the subgroups of H which are commensurable with them are called *arithmetic lattices* (or *arithmetic subgroups*), and the field k is called their *field of definition*.

It can be shown that to define all arithmetic subgroups of H it is sufficient to consider only simply connected, absolutely simple k-groups $\mathbf{G}$ of absolute type $\mathrm{B}_{n/2}$, if n is even, or $\mathrm{D}_{(n+1)/2}$, if n is odd. In this case $\mathbf{G}(k \otimes_{\mathbb{Q}} \mathbb{R}) \cong \widetilde{H} \times K$, where $\widetilde{H} = \mathrm{Spin}(n,1)$ is the simply connected covering of H and K is a compact Lie group. We shall call such groups $\mathbf{G}$ and corresponding fields k *admissible*. The Godement compactness criterion implies that for $n \geq 4$ the quotient $\mathbf{H}^n/\Gamma$ is noncompact if and only if it is defined over $k = \mathbb{Q}$.

From the classification of semisimple algebraic groups [55] it follows that if n is even then $\mathbf{G}$ has to be the spinor group of a quadratic form of signature $(n,1)$ defined over a totally real field k, i.e. in even dimensions the arithmetic subgroups are commensurable with the groups of units of the quadratic forms. For odd n there is another family of arithmetic subgroups corresponding to the groups of units of appropriate Hermitian forms over quater-

nion algebras. Moreover, if $n = 7$ there is also the third type of arithmetic subgroups of H which are associated to the Cayley algebra.

The number theoretic local-global principle gives us a way to construct arithmetic lattices that is particularly suitable for the volume computations. Let $\mathrm{P} = (\mathrm{P}_v)_{v \in V_\mathrm{f}}$ be a collection of parahoric subgroups $\mathrm{P}_v \subset \mathbf{G}(k_v)$, where v runs through all finite places of k and k_v denotes the non-archimedean completion of the field (see e.g. [43, Sec. 0.5] for the definition of parahoric subgroups). The family P is called *coherent* if $\prod_{v \in V_\mathrm{f}} \mathrm{P}_v$ is an open subgroup of the finite adèle group $\mathbf{G}(\mathbb{A}_f(k))$. Following [43], the group

$$\Lambda = \mathbf{G}(k) \cap \prod_{v \in V_\mathrm{f}} \mathrm{P}_v$$

is called the *principal arithmetic subgroup* of $\mathbf{G}(k)$ associated to P. We shall also call $\Lambda' = \phi(\Lambda)$ a principal arithmetic subgroup of H. This construction is motivated by a simple observation that the integers $\mathbb{Z} = \mathbb{Q} \cap \prod_{p \text{ prime}} \mathbb{Z}_p$, where $\mathbb{Q}$ is embedded diagonally into the product of p-adic fields $\prod_{p \text{ prime}} \mathbb{Q}_p$, and can be understood as its generalization to the algebraic groups defined over number fields. We refer to the books by Platonov–Rapinchuk [42] and Witte Morris [59] for more material about arithmetic subgroups and their properties.

The Lie group H carries a Haar measure μ that is defined uniquely up to a scalar factor. We can normalize μ so that the hyperbolic volume satisfies

$$\mathrm{Vol}(\mathbf{H}^n/\Gamma) = \mu(H/\Gamma).$$

The details of this normalization procedure are explained, for instance, in Section 2.1 of [8]. If Γ is a principal arithmetic subgroup, its covolume can be effectively computed. The first computations of this kind can be traced back to the work of Smith, Minkowski and Siegel on masses of lattices in quadratic spaces. After the work of Kneser, Tamagawa and Weil these computations were brought into the framework of algebraic groups and number theory. More precisely, if Γ is an arithmetic subgroup of $\mathbf{G}$ defined over k, then its covolume can be expressed through the volume of $\mathbf{G}(\mathbb{A}_k)/\mathbf{G}(k)$ with respect to a volume form ω associated naturally to Γ, and one can relate ω to the Tamagawa measure of $\mathbf{G}(\mathbb{A}_k)$ by virtue of certain local densities. Assuming that the Tamagawa number of $\mathbf{G}$ is known, the computation of the covolume of Γ is thus reduced to the computation of these local densities. The precise expressions of this form are known as the *volume formulas*, among which we would like to mention the Gauss–Bonnet formula of Harder [26], Borel's volume formula [12], Prasad's formula [43], and its motivic extension by Gross [25]. In his paper, Harder worked out an explicit formula for the split groups $\mathbf{G}$ but in our case, if $n > 3$, the corresponding algebraic groups are never split. In Borel's influential paper the case of the semisimple groups of type A_1 is covered in full generality. This corresponds to the hyperbolic spaces of dimensions 2 and 3 and their products. Our primary interest lies in higher dimensions, where the computations can be carried out via Prasad's volume formula.

Let us recall *Prasad's formula* adapted to our setup. Let Λ be a principal arithmetic subgroup of an admissible group $\mathbf{G}/k$ associated to a coherent collection of parahoric subgroups P. Following [8, Section 2.1], assuming Λ does not contain the center of $\mathbf{G}$, we have

$$\mu(H/\Lambda') = \mathrm{Vol}(\mathbf{S}^n) \cdot \mathcal{D}_k^{\frac{1}{2}\dim(\mathbf{G})} \left(\frac{\mathcal{D}_\ell}{\mathcal{D}_k^{[\ell:k]}} \right)^{\frac{1}{2}s} \left(\prod_{i=1}^{r} \frac{m_i!}{(2\pi)^{m_i+1}} \right)^{[k:\mathbb{Q}]} \tau_k(\mathbf{G})\, \mathcal{E}(\mathrm{P}), \quad (2.1)$$

where

(i) $\mathrm{Vol}(\mathbf{S}^n) = \dfrac{2\pi^{\frac{n+1}{2}}}{\Gamma(\frac{n+1}{2})}$ is the volume of the unit sphere in $\mathbb{R}^{n+1}$;

(ii) $\mathcal{D}_K$ denotes the absolute value of the discriminant of the number field K;

(iii) ℓ is a Galois extension of k defined as in [43, 0.2] (if $\mathbf{G}$ is not a k-form of type ${}^6\mathrm{D}_4$, then ℓ is the splitting field of the quasi-split inner k-form of $\mathbf{G}$, and if $\mathbf{G}$ is of type ${}^6\mathrm{D}_4$, then ℓ is a fixed cubic extension of k contained in the corresponding splitting field; in all cases $[\ell : k] \leq 3$);

(iv) $\dim(\mathbf{G})$, r and m_i denote the dimension, rank and Lie exponents of $\mathbf{G}$:

- if n is even, then $r = \frac{n}{2}$, $\dim(\mathbf{G}) = 2r^2 + r$, and $m_i = 2i - 1$ $(i = 1, \ldots, r)$;
- if n is odd, then $r = \frac{1}{2}(n+1)$, $\dim(\mathbf{G}) = 2r^2 - r$, and $m_i = 2i - 1$ $(i = 1, \ldots, r-1)$, $m_r = r - 1$;

(v) $s = 0$ if n is even and $s = 2r - 1$ for odd dimensions (cf. [43, 0.4]);

(vi) $\tau_k(\mathbf{G})$ is the Tamagawa number of $\mathbf{G}$ over k (since $\mathbf{G}$ is simply connected and k is a number field, $\tau_k(\mathbf{G}) = 1$); and

(vii) $\mathcal{E}(\mathrm{P}) = \prod_{v \in V_f} e_v$ is an Euler product of the local densities $e_v = e(\mathrm{P}_v)$ which can be explicitly computed using Bruhat–Tits theory.

When Λ contains the center of $\mathbf{G}$ its covolume is twice the above value.

In even dimensions the right-hand side of the volume formula is related to the generalized Euler characteristic of the quotient (cf. [14, Section 4.2]) and we obtain a variant of the classical Gauss–Bonnet theorem.

If $\mathcal{O} = \mathbf{H}^n/\Gamma$ is a minimal volume hyperbolic orbifold then Γ is a *maximal lattice* in H. It is known that any maximal arithmetic subgroup Γ can be obtained as the normalizer in H of some principal arithmetic subgroup Λ, and that the index $[\Gamma : \Lambda]$ can be evaluated or estimated using Galois cohomology. We refer for more details and some related computations to the corresponding sections of [5], [6] and [8]. The upshot is that this technique allows us to study the minimal volume arithmetic hyperbolic n-orbifolds using volume formulas.

3. Minimal volume arithmetic hyperbolic orbifolds

The minimal volume 2-orbifold corresponds to the Hurwitz triangle group $\Delta(2, 3, 7)$ (cf. [50]). This group is arithmetic and defined over the cubic field $k = \mathbb{Q}[\cos(\frac{\pi}{7})]$, which follows from Takeuchi's classification of arithmetic triangle groups [53]. The smallest noncompact 2-orbifold corresponds to the modular group $\mathrm{PSL}(2, \mathbb{Z})$. In dimension 3 the minimal covolume arithmetic subgroup was found by Chinburg and Friedman [17], who used Borel's volume formula [12]. Much later Gehring, Martin and Marshall showed that this group solves Siegel's minimal covolume problem in dimension 3 [24, 38]. The noncompact hyperbolic 3-orbifold of minimal volume was found by Meyerhoff [40], it corresponds to the arithmetic Bianchi group $\mathrm{PSL}(2, \mathcal{O}_3)$, with $\mathcal{O}_3$ the ring of integers in $\mathbb{Q}[\sqrt{-3}]$. For even dimensions $n \geq 4$ the minimal volume problem for arithmetic hyperbolic n-orbifolds was solved in my paper [5] (with addendum [6]). The odd dimensional case of this problem for $n \geq 5$ was studied by Emery in his thesis [20] and appeared in our joint paper [8]. These results complete the solution of Siegel's problem for arithmetic hyperbolic n-orbifolds. We shall now review our work and discuss some corollaries.

The main results of [5, 6, 8, 20] can be summarized in two theorems:

Theorem 3.1. *For every dimension $n \geq 4$, there exists a unique orientable compact arithmetic hyperbolic n-orbifold $\mathcal{O}_0^n$ of the smallest volume. It is defined over the field $k_0 = \mathbb{Q}[\sqrt{5}]$ and has $\mathrm{Vol}(\mathcal{O}_0^n) = \omega_c(n)$.*

Theorem 3.2. *For every dimension $n \geq 4$, there exists a unique orientable noncompact arithmetic hyperbolic n-orbifold $\mathcal{O}_1^n$ of the smallest volume. It is defined over the field $k_1 = \mathbb{Q}$ and has $\mathrm{Vol}(\mathcal{O}_1^n) = \omega_{nc}(n)$.*

The values of the minimal volume are as follows:

$$\omega_c(n) = \begin{cases} \frac{4\cdot 5^{r^2+r/2}\cdot(2\pi)^r}{(2r-1)!!}\prod_{i=1}^{r}\frac{(2i-1)!^2}{(2\pi)^{4i}}\zeta_{k_0}(2i), & \text{if } n=2r,\ r \text{ even;} \\ \frac{2\cdot 5^{r^2+r/2}\cdot(2\pi)^r\cdot(4r-1)}{(2r-1)!!}\prod_{i=1}^{r}\frac{(2i-1)!^2}{(2\pi)^{4i}}\zeta_{k_0}(2i), & \text{if } n=2r,\ r \text{ odd;} \\ \frac{5^{r^2-r/2}\cdot 11^{r-1/2}\cdot(r-1)!}{2^{2r-1}\pi^r}\,L_{\ell_0|k_0}(r)\,\prod_{i=1}^{r-1}\frac{(2i-1)!^2}{(2\pi)^{4i}}\zeta_{k_0}(2i), & \text{if } n=2r-1; \end{cases} \tag{3.1}$$

$$\omega_{nc}(n) = \begin{cases} \frac{4\cdot(2\pi)^r}{(2r-1)!!}\prod_{i=1}^{r}\frac{(2i-1)!}{(2\pi)^{2i}}\zeta(2i), & \text{if } n=2r,\ r\equiv 0,\ 1(\mathrm{mod}\ 4); \\ \frac{2\cdot(2^r-1)\cdot(2\pi)^r}{(2r-1)!!}\prod_{i=1}^{r}\frac{(2i-1)!}{(2\pi)^{2i}}\zeta(2i), & \text{if } n=2r,\ r\equiv 2,\ 3(\mathrm{mod}\ 4); \\ \frac{3^{r-1/2}}{2^{r-1}}\,L_{\ell_1|\mathbb{Q}}(r)\,\prod_{i=1}^{r-1}\frac{(2i-1)!}{(2\pi)^{2i}}\zeta(2i), & \text{if } n=2r-1,\ r \text{ even;} \\ \frac{1}{2^{r-2}}\,\zeta(r)\,\prod_{i=1}^{r-1}\frac{(2i-1)!}{(2\pi)^{2i}}\zeta(2i), & \text{if } n=2r-1,\ r\equiv 1(\mathrm{mod}\ 4); \\ \frac{(2^r-1)(2^{r-1}-1)}{3\cdot 2^{r-1}}\,\zeta(r)\,\prod_{i=1}^{r-1}\frac{(2i-1)!}{(2\pi)^{2i}}\zeta(2i), & \text{if } n=2r-1,\ r\equiv 3(\mathrm{mod}\ 4). \end{cases} \tag{3.2}$$

(The fields ℓ_0 and ℓ_1 are defined by $\ell_1 = \mathbb{Q}[\sqrt{-3}]$ and ℓ_0 is the quartic field with a defining polynomial $x^4 - x^3 + 2x - 1$. The functions $\zeta_K(s)$, $L_{L|K}(s)$ and $\zeta(s)$ denote the Dedekind zeta function of a field K, the Dirichlet L-function associated to a quadratic field extension L/K, and the Riemann zeta function, respectively.)

The groups Γ_0^n and Γ_1^n can be described as the normalizers of stabilizers of integral lattices in quadratic spaces (V, f),

$$f = dx_0^2 + x_1^2 + \ldots x_n^2,$$

where for Γ_0^n we take $d = -\frac{1}{2}(1+\sqrt{5})$ if n is even and $d = (-1)^r 3 - 2\sqrt{5}$ if $n = 2r-1$ is odd, and for Γ_1^n we have $d = -1$ except for the case when $n = 2r-1$ is odd and r is even where $d = -3$. In even dimensions the stabilizers of the lattices under consideration appear to be maximal discrete subgroups so the index $[\Gamma_i^{2r} : \Lambda_i^{2r}] = 1$ and Γ_i^{2r} are principal arithmetic subgroups ($i = 0, 1$). In the odd dimensional case the index is equal to 2 except $[\Gamma_1^{2r-1} : \Lambda_1^{2r-1}] = 1$ when $r = 2m+1$ with m even. In the noncompact case the corresponding covolumes (without proof of minimality) were previously computed by Ratcliffe and Tschantz (cf. [45, 47]), who achieved this by explicitly evaluating the limit in the classical Siegel's volume formula [48, 49].

The formulas (3.1)–(3.2) look scary but they are explicit and can be applied for computation and estimation of the volumes. As an example of such computation we can study the growth of minimal volume depending on the dimension of the space. Figure 3.1 presents a graph of the logarithm of the minimal volume of compact/noncompact arithmetic orbifolds in dimensions $n < 30$. The logarithmic graph of the Euler characteristic in even dimensions has a similar shape. By analyzing this image we come up with several interesting corollaries which can be then confirmed analytically (as was done in [5] and [8]):

Corollary 3.3. *The minimal volume decreases with n till $n = 8$ (resp. $n = 17$) in the compact (resp. noncompact) case. After this it starts to grow eventually reaching a very fast super-exponential growth. For every dimension $n \geq 5$, the minimal volume of a noncompact arithmetic hyperbolic n-orbifold is smaller than the volume of any compact arithmetic hyperbolic n-orbifold. Moreover, the ratio between the minimal volumes $\mathrm{Vol}(\mathcal{O}_0^n)/\mathrm{Vol}(\mathcal{O}_1^n)$ grows super-exponentially with n.*

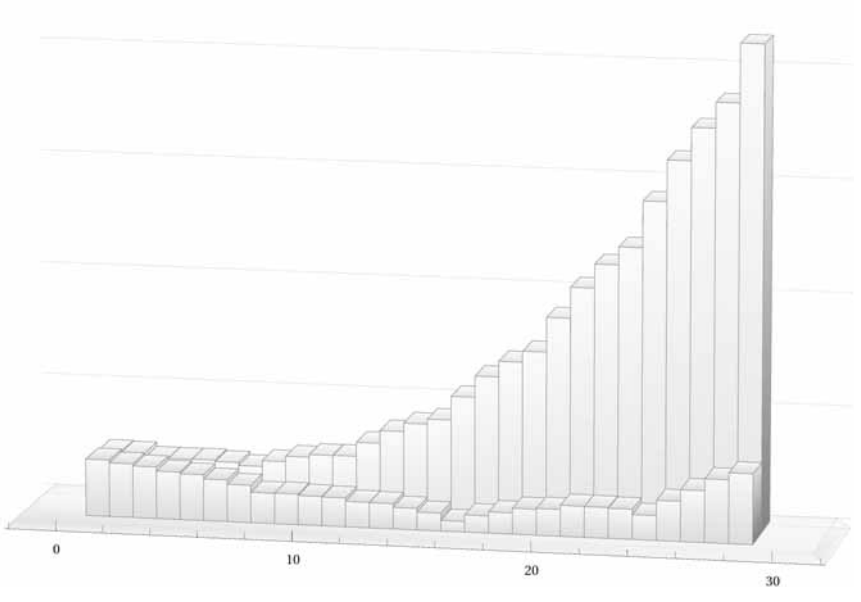

Figure 3.1. The logarithm of the minimal volume of noncompact (front) and compact (back) arithmetic hyperbolic n-orbifolds for $n = 2, 3, \ldots, 29$.

Another interesting corollary of the growth of minimal volume was obtained by Emery:

Theorem 3.4 (Emery, [19]). *For $n > 4$ there is no compact arithmetic hyperbolic n-manifold $\mathcal{M}$ with $|\chi(\mathcal{M})| = 2$.*

In particular, there do not exist arithmetically defined hyperbolic rational homology n-spheres with n even and bigger than 4. We can remark that for $n > 10$ this theorem follows from the results in [5] pertaining to Corollary 3.3, but smaller dimensions are harder and require more careful analysis of the Euler characteristic of arithmetic subgroups.

It is conjectured that all results in this section are true without assuming arithmeticity. We shall discuss this conjecture more carefully in Section 5.

4. Minimal volume manifolds and cusps

An interesting and somewhat surprising corollary of the results about the minimal volume arithmetic hyperbolic n-orbifolds is that for $n \geq 5$ the minimum is attained on *noncompact* hyperbolic n-orbifolds. In a joint work with Emery we observed that the picture becomes even more interesting when we restrict our attention to manifolds. As a result we came up with a conjecture [7]:

Conjecture 4.1. *Let $\mathcal{M}$ be a compact hyperbolic manifold of dimension $n \neq 3$. Then there exists a noncompact hyperbolic n-manifold $\mathcal{M}_1$ whose volume is smaller than the volume of $\mathcal{M}$.*

Dimension $n = 3$ is special because it is the only dimension in which we can perform hyperbolic Dehn fillings on the cusps of a finite volume noncompact manifold $\mathcal{M}_1$ to obtain compact hyperbolic manifolds of smaller volume. This follows from Thurston's Dehn surgery theorem (cf. [54, Sections 5 and 6]). Our conjecture essentially says that this is the only way to produce very small compact hyperbolic n-manifolds.

The conjecture is known to be true in dimensions $n \leq 4$ and 6. More precisely, for these n there exist noncompact hyperbolic n-manifolds $\mathcal{M}$ with $|\chi(\mathcal{M})| = 1$ [22, 46], whereas it is a general fact that the Euler characteristic of a compact hyperbolic manifold is even (cf. [44, Theorem 4.4]). The main result of [7] is a proof of the conjecture for arithmetic hyperbolic n-manifolds of dimension $n \geq 30$. In the next section we shall discuss the minimal volume conjecture (MVC), which together with this result would imply Conjecture 4.1 for $n \geq 30$, however, the above conjecture is weaker than the MVC and we hope that it might be possible to attack it directly.

The proof of the theorem in [7] is based on the results about minimal volume arithmetic hyperbolic n-orbifolds discussed in the previous section combined with a certain control over their manifold covers. For the latter we use explicit arithmetic constructions providing the upper bounds and the orbifold Euler characteristic for the lower bounds. One of our findings was that even in odd dimensions the Euler characteristic could provide an effective tool for bounding the degree of the smooth covers. Indeed, if an orbifold $\mathcal{O}$ under consideration has an even dimensional totally geodesic suborbifold $\mathcal{S}$, then the denominator of $\chi(\mathcal{S})$ gives a lower bound for the degrees of the manifold covers of $\mathcal{O}$. It appears that small volume hyperbolic n-orbifolds tend to contain many totally geodesic codimension-one suborbifolds whose Euler characteristics we can use.

The main feature of noncompact finite volume hyperbolic orbifolds is that they have infinite ends that are called *cusps*. Any such cusp is diffeomorphic to $\mathcal{N} \times [0, +\infty)$ for some closed connected flat $(n-1)$-orbifold $\mathcal{N}$. Geometry of the cusps plays a major role in the study of noncompact hyperbolic orbifolds and their volumes. For example, the cusp volume was used by Meyerhoff in his work on the noncompact minimal volume hyperbolic 3-orbifold [40], and later by Hild in the proof of minimality for hyperbolic n-orbifolds in dimensions $n \leq 9$ [27].

Long and Reid showed that any closed flat $(n-1)$-manifold $\mathcal{N}$ is diffeomorphic to a cusp cross-section of a finite volume hyperbolic n-orbifold $\mathcal{M}$ [37]. It was later proved by McReynolds that the same can be achieved with $\mathcal{M}$ being a manifold [39]. In both constructions the resulting n-orbifold or manifold can be chosen to be arithmetic. By Margulis lemma, any finite volume hyperbolic n-orbifold has a finite number of cusps (cf. [54, Proposition 5.11.1]). In the same paper Long and Reid raised a question about existence of 1-cusped hyperbolic n-manifolds for $n \geq 4$. In dimension 4 this problem was recently solved

by Kolpakov and Martelli [35], who constructed infinite families of hyperbolic 4-manifolds with any given number $k \geq 1$ of cusps. The method of Kolpakov–Martelli is specific for $n = 4$ and not applicable in higher dimensions. In particular, it is not known if there exists a 5-dimensional 1-cusped hyperbolic manifold. On the other hand, Stover [52] has shown that in dimensions $n \geq 30$ there are no 1-cusped arithmetic hyperbolic n-orbifolds (or manifolds). Following our yoga, this suggests that there should be no any 1-cusped hyperbolic n-orbifolds in high dimensions. To conclude the discussion, let us mention that (arithmetic) 1-cusped hyperbolic n-orbifolds in dimensions $n \leq 9$ appear, for example, in Hild's paper [27], and for $n = 10$ and 11 were constructed by Stover in [52]. The existence of 1-cusped orbifolds in dimensions $12 \leq n \leq 29$ is not known and there is not even a conjecture about it.

A careful reader would notice that dimension bound 30 appeared in two independent results discussed in this section. It is also the dimension bound in the celebrated Vinberg's theorem that says that there no arithmetic hyperbolic reflection groups in dimensions $n \geq 30$ [56]. There is no reason, however, to expect that any of these bounds is sharp. The coincidence can be explain by the fact that arithmetic methods work very well in higher dimensions and 30 is about the place where this starts to be noticeable. It might be possible to push down the bounds using the same methods but it would require a considerable effort and obtaining a sharp bound for any of these problems would most likely require some totally new ideas.

5. Minimal volume without arithmeticity

By the Kazhdan–Margulis theorem [31] and the subsequent work of Wang [58], we know that for $n \geq 4$ there exists a minimal volume hyperbolic n-orbifold. The classical results on uniformization of Riemann surfaces and classification of Fuchsian groups imply that the same holds true for $n = 2$, while the work of Jørgensen–Thurston [54, § 5.12] implies the same for $n = 3$. These papers also imply that there are smallest representatives in the restricted classes of compact/noncompact orbifolds or manifolds. Thus for each dimension n we have four positive numbers representing the minimal values in the volume spectra.

A *folklore conjecture*, which we call the *MVC*, says that the minimal volume is always attained on arithmetic quotient spaces. This conjecture was known for a long time for $n = 2$. (Note that the smallest volume for compact or noncompact manifolds in dimension 2 is attained also on nonarithmetic surfaces, and conjecturally this is the only dimension when it happens.) The MVC has now been completely confirmed for $n = 3$ — see [1, 23, 24, 38, 40] for the results covering each of the four cases. The smallest noncompact hyperbolic n-orbifolds for $n \leq 9$ were determined by Hild in his thesis [28] (see also [27]) and they are all arithmetic. For $n = 4$ and $n = 6$ there are examples of noncompact arithmetic hyperbolic n-manifolds $\mathcal{M}$ with $|\chi(\mathcal{M})| = 1$ which is the smallest possible [22, 46]. The smallest known compact orientable hyperbolic 4-manifolds have $\chi = 16$. They were constructed independently by Conder–Maclachlan [18] and Long [36] and can be described as finite-sheeted covers of the smallest compact arithmetic hyperbolic 4-orbifold from [5], but it is not known if there exist any smaller examples. In fact, the problem of finding a compact hyperbolic 4-manifold of minimal volume was one of the main motivations for [5]. Most of the small dimensional examples discussed here are ultimately related to hyperbolic reflection groups and we refer to the survey paper by Kellerhals for more about this connection [32].

So far, these are the only known results supporting the conjecture.

In this section we are going to discuss known general lower bounds for the volume that do not require arithmeticity. These bounds come either from a quantitative analysis of the proof of the Kazhdan–Margulis theorem or from *the Margulis lemma* and related estimates.

Let us recall the Margulis lemma for the case of hyperbolic spaces (cf. [54, Lemma 5.10.1]):

Lemma 5.1. *For every dimension n there is a constant $\mu = \mu_n > 0$ such that for every discrete group $\Gamma < \mathrm{Isom}(\mathbf{H}^n)$ and every $x \in \mathbf{H}^n$, the group $\Gamma_\mu(x) = \langle \gamma \in \Gamma \mid \mathrm{dist}(x, \gamma(x)) \le \mu \rangle$ has an abelian subgroup of finite index.*

For a given discrete group Γ, the maximal value of μ such that $\Gamma_\mu(x)$ is virtually abelian is called the *Margulis number* of $\mathbf{H}^n/\Gamma$, and the constant μ_n from the lemma is called the *Margulis constant* of $G = \mathrm{Isom}(\mathbf{H}^n)$.

If $\mathcal{M} = \mathbf{H}^n/\Gamma$ is a manifold, this result allows us to define its decomposition $\mathcal{M} = \mathcal{M}_{(0,\mu]} \cup \mathcal{M}_{[\mu,\infty)}$ into a thin and thick parts, and then to estimate from below the volume of $\mathcal{M}$ by the volume $v(\epsilon)$ of a hyperbolic ball of radius $\epsilon = \mu/2$ which embeds into the thick part $\mathcal{M}_{[\mu,\infty)}$. The case of orbifolds is much more delicate but still it is possible to use the Margulis lemma to give a lower bound for the volume. This was shown by Gelander in [9]. The resulting bound for the volume of $\mathcal{O}^n = \mathbf{H}^n/\Gamma$ is

$$\mathrm{Vol}(\mathcal{O}^n) \ge \frac{2v(0.25\epsilon)^2}{v(1.25\epsilon)}, \quad \epsilon = \min\{\frac{\mu_n}{10}, 1\}. \tag{5.1}$$

The problem with this bound is that in higher dimensions we do not have a good estimate for the value of μ_n. To my best knowledge the only appropriate general estimate can be found in [4, p. 107]. It gives

$$\mu_n \ge \frac{0.49}{16\left(1 + 2\left(\frac{4\pi}{0.49}\right)^{n(n-1)/2}\right)}. \tag{5.2}$$

In [34], Kellerhals gave a much better bound for the Margulis constant of hyperbolic n-manifolds but it is not clear if her result should extend to orbifolds.

In connection with these results it would be interesting to understand how the Margulis constant depends on the dimension of the hyperbolic space. All known bounds for μ_n decrease to zero exponentially fast when n goes to infinity, but does μ_n actually tend to zero? Note that if we define the arithmetic Margulis constant μ_n^a as the minimal value of the Margulis numbers of arithmetic hyperbolic n-orbifolds, then a positive solution to Lehmer's problem about the Mahler measure of algebraic numbers (cf. [51]) would imply that there is a uniform lower bound for μ_n^a. So conjecturally μ_n^a is bounded. The situation with μ_n is different as it is shown by the following result, which I learnt from M. Kapovich:

Proposition 5.2. *There exists a constant $C > 0$ such that $\mu_n \le \frac{C}{\sqrt{n}}$.*

Proof. The argument is based on ideas from [30].

Let us fix $\epsilon > 0$. We want to construct a discrete group of isometries $\Gamma < \mathrm{Isom}(\mathbf{H}^n)$ for which the Margulis number of $\mathbf{H}^n/\Gamma$ is less than ϵ. Let $\Gamma = F_2 = \langle f, g \rangle$, a two-generator free group. We would like to define a Γ-invariant quasi-isometric embedding of the Cayley graph T of Γ into $\mathbf{H}^n$ such that the generators of Γ act by isometries with small displacement. The graph T is a regular tree of degree four whose edges can be labeled by

the generators f, g and their inverses (starting from the root of T). Let us map the root to $p_0 \in \mathbf{H}^n$ and embed the edge corresponding to f as a geodesic segment $[p_0, p_1]$ of length ϵ. Now choose a geodesic through p_1 orthogonal to $[p_0, p_1]$ and map the g-edge adjacent to p_1 as an ϵ-segment $[p_1, p_2]$ of this geodesic. We can continue this process inductively each time choosing a geodesic which is orthogonal to the subspace containing the previously embedded edges. The process terminates when we get to p_n as n is the dimension of the space. Along the way we have defined the action of the generators f, g on the points $p_0, p_1, \dots, p_n$ which can be extended to isometry of $\mathbf{H}^n$. Now use these isometries to embed the rest of the tree. The construction gives an embedding $\rho : T \to \mathbf{H}^n$ and an isometric action of Γ on $\mathbf{H}^n$ leaving invariant the image $\rho(T)$. It remains to check that ρ is a quasi-isometric embedding.

We need to estimate the distance in $\mathbf{H}^n$ between the images of different vertices $x, y \in T$ and check that it satisfies the quasi-isometric property with respect to $\mathrm{dist}_T(x, y)$. Let $x = p_0$ and $y = p_m$ for some $m > n$ — this is a typical case and all the other easily reduce to it. Let $b_i = \mathrm{dist}_{\mathbf{H}^n}(p_0, p_i)$, so $b_0 = \epsilon$ and $b_n = \mathrm{dist}_{\mathbf{H}^n}(p_0, p_n)$. By the hyperbolic Pythagorean theorem we have

$$\cosh(b_{i+1}) = \cosh(b_i)\cosh(\epsilon),$$

therefore, $\cosh(b_n) = (\cosh(\epsilon))^n$. We now can use the disjoint bisectors test (cf. [30, Section 3]). If the length b_n is bigger than a certain constant (which can be taken $= 2.303$ as in the proof of Lemma 3.2 [loc. cit.]), then the bisectors of $[p_0, p_n]$ and $[p_n, p_{2n}]$ do not intersect and hence are separated by the distance $\delta = \delta(\rho) > 0$. Hence we have $\mathrm{dist}_{\mathbf{H}^n}(p_0, p_m) \geq \delta[m/n]$, as the geodesic joining p_0 and p_m will have to intersect all the intermediate bisectors. It follows that ρ is a quasi-isometry, provided

$$b_n \geq 2.303.$$

It remains to apply [30, Lemma 2.2], which shows that the isometric action of Γ on $\mathbf{H}^n$ is discrete and hence

$$\mu_n \leq \mu(\mathbf{H}^n/\Gamma) = \epsilon.$$

We conclude with an estimate for the constants:

$$\cosh(b_n) = (\cosh(\epsilon))^n \geq \cosh(2.303).$$

When $\epsilon \to 0$, we have $\cosh(\epsilon) \approx 1 + \frac{\epsilon^2}{2}$, so there exists $C > 0$ (can take

$$C = \sqrt{2\log(\cosh(2.303))} = 1.799\dots$$

if n is sufficiently large) such that if $\epsilon \geq \frac{C}{\sqrt{n}}$ then ρ is a quasi-isometric embedding. □

The groups in Proposition 5.2 have infinite covolume. It is tempting to try a similar argument on non-arithmetic lattices with small systole. Such lattices can be obtained by the inbreeding construction found by Agol for $n = 4$ [3] and generalized to higher dimensions in [10] and [11]. However, as it stands for now, it is not clear how to make this work and the problem remains open. The other important open problem is to find a better lower bound for μ_n. We can speculate that some kind of polynomially decreasing lower bound should exist.

The other approach is to bound the volume via quantitative version of the Kazhdan–Margulis theorem. It goes back to the paper [57] by Wang, who found an explicit lower

bound for the radius of a ball embedded into a Zassenhaus neighborhood of a Lie group G (with $G \cong \mathrm{PO}(n,1)^\circ$ in our case). Adeboye and Wei combined this bound with a bound for the sectional curvature of G to obtain an explicit lower bound for the volume [2]. Their main result is

$$\mathrm{Vol}(\mathcal{O}^n) \geq \frac{2^{[\frac{6-n}{4}]}\pi^{[\frac{n}{4}]}(n-2)!(n-4)!\cdots 1}{(2+9n)^{[\frac{n^2+n}{4}]}\Gamma(\frac{n^2+n}{4})} \int_0^{\min[0.08\sqrt{2+9n},\pi]} \sin^{\frac{n^2+n-2}{2}} \rho \; d\rho. \quad (5.3)$$

This lower bound decreases super-exponentially when n goes to infinity and it is currently the best known general lower bound for the volume.

For the noncompact hyperbolic orbifolds and manifolds there is also another approach to bounding the volume. It is based on estimating the density of Euclidean sphere packings associated to cusps. It was used in the papers of Meyerhoff, Adams, and Hild that were mentioned above. For the case of arbitrarily large dimension n, Kellerhals applied this method to obtain the best available lower bound for the volume of non-compact hyperbolic n-manifolds [33]:

$$\mathrm{Vol}(\mathcal{M}_1^n) \geq m\frac{2n}{n(n+1)}\nu_n, \quad (5.4)$$

where m is the number of cusps of the manifold $\mathcal{M}_1^n$ and ν_n denotes the volume of the ideal regular simplex in $\mathbf{H}^n$. Note that by Milnor's formula for large n we have $\nu_n \approx \frac{e\sqrt{n}}{n!}$ and hence again we have a lower bound that decreases super-exponentially with n.

In conclusion, we see that for large dimensions there is a very large gap between the known (*super-exponentially decreasing*) bound and the conjectural (*super-exponentially increasing*) values of the minimal volume. This gap highlights our limited understanding of the complexity and structure of high-dimensional hyperbolic manifolds and orbifolds, especially the non-arithmetic ones. I hope that the future research will shed more light onto this problem.

Acknowledgements. The author is supported by a CNPq research grant. I would like to thank Vincent Emery for the fruitful collaboration throughout the years which gave rise to an essential part of the results that are considered in this report. I thank Misha Kapovich for allowing me to include Proposition 5.2. I also thank Matthew Stover for the comments on a preliminary version of the paper.

Einstein 4-manifolds and singularities

Olivier Biquard

Abstract. In this note we report on recent progress on the desingularization of real Einstein 4-manifolds. A new type of obstruction is introduced, with applications to the compactification of the moduli space of Einstein metrics, and to the correspondence between conformal metrics in dimension d and asymptotically hyperbolic Einstein metrics in dimension $d+1$.

Mathematics Subject Classification (2010). Primary 53C25; Secondary 53A30.

Keywords. Einstein metric, conformal metric, gravitational instantons, AdS/CFT correspondance.

1. The Einstein equation

The Einstein equation reads

$$\mathrm{Ric}(g) = \Lambda g,$$

where g is a metric on a manifold M^n (in local coordinates $g = \sum g_{ij} dx^i dx^j$), Λ is a real number called the cosmological constant, and $\mathrm{Ric}(g) = \sum R_{ij} dx^i dx^j$ is the Ricci tensor of the metric g.

Of course the equation comes from general relativity, in which case the manifold is 4-dimensional and the metric g is Lorentzian, that is of signature (1,3). Here, we consider the case a Riemannian Einstein metric (positive signature), which has deep connections with geometry and topology, as is illustrated by the situation in low dimension that we now review briefly.

In dimension 2, a metric is Einstein if it has constant curvature equal to λ; there always exists an Einstein metric on a compact Riemann surface (this is equivalent to the uniformization theorem), and one has the dichotomy

- $\Lambda > 0$: M is a sphere;
- $\Lambda = 0$: M is a torus;
- $\Lambda < 0$: M is a surface of genus $g \geq 2$.

In dimension 3, again a metric is Einstein if it has constant curvature equal to 2Λ, so we have a similar dichotomy between spherical, flat or hyperbolic geometry according to the sign of Λ. The question of understanding which compact 3-manifolds carry an Einstein metric is completely understood, and deeply connected with the topology: the case $\Lambda > 0$ is that of a 3-sphere (and its finite quotients), and it is related to the Poincaré conjecture (proved by Perelman) saying that a compact simply connected 3-manifold is a 3-sphere—this can be

Proceedings of the International Congress of Mathematicians, Seoul, 2014

phrased by saying that it carries a constant curvature metric, and the Einstein equation plays an important role in the proof through its heat flow, the Ricci flow

$$\frac{dg}{dt} = -2\,\mathrm{Ric}(g).$$

The Ricci flow has been more generally used by Perelman to prove Thurston's geometrization conjecture, according to which any compact 3-manifold is decomposed into pieces, each of which carries one of eight homogeneous geometries (including the three constant curvature ones).

In higher dimension, it is no more true that an Einstein metric has constant curvature: the Ricci tensor is just a part of the Riemannian curvature, which contains another component (the Weyl curvature). The questions of existence and uniqueness are far from being solved. In dimension at least 5, there is no known obstruction to the existence of Einstein metrics. In dimension 4, the situation is more interesting: there is a strong relation between Einstein metrics and topology: this can be illustrated by the Hitchin-Thorpe inequality between the Euler characteristic χ and the signature τ of a compact Einstein 4-manifold:

$$2\chi(M) \geq 3|\tau(M)|. \tag{1.1}$$

This gives a topological restriction on the manifold M. More subtle obstructions are based on Gromov's idea of minimal volume (Besson-Courtois-Gallot) or on Seiberg-Witten theory (LeBrun), see the nice survey of LeBrun [16] and the references there.

The Riemannian Einstein equation is a nonlinear elliptic equation (transversely to the action of the group of diffeomorphisms), and the linearization L is a selfadjoint operator, see for example [5]. This means that one cannot extract much information on the deformations of a solution:

- either $\ker L = 0$, then the solution is rigid;
- either $\ker L \neq 0$, then there are infinitesimal deformations, but there is a space $\mathrm{coker}\, L = \ker L$ of the same dimension of obstructions, so one cannot say anything in general on the local structure of the deformation space. For example there is no known bound on the dimension of the moduli space of Einstein metrics on a given manifold.

Except in the case of special structures (Kähler or other special holonomies like quaternion-Kähler, hyper-Kähler, etc.) there is no general method to produce Einstein metrics (running the Ricci flow is of course a method, but it remains very difficult to analyze in higher dimension). Things are better for Einstein metrics on manifolds with boundary: it turns out that there exists a natural boundary problem for Einstein metrics, on which some general features of Einstein metrics can be tested, and which has its own geometric interest, in relation with conformal geometry. We now explain these ideas which originated in the work of Fefferman and Graham [11].

So let now (M, g) be a manifold with boundary $\partial M = X$, and choose on M a defining function x of X, so that $x > 0$ in the interior of M, and vanishes at first order over X. Given a metric γ on X, we consider metrics g in the interior of M such that, when $x \to 0$,

$$g \sim \frac{dx^2 + \gamma}{x^2}. \tag{1.2}$$

This behaviour depends only on the conformal class $[\gamma]$ of g: indeed, if γ is transformed into $\varphi^2\gamma$, then for $\tilde{x} = \varphi x$ one has $\frac{dx^2+\gamma}{x^2} = \frac{d\tilde{x}^2+\varphi^2\gamma}{\tilde{x}^2} +$ l.o.t. The conformal metric $[\gamma]$ is called the conformal infinity of g.

For example, if g is the hyperbolic metric on the ball, then the conformal infinity is the standard conformal metric on the boundary sphere. More generally, the behaviour (1.2) implies that the sectional curvature of g goes to -1 when $x \to 0$, hence the name of these metrics, which are called asymptotically hyperbolic (AH).

Dirichlet problem at infinity. Given a conformal class $[\gamma]$ on X, find an AH Einstein metric g in M such that the conformal infinity of g is $[\gamma]$.

The motivation of the original work of Fefferman and Graham is the study of conformal geometry through the corresponding Einstein metrics. The idea is that the formal development of g near the boundary captures invariant conformal properties of γ. This perspective was very fruitful, see [6, 12]. The correspondance received a lot of attention because it underlies a physical correspondance, the AdS/CFT correspondance [17, 24].

The global problem is well-behaved: when the metric g is non degenerate (meaning that the linearization of the problem has trivial L^2 kernel, which often happens), then one can fill a small deformation of $[\gamma]$ by a small deformation of g. This was first observed by Graham and Lee [13]. Important ideas to solve the problem were introduced by Anderson (see later in the text), but the main difficulty remains to analyze the compactness problem: is the map which associates to the Einstein metric g its conformal infinity $[\gamma]$ proper ? it is clear that such a property, together with the nice local deformation property, enables to solve the Dirichlet problem by a continuity method.

2. Compactness

So we now pass to compactness problems. We specialize to dimension 4. There is a very good compactness result on Einstein metrics, which was obtained by Anderson [1] and by Bando, Kasue and Nakajima [3].

Theorem 2.1. *Suppose (M_i, g_i) is a sequence of compact Einstein 4-manifolds, with cosmological constant ± 1 or 0, satisfying the following hypothesis:*

(1) *the diameter of (M_i, g_i) is bounded above;*

(2) *the volume of (M_i, g_i) is bounded from below;*

(3) *the L^2 norm of the curvature, $\int_{M_i} |R(g_i)|^2 dvol(g_i)$, is bounded above.*

Then a subsequence (M_i, g_i) converges for the Gromov-Hausdorff distance to a 4-orbifold (M_0, g_0) with isolated orbifold singularities. The convergence is C^∞ outside the singularities.

Moreover, for each singularity, there is a rescaling $\frac{g_i}{t_i}$ with $t_i \to 0$ such that $(M_i, \frac{g_i}{t_i})$ converges to a noncompact Ricci flat 4-manifold which is Asymptotically Locally Euclidean (ALE), that is it has one end and this end is asymptotic to the flat metric on $\mathbb{R}^4/\Gamma$ for some finite subgroup $\Gamma \subset SO_4$.

There has been a lot of progress recently to understand the limits of Einstein manifolds in higher dimension, see the article by Naber in the same volume [18].

The first hypothesis of the theorem guarantees that there is no cusp formation; the second hypothesis that there is no collapsing on a lower dimensional space; the third hypothesis is topological, because for an Einstein metric g on a compact 4-manifold M, one has $\frac{1}{8\pi^2} \int_M |R(g)|^2 d\,\mathrm{vol}(g) = \chi(M)$.

The ALE spaces which appear at the limit are the "bubbles" of the problem. This notion of bubble appears similarly in a lot of geometric problems (pseudo-holomorphic disks, instantons, harmonic maps, etc.). Similarly to these problems, another bubble can appear where a singularity forms, and one gets a tree of bubbles: the smooth ALE space mentioned in the statement is the deepest bubble.

A basic problem in understanding the possible limits of Einstein 4-manifolds is to classify the possible bubbles, that is the Ricci flat ALE 4-manifolds. There is a well-known family of hyper-Kähler (hence Ricci flat) ALE 4-manifolds (also called gravitational instantons), constructed by Kronheimer [14], who also classified all hyper-Kähler ALE 4-manifolds [15]. The finite subgroups of SO_4 which appear are the finite subgroups of SU_2. Also some cyclic subgroups of SO_4 which are not contained into a SU_2 appear as finite quotients of Kronheimer's ALE spaces. It is an old open important question whether all simply connected Ricci flat ALE 4-manifolds are hyper-Kähler (and therefore one of Kronheimer's spaces). Nakajima [19] proved that if one adds the condition that the manifold is spin for a spin structure which is also ALE in some sense, then the answer is yes.

The simplest example of a Ricci flat ALE space is the Eguchi-Hanson space [10]: topologically it is T^*S^2. The Eguchi-Hanson metric g_{EH} is asymptotic to the flat metric on $\mathbb{R}^4/\mathbb{Z}_2$. Actually T^*S^2 with the zero section removed is diffeomorphic to $(\mathbb{R}^4 \setminus \{0\})/\mathbb{Z}_2$; from the complex geometry point of view it is a desingularization of the A_1 singularity $\mathbb{C}^2/\mathbb{Z}_2$; all Kronheimer's spaces are deformations of desingularizations of the Kleinian singularities, that is of $\mathbb{C}^2/\Gamma$ for Γ a finite subgroup of SU_2. In this way one gets a short list of singularities (A_k, D_k, E_6, E_7 and E_8).

The kind of degeneration described in theorem 2.1 does occur. Actually Kähler geometry provides lots of examples. The first one [20, 23] was the singular Kummer surface (M_0, g_0), with

$$M_0 = \mathbb{T}^4/\mathbb{Z}_2,$$

a quotient of the 4-torus by an involution with 16 singular points of type $\mathbb{C}^2/\mathbb{Z}_2$, and g_0 is the flat metric. Then there is a family (M_t, g_t) of smooth K3 surfaces with their Ricci flat metrics g_t (coming from Yau's solution of the Calabi conjecture), which degenerate to (M_0, g_0) exactly in the way described by the theorem. Moreover, one can describe quite concretely the behaviour of g_t when $t \to 0$. Consider the two following regions in M_0 and in the Eguchi-Hanson space:

1. near a singular point $p_0 \in M_0$, note r the radius from p_0, the region

$$A_t = \{t^{\frac{1}{4}} \leq r \leq 2t^{\frac{1}{4}}\};$$

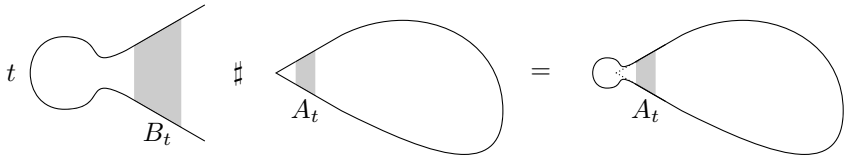
2. at the end of the metric g_{EH}, which is asymptotic to the cone $\mathbb{C}^2/\mathbb{Z}_2$, the region (where R is the radius near infinity)

$$B_t = \{t^{-\frac{1}{4}} \leq R \leq 2t^{-\frac{1}{4}}\}.$$

(Actually g_{EH} is close to the flat cone metric by a factor $O(R^{-4})$).

The homothety h_t of factor $\sqrt{t}$ identifies B_t with A_t, and sends the metric tg_{EH} to a metric which is very close to g_0 when $t \to 0$. So we can construct a new manifold M with a new metric $g_0 \sharp t g_{\mathrm{EH}}$ by gluing at each singular point the region $(\{r \geq t^{\frac{1}{4}}\}, g_0)$ in M_0 with the region $(\{R \leq 2t^{-\frac{1}{4}}\}, tg_{\mathrm{EH}})$ in the Eguchi-Hanson space, identifying A_t and B_t by h_t and

interpolating between the (very close) metrics g_0 and tg_{EH} on A_t. The process is illustrated by the figure below.



The metric $g_0 \sharp t g_{\mathrm{EH}}$ does not satisfy any more the Einstein equation in the damage area, but one can prove that it is indeed a very good approximation of g_t. In particular it illustrates well the behaviour of g_t when $t \to 0$: on one hand, $g_0 \sharp t g_{\mathrm{EH}} \to g_0$, on the other hand $\frac{1}{t}(g_0 \sharp t g_{\mathrm{EH}}) \to g_{\mathrm{EH}}$.

The compactness theorem 2.1 says basically that all the limits arise in this way, but, as mentioned before, there is no classification of the possible Ricci flat ALE spaces at the limit. In the sequel, we will see that it is not true that any 4-orbifold with a singular Einstein metric can be approximated by smooth Einstein metrics in a similar way. This leads to new restrictions on the compactification of the moduli space of Einstein metrics.

3. Desingularization

It is a fundamental algebraic fact that the 2-forms in dimension 4 decompose into selfdual and antiselfdual 2-forms:

$$\Omega^2 = \Omega_+ \oplus \Omega_-. \tag{3.1}$$

The Riemannian curvature tensor can be seen as a symmetric endomorphism of Ω^2. Therefore it decomposes on (3.1), and the various components are

$$\mathbf{R} = \begin{pmatrix} \mathbf{R}_+ & \mathrm{Ric}_0 \\ \mathrm{Ric}_0 & \mathbf{R}_- \end{pmatrix}. \tag{3.2}$$

Moreover, $\mathbf{R}_\pm$ decompose into a scalar part and a trace free part, which can be identified with the Weyl tensor W:

$$\mathbf{R}_\pm = \frac{\mathrm{Scal}}{12} \pm W_\pm. \tag{3.3}$$

We now start from an Einstein 4-orbifold (M_0, g_0), which can be compact or AH. We consider only the case of the simplest singularity $\mathbb{R}^4/\mathbb{Z}_2$. Let p_0 be a singular point (so of type $\mathbb{R}^4/\mathbb{Z}_2$). To simplify the statements, we assume that there is only one point, but the results are unchanged if there are several ones.

The following says that there is an obstruction to the existence of a sequence of metrics which desingularize g_0:

Theorem 3.1 ([8]). *Suppose that a sequence of Einstein manifolds (M_i, g_i) converges to a non degenerate (M_0, g_0), in such a way that g_i is close to $g_0 \sharp t_i g_{\mathrm{EH}}$ for a sequence of real numbers $t_i \to 0$. Then*

$$\det \mathbf{R}_+^{g_0}(p_0) = 0. \tag{3.4}$$

Here 'close' in the theorem refers to some weighted $C^{1,\alpha}$ Hölder norm.

In particular, the spaces of constant curvature $\mathbf{R}_\pm = \frac{\mathrm{Scal}}{12}$, so if the curvature is nonzero then (3.4) cannot be satisfied. It follows that spherical or hyperbolic orbifolds cannot be limits of Einstein manifolds as in the theorem:

Corollary 3.2 ([8]). *Suppose (M_0^4, g_0) satisfies the same hypothesis and has constant curvature ± 1. Then (M_0, g_0) is not the limit of a sequence of Einstein manifolds (M_i, g_i) as in theorem 3.1.*

For example, the corollary applies to the round metric on $S^4/\mathbb{Z}_2$, where the action of $\mathbb{Z}_2$ has two fixed points (the two poles), or to $\mathbb{B}^4/\mathbb{Z}_2$, the quotient of the hyperbolic 4-ball by $\mathbb{Z}_2$; it was already known that there is no U_2-invariant desingularization (U_2-invariant Einstein metrics in dimension 4 are explicitly understood).

Of course the corollary is still a partial result: a stronger result would be: if $(M_i, g_i) \to (M_0, g_0)$ in the Gromov-Hausdorff sense, and at each singularity a rescaling $(M_i, \frac{g_i}{t_i})$ converges Gromov-Hausdorff to the Eguchi-Hanson space, then the obstruction (3.4) is satisfied, and in particular the limit cannot be spherical or hyperbolic. This statement requires to strenghten the convergence of the metric to get the hypothesis of the theorem. Nevertheless we believe that theorem 3.1 already exhibits a new type of restriction on the Einstein metrics which can appear in the compactification of the moduli space of Einstein metrics.

One may also ask the question for the other singularities: for the other Kleinian singularities and their finite quotients, the answer is that the obstruction (3.4) still holds, together with other obstructions: actually the number of scalar obstructions equals the b_2 of the corresponding ALE space (work in preparation). So the corollary should remain true for these singularities. The case of other singularities depend on the question mentioned above of the classification of all Ricci flat ALE spaces.

Now pass to some more precise remarks about theorem 3.1. First, note that if the Eguchi-Hanson space is glued with the opposite orientation (which results in a different topological space) then the condition (3.4) becomes $\det \mathbf{R}_-^{g_0}(p_0) = 0$ (this is clear since the Einstein equation does not depend on the orientation).

Also note that in the Kähler case, choosing a basis $(\omega_1, \omega_2, \omega_3)$ of Ω_+ such that ω_1 is the Kähler form, one has

$$\mathbf{R}_+ = \begin{pmatrix} \frac{\mathrm{Scal}}{4} & & \\ & 0 & \\ & & 0 \end{pmatrix}, \tag{3.5}$$

so the condition (3.4) is automatically satisfied. Indeed it is well known that there is no such obstruction in the Kähler case.

When one considers the gluing $g_0 \sharp t g_{\mathrm{EH}}$, there is an ambiguity which gives a gauge parameter: indeed one can apply an element $u \in SO_4/\mathbb{Z}_2$ when identifying the parts A_t and B_t of the cone $\mathbb{R}^4/\mathbb{Z}_2$ (applying an orientation reversing element of O_4 amounts to changing the orientation of the Eguchi-Hanson space and was considered just above). It turns out that the isometry group of g_{EH} is $\mathrm{Isom}(g_{\mathrm{EH}}) = (U_2/\pm 1) \rtimes \mathbb{Z}_2$ (where $U_2 \subset SO_4$ is the standard unitary subgroup, and the $\mathbb{Z}_2$ is generated by $(z_1, z_2) \mapsto (-\bar{z}_2, \bar{z}_1)$, inducing the antipodal map on S^2). Taking u in $\mathrm{Isom}(g_{\mathrm{EH}})$ does not change $g_0 \sharp t g_{\mathrm{EH}}$, so the remaining parameter is in $SO_4/(U_2 \rtimes \mathbb{Z}_2) = \mathbf{P}\Omega_+(\mathbb{R}^4)$.

This means that the ambiguity u can be interpreted as a real line in $\Omega_+(\mathbb{R}^4)$. This is related to the obstruction (3.4): note u_i the gauge parameter used for $g_0 \sharp t_i g_{\mathrm{EH}}$, then one can add to the statement of the theorem the fact that the directions in $\Omega_+(\mathbb{R}^4)$ corresponding to the limits of the gauge parameters u_i must be in the kernel of $\mathbf{R}_+^{g_0}(p_0)$. (This also fits with

the Kähler picture, since when $\mathrm{Scal} \neq 0$, this condition implies that the complex structure of the orbifold must be glued with a complex structure of the Eguchi-Hanson space which is orthogonal to that of $T^*\mathbb{C}P^1$, and in particular does not admit a holomorphic sphere; but indeed a Kähler-Einstein metric with $\mathrm{Scal} \neq 0$ can not admit a holomorphic sphere of self intersection -2).

In particular, if $\mathrm{rk}\, \mathbf{R}_+^{g_0}(p_0) = 1$, then the kernel of $\mathbf{R}_+^{g_0}(p_0)$ gives a direction in $\Omega_+(\mathbb{R}^4)$, so a gauge parameter $u = \lim u_i$. This is of importance in the reverse construction, that we now describe.

To see if the condition (3.4) is the only local obstruction to the desingularization, it is important to produce an Einstein desingularization (M, g_t) from the singular (M, g_0). It turns out that this is not possible in general on a compact manifold, because, as mentioned earlier, there are always global obstructions to deformation which make the problem untractable. Fortunately, the problem becomes much better in the AH setting:

Theorem 3.3 ([8]). *Suppose that (M_0, g_0) is a non degenerate AH Einstein orbifold, with a singularity of type $\mathbb{R}^4/\mathbb{Z}_2$ at the point p_0. If g_0 satisfies the condition (3.4), then there exists a family of AH Einstein metrics g_t on a topological desingularization M such that (M_0, g_0) is the limit of (M, g_t) when $t \to 0$.*

Again the theorem is still valid if there are several singular points: the topological desingularization M is obtained by replacing each singular point by a sphere of self intersection -2.

An important fact to note in the theorem is that the conformal infinity γ_t induced by g_t on ∂M depends on t, and converges to the conformal infinity γ_0 of g_0 on $\partial M_0 = \partial M$: it is this flexibility which enables to solve the problem in the AH case.

There is an explicit family [4, 21], called the AdS-Taub-Bolt family, of U_2 invariant metrics on T^*S^2, which converge to an orbifold metric on $\mathbb{B}^4/\mathbb{Z}_2$. The limit is not the hyperbolic metric (this is impossible by corollary 3.2), but a $\mathbb{Z}_2$ quotient of a selfdual Einstein metric on $\mathbb{B}^4$, which is a member of a 1-parameter family found by Pedersen [22]; more precisely, it is the unique member of this family which satisfies the obstruction (3.4).

4. Degree theory and wall crossing

We now consider the AH setting, and study the consequences of theorem 3.3 on the Dirichlet problem at infinity stated in section 1.

Let (M_0, g_0) be an AH Einstein 4-orbifold, with conformal infinity $[\gamma_0]$ on the boundary $\partial M_0 = X$. Again for simplicity, suppose that we have only one singular point. We still restrict to the simplest singularity A_1, and we ask g_0 to be non degenerate (remind this means that the L^2 kernel of the linearization vanishes). This implies that, given a small deformation γ of γ_0, there exists a deformation g_0^γ of g_0, which is an AH Einstein orbifold with conformal infinity γ.

We also suppose that condition (3.4) holds for g_0. Then, inside the space $\mathscr{C}$ of all conformal metrics on X, we can consider, at least near γ_0, the space of conformal metrics on X such that the corresponding orbifold Einstein metric also satisfies (3.4):

$$\mathscr{C}_0 = \{\gamma \in \mathscr{C}, \det \mathbf{R}_+^{g_0^\gamma}(p_0) = 0\}. \tag{4.1}$$

Therefore, all the metrics g_0^γ with $\gamma \in \mathscr{C}_0$ can be desingularized by theorem 3.3, leading to AH Einstein metrics g_t^γ ($t > 0$) on the topological desingularization M of M_0.

Theorem 4.1 ([8, 9]). *Suppose that* $\mathrm{rk}\, \mathbf{R}_+^{g_0}(p_0) = 2$ *(this is a way to say that the vanishing of* $\det \mathbf{R}_+^{g_0}(p_0)$ *is non degenerate). Then*

(1) *The set* $\mathscr{C}_0$ *is a smooth hypersurface of* $\mathscr{C}$ *near* γ_0.

(2) *For* γ *near* $\mathscr{C}_0$*, all the desingularized Einstein metrics have their conformal infinity on the side of* $\mathscr{C}_0$ *determined by*

$$\det \mathbf{R}_+^{g_0^\gamma}(p_0) > 0. \tag{4.2}$$

This result means that $\mathscr{C}_0$ is a 'wall' for the Dirichlet problem at infinity on M: for a conformal infinity on the side (4.2) of the wall, there is an AH Einstein metric with this conformal infinity (one of the metrics g_t^γ); when the conformal infinity goes to the wall, the Einstein metric degenerates, and disappears on the other side.

This is better understood in the setting of the degree theory proposed by Anderson [2] for the Dirichlet problem at infinity. The idea is the following: let $\mathscr{M}$ be the space of all AH Einstein metrics on M, and consider the map

$$\Phi : \mathscr{M} \longrightarrow \mathscr{C} \tag{4.3}$$

defined by: $\Phi(g)$ is the conformal infinity of g. Anderson proved that, in a suitable Banach topology, if $\pi_1(M, X) = 0$, the map Φ is Fredholm of index 0. If there exists some open set $U \subset \mathscr{C}$ over which the map Φ is proper, then Sard-Smale theory gives a well-defined notion of degree of Φ which counts the number of preimages of an element of U. A priori, the degree is only defined in $\mathbb{Z}_2$, but there is a way to count the solutions with sign (the sign is the number of negative eigenvalues of the linearization) and to define a degree with values in $\mathbb{Z}$. In some cases, one may hope to calculate the degree at some special points of U, and if it does not vanish, this implies that the map Φ is surjective over U.

It turns out that the properness of the map (4.3) is a difficult problem, which is far from being solved in general. The paper [2] is written under the following assumptions:

1. $\dim M = 4$: this is to be able to use the strong compactness results for Einstein metrics in dimension 4;
2. $U = \{\gamma \text{ on } X, \mathrm{Scal}^\gamma > 0\}$: this is used to avoid cusp formation in the limits, and is also natural from the point of view of the physicists; it replaces the hypothesis on the volume in theorem 2.1; there are also counterexamples to to properness with flat conformal infinities;
3. the map $H_2(X, \Bbbk) \to H_2(M, \Bbbk)$ is surjective for any field $\Bbbk$: this is to avoid the degeneration to an Einstein orbifold, because in that case some 2-homology must exist in the interior of M (for example, the 2-sphere in the case of the degeneration to a $\mathbb{R}^4/\mathbb{Z}_2$ singularity).

The general case to consider in dimension 4 is when one relaxes the third hypothesis. Here, theorem 4.1 gives insight on what to expect. We are far from being able to prove something here, but the following speculations may help to understand the meaning of the theorem.

It is clear that in this general case, the map Φ is not proper: indeed we have explicit examples of orbifold degenerations of AH Einstein metrics. But we at least understand what

is happening when there is a degeneration of M to an orbifold M_0 with an A_1 singularity, obtained by contracting a 2-sphere of self intersection -2: the number of preimages of Φ changes when one goes through the wall $\mathscr{C}_0$ defined by (4.1), in the precise way given by theorem 4.1. In this way, theorem 4.1 can be interpreted as a wall crossing formula calculating the jump of the degree on M when one goes across $\mathscr{C}_0$.

Of course in general there are several (-2) spheres which can be contracted, so they give rise to several walls in $\mathscr{C}$: one can hope to have Φ proper in the regions delimited by these walls, and jumping across the walls like in theorem 4.1.

Now, all this is for A_1 singularities, so what is happening for the other singularities? the other Kleinian singularities are obtained by contracting a number of (-2) spheres, say k, and indeed one expects to obtain k obstructions to desingularization: so it seems that the generic case is that of A_1 singularities, the other Kleinian singularities being obtained when k walls intersect in a certain way; so the wall crossing formula for the A_1 case might be sufficient. The case of finite quotients of Kleinian singularities is also similar.

To transform these speculations into a proof, one would need to prove the properness of the map Φ outside the walls obtained from the various possible orbifolds obtained from M: in particular, this requires the classification of the Ricci flat ALE spaces, mentioned in section 2.1, and a better understanding of the behaviour of a degenerating Einstein metric.

5. Some ideas of the proofs

The beginning of the proof builds on usual ideas in 'gluing problems' appearing in geometric analysis. For small t we have a metric $g_0 \sharp t g_{\mathrm{EH}}$ which is an approximate solution of the Einstein equation, which is better and better when $t \to 0$, and one wants to deform it into a true solution if t is small enough. In general, this is possible if the two pieces (here g_0 and g_{EH}) are not obstructed for the deformation theory of the Einstein problem. The point is that this is never true for g_{EH} (or more generally for any ALE space), because g_{EH} comes in a 1-parameter family given by scaling. More precisely, the linearization of the Einstein equation on the Eguchi-Hanson space (or more generally any hyper-Kähler space) is

$$L = d_-^* d_- : \Omega_- \Omega_+ \longrightarrow \Omega_- \Omega_+, \tag{5.1}$$

where one uses the identification $\Omega_-(\mathbb{R}^4)\Omega_+(\mathbb{R}^4) = \mathrm{Sym}_0^2(\mathbb{R}^4)$ given by $u \otimes v \mapsto u \circ v$. (The operator on the trace part is just the usual Laplacian). On a hyper-Kähler manifold, the bundle Ω_+ is a flat trivial bundle: $\Omega_+ = \mathbb{R}^3$. So the operator L is identified with the Laplacian $d_-^* d_-$ acting on $\Omega_- \otimes \mathbb{R}^3$, and its L^2-kernel is therefore the L^2 cohomology of the Eguchi-Hanson space:

$$\ker_{L^2} L = L^2 H^2 \otimes \mathbb{R}^3 \simeq \mathbb{R}^3. \tag{5.2}$$

Indeed the L^2 cohomology of Eguchi-Hanson is generated by the Poincaré dual of the 2-sphere. Let choose a basis (o_1, o_2, o_3) of this obstruction space. Then usual techniques enable to deform $g_0 \sharp t g_{\mathrm{EH}}$ into a (basically unique) solution of the Einstein equation modulo these obstructions:

$$\mathrm{Ric}(g_t) - \Lambda g_t = \sum_1^3 \lambda_i(t) o_i. \tag{5.3}$$

(This is not the exact equation to be solved because one must respect the Bianchi identity, but it gives the idea). The problem becomes to analyse the functions $\lambda_i(t)$ and their possible vanishing.

The way to do this is to refine the approximate metric $g_0 \sharp t g_{\mathrm{EH}}$: if one has an approximation to a better order of a solution of (5.3), then g_t will be closer to this new approximation and this can give the first terms of the development of $\lambda_i(t)$.

The idea here is to refine the ALE metric g_{EH} into a metric h_t before gluing it to g_0: the metric h_t is a perturbation of g_{EH} which should satisfy the equation

$$\mathrm{Ric}(h_t) = t\Lambda h_t \tag{5.4}$$

instead of $\mathrm{Ric}(g_{\mathrm{EH}}) = 0$ (so that $\mathrm{Ric}(th_t) = \Lambda(th_t)$); and it should match better $\frac{g_0}{t}$ near infinity: denote euc the standard Euclidean metric, then near p_0, in normal coordinates, one has

$$g_0 = \mathrm{euc} + g_2 + O(r^4), \tag{5.5}$$

where g_2 is an order 2 term:

$$g_2 = \sum a_{ijkl} x^i x^j dx^k dx^l. \tag{5.6}$$

We can ask h_t to match these order 2 terms in the following way: when we perform the homothety h_t, we transfer the coordinates x^i near 0 into the coordinates $X^i = t^{-\frac{1}{2}} x^i$ near infinity on Eguchi-Hanson, so

$$\frac{g_2}{t} = t \sum a_{ijkl} X^i X^j dX^k dX^l. \tag{5.7}$$

So it is natural to look for a first order deformation $h_t = g_{\mathrm{EH}} + th$ which satisfies at infinity

$$h \sim \sum a_{ijkl} X^i X^j dX^k dX^l \tag{5.8}$$

while (5.4) becomes

$$Lh = \Lambda g_{\mathrm{EH}}. \tag{5.9}$$

The first order deformation $g_{\mathrm{EH}} + th$ is not a metric on the whole Eguchi-Hanson space, since the perturbation h blows up at infinity. Nevertheless it will define a metric on the region which is considered in the gluing, that is $R \leq 2t^{-\frac{1}{4}}$.

Now it turns out that the system (5.8) (5.9) is obstructed and has no solution in general, because of the cokernel of L (which equals its kernel). Actually, instead of (5.9), one can only solve

$$Lh = \Lambda g_{\mathrm{EH}} + \sum_1^3 \lambda_i o_i, \tag{5.10}$$

where the real numbers λ_i are also unknown.

At the end, the system (5.8) (5.10) has a solution (h, λ_i), and the λ_i depends only on the second order terms g_2 of g_0 at p_0, that is on the curvature of g_0 at p_0. There are some arguments using in particular the invariance of the system to calculate precisely the λ_i and one finds (up to a constant)

$$\lambda_i = \langle \mathbf{R}_+^{g_0}(p_0)\omega_1, \omega_i \rangle, \tag{5.11}$$

where (ω_i) is an orthonormal basis of Ω_+. Then, using the approximate metric $g_0 \sharp t(g_{\mathrm{EH}} + th)$, one can show that the coefficient $\lambda_i(t)$ appearing in (5.3) has the expansion

$$\lambda_i(t) = t\lambda_i + O(t^2). \tag{5.12}$$

In particular, the vanishing of $\lambda_i(t)$ forces $\lambda_i = 0$, which by (5.11) means

$$\mathbf{R}_+^{g_0}(p_0)\omega_1 = 0. \tag{5.13}$$

Therefore $\mathbf{R}_+^{g_0}(p_0)$ has a kernel; using the gauge freedom, one can reduce this condition to $\det \mathbf{R}_+^{g_0}(p_0) = 0$, which proves theorem 3.1.

For the desingularization itself (theorem 3.3), the work is far from being finished, since from the hypothesis $\mathbf{R}_+^{g_0}(p_0)\omega_1 = 0$ we have killed only the first term in the development of $\lambda_i(t)$. Here one uses the fact that (M_0, g_0) is an AH Einstein manifold, which gives the flexibility to vary g_0 varying its conformal infinity γ_0. In particular, one considers the map $F = (F_1, F_2, F_3) : \mathscr{C} \to \mathbb{R}^3$ defined by

$$\gamma \longmapsto (\lambda_1(g_0^\gamma), \lambda_2(g_0^\gamma), \lambda_3(g_0^\gamma)), \tag{5.14}$$

where g_0^γ is the Einstein orbifold metric on M_0 with conformal infinity γ, and the λ_i are defined by (5.11). Then one proves that the map F is submersive at γ_0: despite the fact that the space $\mathscr{C}$ is infinite dimensional, this is not an obvious fact, and the proof relies in particular on a unique continuation theorem proved in [7]. This means that there exist directions γ_i in the space of conformal structures, such that

$$d_{\gamma_0} F_i(\gamma_j) = \delta_{ij}. \tag{5.15}$$

Consider now the metric g_t and the functions $\lambda_i(t)$ in (5.3) as depending also of the conformal infinity γ, and note this dependence as $g_t(\gamma)$, $\lambda_i(t, \gamma)$. From equations (5.12) and (5.15) it is now immediate that there exist functions $a_i(t) = O(t)$ such that

$$\lambda_i(t, \gamma_0 + \sum_1^3 a_j(t)\gamma_j) = 0, \tag{5.16}$$

which means that the metric $g_t(\gamma_0 + \sum_1^3 a_j(t)\gamma_j)$ is the expected solution of the Einstein equation.

Proving theorem 4.1 requires substantially new arguments. The first step is to refine the previous arguments.

If $\mathrm{rk}\, \mathbf{R}_+^{g_0}(p_0) = 2$, one can show that actually $\lambda_2(t)$ and $\lambda_3(t)$ can be killed just by varying the gauge parameter, so there is no need to deform the conformal infinity in the directions γ_2 and γ_3, the direction γ_1 is sufficient. So one can obtain a solution $g_t(\gamma_0 + a_1(t)\gamma_1)$.

Moreover one can construct a more refined deformation of g_{EH} which matches even better g_0 at infinity before gluing, by obtaining the coincidence not only of the terms of order 2, but also the terms of order 4; the whole construction is then refined to obtain a better expansion of $\lambda_1(t)$:

$$\lambda_1(t) = t\lambda_1 + t^2\mu_1 + O(t^3), \tag{5.17}$$

where μ_1 is some a priori non explicit number, obtained when finding the second order terms of the solution modulo obstructions of the equation (5.4). Then it is clear that the function $a_1(t)$ such that $g_t(\gamma_0 + a_1(t)\gamma_1)$ is the expected Einstein metric satisfies

$$a_1(t) \sim -\mu_1 t \tag{5.18}$$

when $t \to 0$. If μ_1 has a sign, then all the solutions are exactly on the side of $\mathscr{C}_0$ determined by the direction $-\mu_1\gamma_1$ at γ_0.

Calculating μ_1 is difficult. Up to now, the analysis used essentially the linearization the Einstein equation (and some global properties). But calculating μ_1 involves understanding the second order terms of the equation, in order to find the second order terms of the solution of (5.4). We will not give any detail here, see [9], except to say that the hyper-Kähler nature of g_{EH} helps a lot to get insight on these second order terms and on the calculation of μ_1. From this theorem 4.1 is deduced.

Finally let us say that the proofs of both theorems do not rely on the precise form of the Eguchi-Hanson metric, but more on the fact that the Eguchi-Hanson space has a one dimensional L^2-cohomology and has a Hamiltonian circle action which rotates the other complex structures. There are lots of other spaces with the same geometric properties, if one allows orbifold singularities inside. For example, the A_k singularity $\mathbb{C}^2/\mathbb{Z}_{k+1}$ has a partial desingularization satisfying the same properties, but with an orbifold point with a A_{k-1} singularity. Using the same techniques as above, one can calculate an expansion for $\det \mathbf{R}_+$ at the singular point and find an obstruction to continuing the desingularization. So it seems that an inductive process can be started, leading to k obstructions to desingularization. Unfortunately this process can not be carried out so easily, because the non degeneracy hypothesis seems difficult to prove for the partial desingularizations. Nevertheless the author believes he is able to overcome this technical problem using some refined analysis.

Non-negatively curved manifolds and Tits geometry

Fuquan Fang

Abstract. We explain a surprising passage from non-negatively curved manifolds with polar actions to Tits geometries, which is the basic tool for the rigidity theorem on positively curved polar manifolds established in [13], as well as for works in progress for further rigidity theorems on non-negatively curved hyperpolar manifolds. The latter possibly leads to a new characterization of riemannian symmetric spaces.

Mathematics Subject Classification (2010). Primary 53C24; Secondary 53C35.

Keywords. Curvature, polar actions, Chamber system, Tits building.

1. From non-negative curvature to topology, a brief review

The interest in positively/non-negatively curved manifolds goes back to the 19-th century. From the Gauss-Bonnet theorem, a compact surface with a positively curved metric is either diffeomorphic to $\mathbb{S}^2$ or $\mathbb{RP}^2$. But it was not known untill the early 1980's, after the fundamental work of Hamilton, that all compact 3-dimensional manifolds with positively curved metrics are diffeomorphic to spherical space forms. In dimensions larger than 24, there are no known examples of compact simply connected manifolds with positive sectional curvature other than the rank one symmetric spaces. Surprisingly, infinitely many positively (pinched) curved simply connected manifolds were found only in dimensions 7 and 13, among others, e.g.,

- the Aloff-Wallach spaces $\mathsf{SU}(3)/i_{p,q}(\mathsf{S}^1)$, where $i_{p,q}(\mathsf{S}^1) \subset \mathsf{T}^2$ is a family of circles in the maximal torus T^2 parameterized by pairs of coprime integers p, q;
- the Bazaikin spaces $i_{q_1,\cdots,q_6}(\mathsf{S}^1) \setminus \mathsf{SU}(6)/\mathsf{Sp}(3)$, where $i_{q_1,\cdots,q_6}(\mathsf{S}^1) \subset \mathsf{SU}(6)$ is a diagonal circle subgroup parameterized by six odd integers $q_1, \cdots, q_6$ such that the biquotients are manifolds.

The structure of positively/non-negatively curved manifolds has not yet been well-understood, except for a few well-known general topological constraints, such as the Bonnet-Meyer theorem, the Synge theorem, Gromov's Betti number theorem, and the vanishing of the $\hat{A}$-genus (α-invariant) for Spin manifolds with positive scalar curvature.

For a compact riemannian manifold, one can always normalize the metric so that the maximum of the sectional curvature is 1. The curvature is said to be δ-*pinched* if $\delta < \sec \leq 1$ everywhere. A very challenging conjecture is (cf. Berger [Be]):

Proceedings of the International Congress of Mathematicians, Seoul, 2014

Conjecture (Optimal pinching constant). *For any given integer $n > 1$, there is a positive constant $\delta(n)$ depending only on n, such that, every compact positively curved n-manifold admits a $\delta(n)$-pinched metric.*

For positively pinched manifolds, the following finiteness theorem of Cheeger (Weinstein obtained homotopy type finiteness) explains how small the class is:

Theorem 1.1 (Cheeger, Weinstein). *For any given positive constant $\delta < 1$, up to diffeomorphism, there are only finitely many $2n$-dimensional riemannian manifolds with δ-pinched curvature.*

The same statement can not be true in any odd dimensions, because there are infinitely many spherical space forms in every odd dimension $2n + 1$. Furthermore, in dimension 7 (also 13), the Aloff-Wallach (also Bazaikin) spaces indeed contain infinitely many curvature uniformly pinched manifolds with pairwisely different topological types (cf. Puttmann [Pu]), hence the same statement fails even for simply connected positively δ-pinched curved manifolds. However, one has the following analogue of the above Cheeger-Weinstein theorem:

Theorem 1.2 (Fang-Rong [14, 15], Petrunin-Tuschmann [25]). *For any given positive constant $\delta < 1$, up to diffeomorphism, there are only finitely many $(2n + 1)$-dimensional positively δ-pinched curved, simply connected riemannian manifolds with trivial second rational Betti numbers.*

In contrast, there are many more examples of manifolds with non-negatively curved metrics. Products of non-negatively curved manifolds are still non-negatively curved. All compact Lie groups, and in fact all symmetric spaces of compact type have non-negative sectional curvature. By Cheeger, the connected sums of two complex/quaternionic projective spaces admit non-negatively curved riemannian metrics. Starting from cohomogeneity one actions, Grove-Ziller found infinitely many new examples of non-negatively curved manifolds, which includes in particular 10 of the 14 unoriented exotic 7-spheres (cf. [GZ]). It is natural to ask whether this sort of construction can be extended to higher cohomogeneity to create new families of examples. As we will see in later sections, it is much more rigid for polar actions in higher cohomogeneity.

We finally mention a few important conjectures:

- (Hopf) There exists no metric with positive sectional curvature on $\mathbb{S}^2 \times \mathbb{S}^2$. More generally, there are no positively curved metrics on the product of two compact manifolds, or on a symmetric space of rank at least two.
- (Hopf) A compact manifold with sec ≥ 0 has non-negative Euler characteristic. An even dimensional manifold with positive curvature has positive Euler characteristic.
- (Bott-Grove-Halperin) A compact simply connected manifold M with sec ≥ 0 is rational elliptic, i.e., the sequence of rational Betti numbers of the loop space of M grows at most polynomially.
- (Klingenberg-Sakai-Yau) There are only finitely many diffeomorphism classes of positively curved manifolds in a given homotopy type.

2. Reflection groups in Non-negatively curved manifolds

The theory of discrete groups of motions generated by reflections originates in the study of plane regular polygons and space polyhedra. An extensive account of the history of the theory of reflection groups in euclidean and spherical spaces appeared in Bourbaki, Groupes et Algèbres de Lie, Chapters IV-VI [5]. According to this account the modern theory originates from the works of geometers A. Möbius and L. Schläfli in the middle of the 19th century, then was extended and applied to the theory of Lie algebras in the works of E. Cartan and W. Killing at the end of the same century, and culminated in the works of H. S. M. Coxeter [8].

Reflection groups in the hyperbolic plane were described at least back in 1882 by Poincaré in a memoir on Fuchsian groups [28], and by von Dyck [11]. A complete classification of reflection groups in hyperbolic 3-space was achieved by Andreev [2] (cf. also [30]). Hyperbolic reflection groups in higher dimensions are very rich and far from being classified. A surprising theorem of Vinberg [37] asserts there are no co-compact hyperbolic reflection groups in dimensions ≥ 30. An extended non-existence theorem was established by Khovanskii [20] for co-finite volume hyperbolic reflection groups in dimension at least 995.

In this section we present a joint work with Karsten Grove [12].

Assume Σ is an n-dimensional nonnegatively curved complete manifold with a discrete reflection group W, such that the orbit space Σ/W is compact (equivalent to *finite covolume*). Here a reflection refers to an isometric involution with a codimension 1 fixed point set, and a mirror refers to a codimension 1 component. In this generality, a *mirror* may not separate the manifold. We will give a complete description not only of the reflection group, but also of the equivariant structure of the manifold.

Note, if Σ is non compact but Σ/W is compact, it follows from Cheeger-Gromoll soul theorem that Σ splits into a metric product of a flat $\mathbb{R}^k$ with the soul, a compact totally geodesic submanifold. Therefore, Σ/W splits into a metric product of eucledian simplices and the orbit space of a reflection group on the soul.

The mirrors of all reflections in W form a configuration in Σ. A Dirichlet domain will be called an open *chamber* which is a locally convex set. We point out that, it often happens that there are more faces in the closure of the chamber than the minimal number of generators of W. For instance, A_2 acts on the tiling of a flat torus $\mathbb{T}^2$ by six equilateral flat triangles, A_2 is generated by any two of the three reflections.

To explain the appearance of building blocks, we say that the action $\mathsf{W} \times \Sigma \to \Sigma$ is *decomposable* if the orbitspace Σ/W metrically is a finite quotient of a product, and *indecomposable* otherwise. With this terminology one of our main results is the following *Rigidity Theorem*

Theorem 2.1 (Fang-Grove [12]). *A nonnegatively curved manifold Σ^n with an indecomposable cocompact action by a reflection group W is isometric to either $\mathbb{R}^n$, or $\mathbb{T}^n$, or equivariantly diffeomorphic to either $\mathbb{S}^n$, or $\mathbb{RP}^n$ with a linear action, unless all mirrors in Σ meet.*

Here the spherical case relies on showing that the orbit space is a simplex, whereas the part where the universal cover of Σ is non-compact also relies on Cheeger- Gromoll splitting results for cocompact actions and for compact manifolds with infinite fundamental group, as well as on Bieberbach's celebrated Theorem (cf. [12]). Recall, that by the latter, any compact flat manifold is finitely covered by a flat torus, i.e., $\Sigma = \mathbb{T}^n/\,\mathsf{G}$, where $\mathsf{G} \subset \mathsf{O}(n)$ is the holonomy. In particular, Theorem 2.1 shows that the holonomy group G must be trivial

when the action is indecomposible. More generally, we point out that, if the orbit space splits as a metric product of eucledian simplices, then $\mathbb{T}^n/\,\mathsf{G}$ must be an iterated torus bundle, with holonomy group G a very special elementary abelian 2-group in $\mathsf{GL}(\mathbb{Z}, n)$. The Klein bottle serves as the simplest example.

To describe the structure that arises when all mirrors meet let us introduce the fibre product

$$\prod(\nu_1 \oplus \varepsilon^{k_1}, \cdots, \nu_\ell \oplus \varepsilon^{k_\ell})$$

of the sphere bundles $\mathbb{S}(\nu_1 \oplus \varepsilon^{k_1}), \cdots, \mathbb{S}(\nu_\ell \oplus \varepsilon^{k_\ell})$ over a compact manifold X: the subset of the product $\mathbb{S}(\nu_1 \oplus \varepsilon^{k_1}) \times \cdots \times \mathbb{S}(\nu_\ell \oplus \varepsilon^{k_\ell})$ which projects to the diagonal Δ in X^ℓ, where $\nu_1, \cdots, \nu_\ell$ are vector bundles and ε is a trivial line bundle. Notice, $\prod(\nu_1 \oplus \varepsilon^{k_1}, \cdots, \nu_\ell \oplus \varepsilon^{k_\ell})$, admits a fiberwise product linear action by the product of spherical Coxeter groups $\mathsf{W}_1 \times \cdots \times \mathsf{W}_\ell$.

Theorem 2.2 (Fang-Grove [12]). *Given a spherical reflection group W, a nonnegatively curved compact simply connected W-manifold whose all mirrors meet is equivariantly diffeomorphic to*

$$\prod(\nu_1 \oplus \varepsilon^{k_1}, \cdots, \nu_\ell \oplus \varepsilon^{k_\ell})$$

where $\nu_1, \cdots, \nu_\ell$ are vector bundles with non-negative sectional curvature over a soul X.

When passing to the universal cover, the above results in particular lead to the following general *Splitting Theorem*

Theorem 2.3 (Fang-Grove [12]). *Let Σ be a complete non negatively curved manifold with co-compact reflection group W. Then the lifted reflection group $\hat{\mathsf{W}}$ on the universal cover $\tilde{\Sigma}$ is a product of Coxeter groups,*

$$\hat{\mathsf{W}} = \hat{\mathsf{W}}_0 \times \hat{\mathsf{W}}_1 \times \cdots \times \hat{\mathsf{W}}_{\ell-1} \times\ \hat{\mathsf{W}}_\ell,$$

where $\hat{\mathsf{W}}_0$ is affine, and the remaining factors are spherical. Correspondingly, $\tilde{\Sigma}$ admits a $\hat{\mathsf{W}}$ invariant metric splitting,

$$\tilde{\Sigma} = \mathbb{R}^k \times \mathbb{S}^{k_1} \times \cdots \times \mathbb{S}^{k_{\ell-1}} \times \Theta_\ell \times N,$$

where N can be any simply connected compact manifold of nonnegative curvature on which all $\hat{\mathsf{W}}_i$ act trivially, $\mathbb{S}^{k_i}$ is a non negatively curved standard sphere with a linear $\hat{\mathsf{W}}_i$ action, and Θ_ℓ is a compact simply connected non-negatively curved manifold as in Theorem B.

As a consequence we derive the following *Group Structure Theorem*,

Corollary 2.4 (Fang-Grove [12]). *A group W is a co-compact reflection group of a complete non negatively curved manifold if and only if*

$$\mathsf{W} \cong \hat{\mathsf{W}}_0 \times \cdots \times \hat{\mathsf{W}}_\ell/\mathsf{N},$$

where $\hat{\mathsf{W}}_0$ is an affine Coxeter group, $\hat{\mathsf{W}}_i$, $1 \le i \le \ell$, is a spherical Coxeter group, and $\mathsf{N} \lhd \hat{\mathsf{W}}$ a normal subgroup isomorphic to a product of a torsion free lattice and an elementary abelian 2-group.

The overall strategy in our approach is based on the fact that follows from the work of Wörner [39] that the chamber C for a Coxeter action is a product $C = C_0 \times C_1 \times C_2 \times \ldots \times C_\ell$ where C_0 is a manifold without boundary (typically a point), and each C_i, $i \ge 1$ is a smooth non negatively curved convex manifold with corners, and either

(1) C_i has more than $n_i = \dim C_i$ faces, but any n_i faces of C_i meet,

or

(2) C_i has $k_i \leq n_i$ faces and they all meet.

Based on critical point theory of distance functions we can prove that, if there is only one factor and it is of type (1) then C is a simplex, which is a key to prove theorem 2.1.

3. Polar actions

Introduced by Szenthe [Sz] and independently Palais-Terng [PTe], an isometric action of a Lie group G on a compact Riemannian manifold M is said to be *polar* if there is a complete isometrically immersed submanifold $\Sigma \looparrowright M$, called a *section*, that meets all orbits of G and all intersections of Σ with orbits of G are perpendicular. It is clear that the dimension of Σ is equal to the cohomogeneity of the action. Observe that

- a section is always totally geodesic.

A polar action is called *hyperpolar* if the section Σ is flat.
Simple examples of polar Actions are

- *The rotation of* $\mathsf{SO}(2)$ *on* $\mathbb{R}^2$. A line passing through the origin is a section.
- *Every isometric action of cohomogeneity* 1. A normal geodesic that starts perpendicularly to a principal orbit is a section.
- *The linear conjugation action of* $\mathsf{SO}(n)$ *on the vector space* V *of real symmetric* $n \times n$ *matrices with trace zero.* The subspace of diagonal matrices in V serves as a section.
- *The conjugation action of a compact Lie group* G *on itself with a bi-invariant Riemannian metric.* The maximal tori are the sections.
- *The left action of* K *on the symmetric space* $\mathsf{G}\,/\,\mathsf{H}$*, and vice-versa left* H*-action on* $\mathsf{G}\,/\,\mathsf{K}$ where (G, K) and (G, H) are symmetric pairs. Such actions are called *Hermann actions.*
- *The isotropy representation of* K *of a symmetric space* $\mathsf{G}\,/\,\mathsf{K}$.

We recall that isometric actions of Lie groups G_1 and G_2 on Riemannian manifolds M_1 and M_2 respectively are said to be *orbit equivalent* if there is an isometry between M_1 and M_2 under which the orbits of G_1 and G_2 correspond.

Theorem 3.1 (Dadok [9]). *Let* K *be a connected compact Lie group and* $\rho : \mathsf{K} \to \mathsf{SO}(n)$ *a polar representation. Then there is a symmetric space* M *such that* ρ *is orbit equivalent to the isotropy representation of* M.

An easy but basic lemma due to Palais and Terng is

Lemma 3.2 (Palais-Terng [24]). *For any polar action of a Lie group* G *on a riemannian manifold, all of its slice representations are polar.*

Therefore, given a polar G action, by Dadok's theorem there is a symmetric space associated to the slice of every singular orbit. Moreover, given a section Σ through a singular point p, the tangent space $T_p\Sigma$ is the section of the slice representation of the isotropy group G_p. Let W_p be the Weyl group of the symmetric space, a linear reflection group on $T_p\Sigma$.

Definition 3.3 (Reflection Group). The reflection group W_Σ associated to a section Σ is the group generated by W_p for all singular orbit $p \in \Sigma$.

For a polar G action it is natural to make a

Definition 3.4 (Generalized Weyl group). Let G be a compact connected Lie group acting on a riemannian manifold M in a polar fashion. For a section Σ, the generalized Weyl group $\Pi_\Sigma(\mathsf{G}) = \mathsf{N}_\Sigma(\mathsf{G})/Z_\Sigma(\mathsf{G})$, where $N_\Sigma(\mathsf{G}) = \{g \in \mathsf{G} : g(\Sigma) = \Sigma\}$ is the stabilizer of Σ, and $Z_\Sigma(\mathsf{G})$ is the kernel of $N_\Sigma(\mathsf{G})$ action on Σ.

It is clear that the generalized Weyl group does not depend on the choice of a particular section. In the case the polar action is the conjugation action of a Lie group on itself, the generalized Weyl group is exactly the Weyl group of the Lie group.

Lemma 3.5 (Alexandrino [1]). *If M is simply connected, then $\Pi_\Sigma = \mathsf{W}_\Sigma$.*

• *Coisotropic actions and polar actions*. Recall that a submanifold N of a symplectic manifold $(M;\omega)$ is called *coisotropic* if

$$(T_pN)^{\perp_\omega} \subset T_pN$$

for all $p \in N$, where $(T_pN)^{\perp_\omega}$ denotes the subspace of T_pM that is ω-orthogonal to T_pN. In the special case that (M,ω) is a Kähler manifold it is easy to see that a submanifold N of M is coisotropic if and only if $J(\nu_pN) \subset T_pN$ for all $p \in N$, where J denotes the complex structure of M, and ν_pN the normal space of N in p.

A symplectic G-action on (M,ω) is called *Poisson* if there is a Lie algebra homomorphism $\lambda : \mathfrak{g} \to C^\infty(M)$ such that the hamiltonian vector field $X_{\lambda(\xi)}$ agrees with the infinitesimal action of ξ on M. The moment map of a Poisson action is defined as

$$\Phi : M \to \mathfrak{g}^*, \Phi(p)(\xi) = \lambda(\xi)(p)$$

For a compact Kähler manifold (M,ω), an isometric G action is called *multiplicity-free* ([18]) or *coisotropic* ([19]) if the principal G-orbits are coisotropic with respect to ω.

Let $\mathfrak{t}^*_+$ be the Weyl chamber of the dual abelian Lie algebra $\mathfrak{t}^*$. General convexity theorem established in [18, 21] claims that $\Phi(M)\cap\mathfrak{t}^*$ is a convex polytope. The following result, essentially due to [27], identifies a chamber of a polar action with the image of the moment map.

Theorem 3.6 (Podesta-Thorbergsson [27]). *Let $M \subset \mathbb{P}^n(\mathbb{C})$ be an irreducible smooth projective variety with the Fubini-Study metric. If G is a compact connected Lie group acting isometrically on M in a polar fashion. Then the orbit space M/G is homeomorphic to the convex polytope $\Phi(M) \cap \mathfrak{t}^*_+$.*

4. Polar actions and chamber systems

Let M be a compact, simply connected Riemannian manifold with a polar action by a compact Lie group G. Let Σ be a section. By 3.5 the generalized Weyl group Π (:=Π_Σ) coincides with the reflection group W, and hence acts on Σ by reflections. Let C be a closed chamber. Notice that C is isometric to $M/\mathsf{G} = \Sigma/\mathsf{W}$. Moreover, W may not be a Coxeter group in this generality, but is generated by finitely many reflections $s_1, s_2, \cdots, s_k$ satisfying

- $(s_i s_j)^{m_{ij}} = 1$ where $m_{ii} = 1$, and $m_{ij} = m_{ji} \in \mathbb{N}_{\geq 2} \cup \infty$.

Let $\mathsf{M} = (m_{ij})$ denote the symmetric $k \times k$ matrix. In this special case where W is a Coxeter group, M is the Coxeter matrix. In general W may have additional relations. The codimension 1 faces of C are named as types in $I = \{1, 2, \cdots, k\}$, corresponding to $s_1, \cdots, s_k$.

One can associate a (homogeneous) *chamber system* $\mathcal{C}(M; \mathsf{G})$ of type I by setting

$$\mathcal{C}(M; \mathsf{G}) = \bigcup\nolimits_{g \in \mathsf{G}} gC$$

with adjacency relations as follows: chambers $g_1 C$ and $g_2 C$ are called i-adjacent, denoted by $g_1 C \sim_i g_2 C$, if they share a face of type i. It is clear that every point of M is contained in some chamber gC.

We now recall some basic concepts from Tits geometry (cf. [30, 36]).

A chamber system $\mathcal{C}$ is called *connected* if any two chambers can be joint by a (finite) sequence of adjacent chambers, a *gallery*. In our circumstance, if $\mathcal{C}(M; \mathsf{G})$ is a connected chamber system, we can have a length metric d_H on M, namely, $d_H(x, y)$ being the length of shortest horizontal curves connecting x and y.

- *J-Residue*. For a subset $J \subset I$, a J-residue in a chamber subsystem of $\mathcal{C}$ is a set of chambers maximal with respect to being connected by J-galleries, i.e, galleries of types $i_1 \cdots i_\ell$ where all $i_j \in J$, it is, in particular, a connected chamber system over J.
- *Generalized m-gon*. For any integer $m \geq 1$, or for $m = \infty$, a generalized m-gon is a connected, bipartite graph of diameter m and girth $2m$, in which each vertex lies on at least two edges. Recall that a graph is bipartite if its set of vertices can be partitioned into two disjoint subsets such that no two vertices in the same subset lie on a common edge; the diameter is the maximum distance between two vertices, and the girth is the length of a shortest circuit. If $m = \infty$, this is simply a tree with no end points.

A generalized m-gon can be considered as a chamber system by taking the edges as chambers, and adjacency to mean having a common vertex, of one of the two appropriate types.

- *Geometry of Type* M. By definition a chamber system $\mathcal{C}$ is of type M, if for every $i \neq j$, the residue of type $\{i, j\}$ is a generalized m_{ij}-gon.
- *Buildings of Type* M. Let W be a Coxeter group with Coxeter matrix M. For a gallery of type $f = i_1 \cdots i_\ell$ there is an associated element $s_{i_1} \cdots s_{i_\ell} \in \mathsf{W}$. A *building* of type M is a chamber system $\mathcal{C}$ over I such that each codim. one face lies on at least two chambers, and having a W-distance function

$$\delta : \mathcal{C} \times \mathcal{C} \to \mathsf{W}$$

such that if f is a reduced word (i.e., minimal), then $\delta(C_1, C_2) = s_f$ if and only if C_1 and C_2 can be joined by a gallery of type f. In particular, any two chambers can be joined by a minimal gallery.

Example 4.1 (Polar Representations). The chamber system, $\mathcal{C}(\mathbb{S}^n; \mathsf{K})$ associated to the restriction of a polar representation of a compact Lie group K to the unit sphere $\mathbb{S}^n$ (without fixed points) is a fundamental example of a (spherical) Tits building (see [9, 35]).

Example 4.2 (Thin building). For a spherical Coxeter group W generated by reflections $s_1, \cdots, s_k$, the Coxeter complex is a $(k-1)$-dimensional simplicial complex which is a tiling of the sphere $\mathbb{S}^{k-1}$ by spherical simplices isometric to Δ^{k-1}. Coxeter complex is a *thin* building.

For a chamber system $\mathcal{C}$, there is a canonical associated complex $|\mathcal{C}|$, called the *geometric realization*. In particular, if $\mathcal{C}$ is a building, then $|\mathcal{C}|$ is a simplcial complex. A subcomplex of $|\mathcal{C}|$ isomorphic to a Coxeter complex (thin building) is called an *apartment*. We refer [4] for an equivalent definition of buildings in terms of axioms on apartments.

In the case that all proper residues are buildings, the so-called *universal cover* $\tilde{\mathcal{C}}$ can be viewed in the thin (length metric) topology on $\mathcal{C}$ as the usual topological universal cover. This cover clearly inherits the structure of a chamber system, and its fundamental group (deck transformations) acts freely as a group of automorphisms on it.

By invoking the following corollary of a profound theorem of Tits [36], Corollary 3 in Section 5.3 (cf. also [30], Theorem 4.9), we get

Theorem 4.3 (Tits). *The universal cover $\tilde{\mathcal{C}}$ of a connected chamber system $\mathcal{C}$ of type M over I is a building if and only if all residues of rank three are covered by buildings.*

From this we conclude that

Theorem 4.4 (Fang-Grove-Thorbergsson [13]). *Suppose M is a simply connected positively curved polar G manifold with orbit space M/G a simplex. If M is the Coxeter matrix of a spherical Coxeter group of rank at least 4, then the universal cover $\tilde{\mathcal{C}}(M; \mathsf{G})$ of the chamber system $\mathcal{C}(M; \mathsf{G})$ is a spherical building.*

We remark that the connectedness of the chamber system $\mathcal{C}(M; \mathsf{G})$ in the above theorem follows from a result of B. Wilking on dual foliations. Similarly, we have

Theorem 4.5. *Suppose M is a compact simply connected hyperpolar G manifold with orbit space M/G a simplex. If M is the Coxeter matrix of an affine Coxeter group of rank at least 3, then the universal cover $\tilde{\mathcal{C}}(M; \mathsf{G})$ of the chamber system $\mathcal{C}(M; \mathsf{G})$ is an affine building, provided $\mathcal{C}(M; \mathsf{G})$ is connected.*

Remark 4.6. The reflection group W in the above theorems may not be a Coxeter group, but its lifting $\hat{\mathsf{W}}$ is a Coxeter group of spherical type or affine type.

5. Polar actions on positively curved manifolds

In this section we present the rigidity theorem in [13] on polar actions on compact positively curved riemannian manifolds. The rigidity theorem completely classifies positively

curved polar manifolds of cohomogeneity at least 2, which in particular, broke the dream of constructing new examples of positively curved manifolds from polar actions in higher cohomogeneity.

Theorem 5.1 (Fang-Grove-Thorbergsson [13]). *A polar action on a simply connected, compact, positively curved manifold of cohomogeneity at least two is equivariantly diffeomorphic to a polar action on a compact rank one symmetric space.*

Remark 5.2. This is reminiscent of the situation for *isoparametric* submanifolds in euclidean spheres, where many isoparametric hypersurfaces are not homogeneous, whereas in higher codimensions by [34] they are the orbits of linear polar actions if they are irreducible or equivalently the orbits of isotropy representations of compact symmetric spaces by [9].

Remark 5.3. The above theorem is not true for cohomogeneity one actions. In fact infinite subfamilies of the Escheburg as well as of the Bazaikin spaces support cohomogeneity one actions as does a new example, non of which are even homogeneous spaces.

Remark 5.4. All polar actions on the simply connected, compact rank one symmetric spaces, i.e., the spheres and projective spaces, $\mathbb{S}^n, \mathbb{CP}^n, \mathbb{HP}^n$ and $\mathbb{OP}^2$ were classified in [9] and [26]. In all cases but the Cayley plane $\mathbb{OP}^2$ they are either linear polar actions on a sphere or they descend from such actions to a projective space.

For a polar G action on a positively curved manifold, notice that, since the sections are totally geodesic, hence positively curved as well. As a special case discussed in section 2 we have

Theorem 5.5 (Fang-Grove-Thorbergsson [13]). *The polar group* W *of a simply connected positively curved polar manifold of cohomogeneity at least two is a spherical Coxeter group or a* $\mathbb{Z}_2$ *quotient thereof. Moreover, the section with this action is equivariantly diffeomorphic to a sphere, respectively a real projective space with a linear action.*

• *Topological Tits Buildings of spherical type*. Recall, that a compact (spherical) building according to [BSp] is a Tits building $\tilde{\mathcal{C}}$ with a Hausdorff topology on the set $\mathrm{Vert}(\tilde{\mathcal{C}}) = V_1 \cup \cdots \cup V_{k+1}$ of all vertices such that the set $\tilde{\mathcal{C}}_{i_1,\cdots,i_{r+1}}$ of all simplices of type $(i_1, \cdots, i_{r+1})$ is closed in the product $V_{i_1} \times \cdots \times V_{i_{r+1}}$. With the induced topology on the k simplices $\tilde{\mathcal{C}}_{1,\cdots,k+1}$, $\tilde{\mathcal{C}}$ is called *compact, locally connected, infinite, metric* if $\tilde{\mathcal{C}}_{1,\cdots,k+1}$ has the appropriate property.

Example 5.6 (Classical Buildings). Let (U, K) be a symmetric pair, where U is a connected non-compact real semisimple Lie group without center. The isometric action of U on the symmetric space induces an action on the boundary sphere at infinity, $\mathbb{S}_\infty$, orbit equivalent to the subaction by K. The building at infinity of (U, K), or equivalently, the building associated to the polar K action on $\mathbb{S}_\infty$, is called the *classical building*.

The following main result of [6] is important for the proof of Theorem 5.1:

Theorem 5.7 (Burns-Spatzier). *An infinite, irreducible, locally connected, compact, metric, topologically Moufang building of rank at least* 2 *is classical.*

A key step in the proof of Theorem 5.1 is to endow a thick topology on the universal covering $\tilde{\mathcal{C}}(M, \mathsf{G})$ using the Hausdorff topology on compact subsets of M. We have

Theorem 5.8 (Fang-Grove-Thorbergsson [13]). *Whenever the universal cover $\tilde{\mathcal{C}}(M,\mathsf{G})$ of $\mathcal{C}(M,\mathsf{G})$ is a building, it admits the structure of a compact topological Moufang building.*

When the Coxeter diagram for M is connected of rank at least 4, by Theorem 4.4 and the above work of Burns and Spatzier [6], $\tilde{\mathcal{C}}(M;\mathsf{G})$ is a classical building. Our original polar G-action on the chamber system $\mathcal{C}(M,\mathsf{G})$ lifts to an action of $\tilde{\mathsf{G}}$ on the universal cover $\tilde{\mathcal{C}}(M;\mathsf{G})$, where $\tilde{\mathsf{G}}$ is a normal extension of the fundamental group π (of the chamber system $\mathcal{C}(M;\mathsf{G})$) by G. In the thick topology it turns out that both π and $\tilde{\mathsf{G}}$ are compact Lie subgroups of the topological automorphism group of the topological building $\tilde{\mathcal{C}}(M,\mathsf{G})$. Therefore, $\tilde{\mathcal{C}}(M,\mathsf{G})$ is homeomorphic to the sphere $\mathbb{S}_\infty$, and the action of $\tilde{\mathsf{G}}$ is orbit equivalent to a linear polar representation of the maximal compact subgroup of the topological automorphism group. In particular, π acts freely on the sphere in a continuous fashion, hence π is trivial, S^1 or S^3. From this Theorem 5.1 follows in the case M is irreducible of rank at least 4.

As a by-product we have the following simply connected C_3 geometry which is not building:

Theorem 5.9 (Fang-Grove-Thorbergsson [13]). *The universal cover $\tilde{\mathcal{C}}$ of the chamber system $\mathcal{C}(\mathbb{OP}^2,\mathsf{SU}(3)\,\mathsf{SU}(3))$ for the exceptional action on $\mathbb{OP}^2$ is a C_3 geometry which is not a building.*

The existence of such C_3 geometries is well known in the "real estate community" (see [23]), but this particular example which arises very naturally in our context was not known until now (see also [22]).

6. Bruhat-Tits buildings and hyperpolar actions on non-negatively curved manifolds

It is more flexible to construct hyperpolar actions on non-negatively curved manifolds using simple operations, e.g., the componentwise product of hyperpolar actions on M and N will be a hyperpolar action on the product $M\times N$; moreover, given a hyperpolar action by a compact Lie group K on M, and a compact Lie group $\mathsf{G}\supset\mathsf{K}$, the balanced product $\mathsf{G}\times_{\mathsf{K}}M$ with the action of G is again hyperpolar, with induced metric from the product metric on $\mathsf{G}\times M$. In order to concentrate to some fundamental building blocks, it is necessary to introduce

Definition 6.1. A hyperpolar G-action on M is *irreducible* if the lifted affine Coxeter group $\hat{\mathsf{W}}$ is irreducible.

The following is a special and more precisely stated version of a conjecture from [13]:

Conjecture. *An irreducible hyperpolar action of cohomogeneity at least 2 on a simply connected nonnegatively curved compact manifold is equivariantly diffeomorphic to a quotient of a polar action on a symmetric space.*

Remark 6.2. Recall that the conjugation action of a Lie group on itself, as well as the Hermann actions are all hyperpolar. An affirmative answer to the above conjecture provides essentially a riemannian geometric characterization of irreducible symmetric spaces. The conjecture however is not true for cohomogeneity 1 actions.

The following confirms the conjecture when the Coxeter diagram does not have double bonds of rank at least 3:

Theorem 6.3. *Assume (M, G) is an irreducible hyperpolar manifold of rank at least 3. If the chamber system $\mathcal{C}(M;\mathsf{G})$ is connected of types $\tilde{\mathsf{A}}_n$, $\tilde{\mathsf{D}}_n$, $\tilde{\mathsf{E}}_6$, $\tilde{\mathsf{E}}_7$ or $\tilde{\mathsf{E}}_8$. Then, there is a G-equivariant principal L-bundle $\hat{M} \to M$, such that $\hat{M}$ is $\mathsf{G}\times\mathsf{L}$-equivariant diffeomorphic to a compact Lie group with a hyperpolar isometric action.*

Remark 6.4. Results in the above theorem can be made more precisely, depending on the multiplicity m, as follows

(I) Assume $\mathcal{C}(M;\mathsf{G})$ is of type $\tilde{\mathsf{A}}_n$;

- $(\hat{M}, \mathsf{G}\times\mathsf{L}) = (\mathsf{SU}(n), \mathsf{SO}(n)\times\mathsf{SO}(n))$ if $m = 1$.
- $(\hat{M}, \mathsf{G}\times\mathsf{L}) = (\mathsf{SU}(n); \mathsf{SU}(n))$ or $(\mathsf{SU}(2n); \mathsf{Sp}(n)\times\mathsf{SO}(2n))$ if $m = 2$.
- $(\hat{M}, \mathsf{G}\times\mathsf{L}) = (\mathsf{SU}(2n); \mathsf{Sp}(n)\times\mathsf{Sp}(n))$ if $m = 4$.

(II) Assume $\mathcal{C}(M;\mathsf{G})$ is of type $\tilde{\mathsf{D}}_n$;

- $(\hat{M}, \mathsf{G}\times\mathsf{L}) = (\mathsf{SO}(2n), \mathsf{SO}(n)\times\mathsf{SO}(n)\times\mathsf{SO}(n)\times\mathsf{SO}(n))$ if $m = 1$.
- $(\hat{M}, \mathsf{G}\times\mathsf{L}) = (\mathsf{SO}(2n), \mathsf{SO}(2n))$ if $m = 2$.

(III) Assume $\mathcal{C}(M;\mathsf{G})$ is of type $\tilde{\mathsf{E}}_6$;

- $(\hat{M}, \mathsf{G}\times\mathsf{L}) = (\mathsf{E}_6, \mathsf{Sp}(4)/\mathbb{Z}_2\times\mathsf{Sp}(4)/\mathbb{Z}_2)$ if $m = 1$.
- $(\hat{M}, \mathsf{G}\times\mathsf{L}) = (\mathsf{E}_6, \mathsf{E}_6)$ if $m = 2$.

(IV) Assume $\mathcal{C}(M;\mathsf{G})$ is of type $\tilde{\mathsf{E}}_7$;

- $(\hat{M}, \mathsf{G}\times\mathsf{L}) = (\mathsf{E}_7, \mathsf{SU}(8)/\mathbb{Z}_2\times\mathsf{SU}(8)/\mathbb{Z}_2)$ if $m = 1$.
- $(\hat{M}, \mathsf{G}\times\mathsf{L}) = (\mathsf{E}_7, \mathsf{E}_7)$ if $m = 2$.

(V) Assume $\mathcal{C}(M;\mathsf{G})$ is of type $\tilde{\mathsf{E}}_8$;

- $(\hat{M}, \mathsf{G}\times\mathsf{L}) = (\mathsf{E}_8, \mathsf{SO}(16)/\mathbb{Z}_2\times\mathsf{SO}(16)/\mathbb{Z}_2)$ if $m = 1$.
- $(\hat{M}, \mathsf{G}\times\mathsf{L}) = (\mathsf{E}_8, \mathsf{E}_8)$ if $m = 2$.

Remark 6.5. For the remaining types $\tilde{\mathsf{B}}_n, \tilde{\mathsf{C}}_n, \tilde{\mathsf{F}}_4$ it is more difficult, but work is in progress.

Remark 6.6. If the chamber system $\mathcal{C}(M;\mathsf{G})$ is not connected, then $M = \mathsf{G}\times_{\mathsf{K}} N$, where K is a compact Lie subgroup, N is a polar K manifold whose chamber system $\mathcal{C}(N;\mathsf{K})$ is a gallery connected component of $\mathcal{C}(M;\mathsf{G})$. For this reason it suffices to consider connected chamber system.

According to Theorem 4.5, the universal cover $\tilde{\mathcal{C}}(M;\mathsf{G})$ of the chamber system $\mathcal{C}(M;\mathsf{G})$, associated to a hyperpolar G action on M, is an affine Bruhat-Tits building, if the rank is at least 3. However, we do not have an analouge of the Burns-Spatzier theory for "topological" Bruhat-Tits buildings.

• *Bruhat-Tits buildings of types $\tilde{\mathsf{A}}_n$, $\tilde{\mathsf{D}}_n$, $\tilde{\mathsf{E}}_6$, $\tilde{\mathsf{E}}_7$ or $\tilde{\mathsf{E}}_8$.*

For the affine building $\tilde{\mathcal{C}}(M;\mathsf{G})$, consider the maximal apartment system, the union of all Coxeter subbuildings in $\tilde{\mathcal{C}}(M;\mathsf{G})$. According to Bruhat-Tits ([30, 38]), there is a complete

discrete valuation field $\mathbb{K}$ associate to the building $\tilde{\mathcal{C}}(M;\mathsf{G})$, whose residue field k is determined by the spherical residues. It is obvious, in our cases, since the spherical residues are the buildings associated to the slice representations of compact Lie groups, that the residue field k must be $\mathbb{R}, \mathbb{C}$ or $\mathbb{H}$. Moreover, the non-commutative division algebra $\mathbb{H}$ occurs only when the type is $\tilde{\mathsf{A}}_n$ (since our diagram is simply laced, cf. [30, 35]). It follows from algebra that the complete discrete valuation field $\mathbb{K} = k((t))$, the field (division algebra) of formal Laurent series, and the valuation $v(f) \in \mathbb{Z}$ is the lowest degree of f with nonzero coefficient.

According to Bruhat-Tits, given a *special type* vertex o in the Coxeter diagram, the equivalence classes of sectors of type o defines a spherical building of type $\Pi - \{o\}$ where Π is the Coxeter diagram, called the spherical building at infinity. The spherical building at ∞ depends on the field $\mathbb{K}$. By Bruhat-Tits, if $\mathbb{K}$ is complete, then an affine building $\mathcal{C}$ of rank at least 4 is determined by the spherical building at ∞, denoted by $\mathcal{C}(\infty)$. The automorphism group $\mathcal{A}$ of the building $\mathcal{C}$ is the same as the automorphism group of the spherical building $\mathcal{C}(\infty)$, which is an algebraic group over $\mathbb{K}$.

It is an important feature of the affine buildings of types $\tilde{\mathsf{A}}_n$, $\tilde{\mathsf{D}}_n$, $\tilde{\mathsf{E}}_6$, $\tilde{\mathsf{E}}_7$, $\tilde{\mathsf{E}}_8$, that they are uniquely determined by the valuation field $(\mathbb{K}, v)$. Moreover, the residue field k is commutative unless the type is $\tilde{\mathsf{A}}_n$. The group $\mathcal{A}$ must be a split algebraic group over $\mathbb{K}$ of the same type. We point out that this is no longer true if the diagram has double bonds! In particular, for an $\tilde{\mathsf{A}}_n$ building, $\mathcal{A}$ contains $\mathsf{SL}_{n+1}(\mathbb{K})$ as a normal subgroup with quotient the automorphism group of the field $\mathbb{K}$ and diagram automorphism $\mathbb{Z}_2$.

• *Bruhat-Tits buildings and polar actions on Hilbert spaces*. As noticed above, spherical buildings over the classical fields are in 1-1 correspondence with polar representations. It is not completely clear yet, what should be the analogous correspondence for Bruhat-Tits buildings, but polar actions on Hilbert spaces first studied by Terng, seems to provide a model.

Let G be a compact connected semi-simple Lie group. The action of H^1-loops $H^1(\mathsf{S}^1, \mathsf{G})$ on the Hilbert space $V = H^1(\mathsf{S}^1, \mathfrak{g})$ given by the gauge transformation

$$g \cdot u = gug^{-1} - g'g^{-1}$$

is polar, and the constant loops with values in a Cartan subalgebra $\mathfrak{t}$ is a section. More generally, we have the following

Theorem 6.7 (Terng [33]). *Let G be a compact Lie group and $\mathsf{H} \subset \mathsf{G} \times \mathsf{G}$ be a closed Lie subgroup. Assume the biaction of H on G is polar with a flat torus section A. Let $\mathfrak{a}$ denote the Lie algebra of A. Let $P(\mathsf{G};\mathsf{H}) = \{g \in H^1([0,1];G) | (g(0);g(1)) \in \mathsf{H}\}$ and $V = H^0([0,1];\mathfrak{g})$. Then the gauge action of $P(\mathsf{G};\mathsf{H})$ on V is polar with section $\hat{\mathfrak{a}}$, the constant loops in $\mathfrak{a}$.*

We conjecture that every gallery connected component of the chamber system associated to the $P(\mathsf{G};\mathsf{H})$ action on V is an affine Bruhat-Tits building.

Loop products, Poincaré duality, index growth and dynamics

Nancy Hingston

Abstract. A metric on a compact manifold M gives rise to a length function on the free loop space ΛM whose critical points are the closed geodesics on M in the given metric. Morse theory gives a link between Hamiltonian dynamics and the topology of loop spaces, between iteration of closed geodesics and the algebraic structure given by the Chas-Sullivan product on the homology of ΛM. Poincaré Duality reveals the existence of a related product on the cohomology of ΛM.

A number of known results on the existence of closed geodesics are naturally expressed in terms of nilpotence of products. We use products to prove a resonance result for the loop homology of spheres. There are interesting consequences for the length spectrum. We discuss briefly related results in Floer and contact theory.

Mark Goresky and Hans-Bert Rademacher are collaborators.

Mathematics Subject Classification (2010). Primary 58E10; Secondary 55P50.

Keywords. Closed geodesics, string topology, Morse theory.

1. Introduction

The search for closed geodesics on metric spheres has a long and very interesting history [10, 36, 51, 55, 57]. It features a number of beautiful and simple ideas whose details took decades to work out correctly. The history is also rich because of the variety of methods used to attack to the problem. The approach of dynamics is to look among the geodesics for those that close up, that is, to look for periodic orbits of the geodesic flow. The variational approach is to look among the closed curves for those that are geodesic. This latter method was developed extensively by Morse and is based on the fact that closed geodesics are critical points of the length or energy function.

Let M be a compact, simply connected manifold of dimension n with a Riemannian metric g. Let ΩM be the *based loop space* and ΛM the *free loop space* of M:

$$\begin{aligned} \Omega = &\quad \Omega M = H^{1,2}((S^1,*),(M,*)) \\ \subset &\quad \Lambda = \Lambda M = H^{1,2}(S^1,M). \end{aligned}$$

For technical reasons it turns out best to use not the length or the energy function, but the square-root of the energy:

$$F:\ \Lambda \to \mathbb{R}$$

Proceedings of the International Congress of Mathematicians, Seoul, 2014

$$F(\gamma) = \sqrt{\int |\dot{\gamma}|^2 dt}.$$

Then $F(\gamma)$ has units of length, and $F(\gamma) \geq length(\gamma)$, with equality if and only if γ has constant speed. *The reader will not go wrong in thinking that F is the length function.* The critical points of F are precisely the closed gedesics on (M, g), and thus one can walk in the footsteps of Morse [55] and use the topology of Λ to find closed geodesics on M. The (approximate) correspondence between the topology of Λ and critical points/values of F works more specifically like this:

$$H_k(\Lambda) \approx \text{ critical points of index } k$$

(A *critical point* of F is a loop $\gamma \in \Lambda$ where all the first partial derivatives of F vanish. The *index* of γ is the maximal dimension of a subspace of the tangent space to Λ at γ where the second derivative is negative definite.) We get a map

$$X \in H_k(\Lambda) \to Cr(X) \in \mathbb{R}$$

where

$$Cr(X) =: \inf\{a \in \mathbb{R} : X \text{ has a representative in } \Lambda^{\leq a} =: F^{-1}[0, a]\}$$

is the *critical level* of the homology class X.

The "correspondence" follows from the fact that $Cr(X)$ is a critical value of F; and there is a critical point (or points) $\gamma \in \Lambda$ of length $Cr(X)$ with

$$index(\gamma) \leq \deg X \leq index(\gamma) + nullity(\gamma)$$

on which the homology class X is said to "lie hanging". Thus one can hope to get a rough "count" of closed geodesics by taking a "count" of homology classes. There is however a major difficulty: *iteration*. If $\gamma \in \Lambda$ is a closed geodesic, then so is each of its iterates $\gamma^m \in \Lambda$, where

$$\gamma^m(t) = \gamma(mt).$$

These iterates are geometrically indistinguishable, and should together contribute just 1 to our count of geodesics. But they are very different points in Λ; they have different lengths,

$$\ell(\gamma^m) = m\ell(\gamma)$$

and in general they have different indices as critical points. From the point of view of critical point theory, one closed geodesic looks like an army!

Bott [11] proved that the index of the iterates grows approximately linearly, and Gromoll and Meyer [34] that the contributions to the homology from the iterates of a single closed geodesic are bounded. Together these results led to the Theorem of Gromoll and Meyer: If the rank of $H_k(\Lambda; \mathbb{Q})$ is unbounded, then for any metric on M there must be infinitely many closed geodesics.

Sullivan and Vigué-Poirrier [66] proved that (for M compact and simply connected) the rank of $H_k(\Lambda; \mathbb{Q})$ is unbounded if and only if the cohomology ring $H^*(M; \mathbb{Q})$ is not a truncated polynomial ring in one generator; thus the Theorem of Gromoll and Meyer applies to "most" such manifolds. However for spheres and projective spaces the rank of $H_k(\Lambda; \mathbb{Q})$

is bounded (the groups $H_k(\Lambda;\mathbb{Q})$ are periodic in k for large k), and the Theorem does not apply. While for the standard metric on these spaces all geodesics are closed, it is not known whether there is a metric on a sphere or projective space of dimension > 2 with closed geodesics, or a metric with only one closed geodesic! It is known ([6, 8, 10, 27, 33, 39, 51]) that for any metric on S^2, and [38, 59] for a *generic* metric on a sphere or projective space, there are infinitely many closed geodesics. There are *Finsler* metrics on spheres and projective spaces with only finitely many closed geodesics [46, 68]. For our purposes the difference between Finsler metrics and Riemannian metrics is that for a Finsler metric the metric is not required to be reversible; thus reversing the direction will likely change the length of a path. Most of the methods from Riemannian geometry for proving the existence of closed geodesics also work for Finsler metrics, but "curve-shortening" [33] may introduce self-intersections.

If we hope to count closed geodesics on M via the correspondence between homology and critical points, we are led to the question: *Is there an algebraic operation on $H_k(\Lambda)$ that corresponds to iteration of closed geodesics?* In some critical cases the answer is yes.

2. Products

We begin with the Pontryagin product [58]

$$\bullet_\Omega : H_j(\Omega) \times H_k(\Omega) \to H_{j+k}(\Omega).$$

It is induced by the concatenation product on loops

$$\begin{aligned} \bullet = \ : \bullet_\Omega : \Omega \times \Omega &\to \Omega \\ (\alpha, \beta) &\to \alpha \bullet_\Omega \beta \end{aligned}$$

(First go around α, then β.) We (abusively) think of cycles X, Y in Ω as subsets: $X = \{\alpha\} \subset \Omega$, $Y = \{\beta\} \subset \Omega$; then in $H_*(\Omega)$ the product is given by

$$\begin{aligned} [X] \bullet_\Omega [Y] &= : [X \bullet_\Omega Y] \\ &= : [\{\alpha \bullet_\Omega \beta\}_{\alpha \in X; \beta \in Y}] \end{aligned}$$

Example 2.1. Let $M = S^n$ be the round sphere of radius 1 in $\mathbb{R}^{n+1}$ Then every geodesic on M is closed, and the critical values of F are the numbers $2m\pi$, $m \in \mathbb{Z}^{\geq 0}$ A *circle* on S^n is the intersection of S^n with a 2-plane in $\mathbb{R}^{n+1}$, parameterized with constant speed and with minimal period 1 (unless constant). Pick a vector $\overrightarrow{V}$ at the basepoint $*$ in S^n. Let A be the $(n-1)$-dimensional cycle on ΛS^n consisting of all circles on S^n beginning at $(*)$ with tangent vector $\lambda \overrightarrow{V}$ for some $\lambda \geq 0$, and let U be the 0-dimensional cycle on ΛS^n consisting of the constant loop at $(*)$. We invite the reader to check that

$$\begin{aligned} Cr[U] &= 0 \\ Cr[A] &= 2\pi \\ [U] \bullet_\Omega [A] &= [A] \bullet_\Omega [U] = [A], \end{aligned}$$

and that $[U]$ is the identity element in the Pontryagin ring.

Next what is

$$[A] \bullet_\Omega [A] =: [A]^2 \ ?$$

It should be clear that

$$Cr([A]^2) \leq 2Cr[A] = 4\pi;$$

indeed using the fact that $[A] \bullet_\Omega [A] = [A] \bullet_\Omega [A']$, where A' is the cycle on ΛS^n consisting of all circles on S^n beginning at $(*)$ with tangent vector $\lambda \overrightarrow{V'}$ with $\overrightarrow{V'} \neq \overrightarrow{V}$, and the fact that every loop in $A \bullet_\Omega A'$ of length $\geq 2\pi$ has a "corner" that can be cut to make it shorter, we see that $Cr[A \bullet_\Omega A] < 4\pi$, from which it follows that $Cr[A \bullet_\Omega A] \leq 2\pi$ (since $Cr[A \bullet_\Omega A]$ is a critical value of F). In fact $[A \bullet_\Omega A] = [B]$, where B is the $(2n-1)$-cycle consisting of all circles beginning at $(*)$, and the Pontryagin ring is the polynomial ring

$$H_*(\Omega S^n) = \mathbb{Z}[A].$$

Note that $[A]$ is *nonnilpotent*, that is for all m we have $[A]^m \neq [0]$, but $[A]$ is *level nilpotent*, by which we mean that, for some $m > 1$, $Cr\ [A]^m < mCr\ [A]$: One can show that

$$Cr\ [A]^{2m-1} = Cr\ [A]^{2m} = Cr\ [B]^m = 2m\pi.$$

So $[B]$ *is* level nonnilpotent.

Chas Sullivan product. This is a product on the homology of the free loop space $H_*(\Lambda)$, with degree $-n$:

$$\bullet_{CS} : H_j(\Lambda) \times H_k(\Lambda) \to H_{j+k-n}(\Lambda)$$

We give here the intuitive idea of the definition from the original paper [16] of Chas and Sullivan; for a more rigorous definition see [18, 19]. Let

$$e : \ \Lambda \to M$$
$$e(\gamma) = \gamma(0)$$

be the evaluation map. Let $X = \{\alpha\}$ and $Y = \{\beta\}$ be cycles in Λ. Assume that eX and eY intersect transversally in M. Then

$$[X] \bullet_{CS} [Y] =: [\{\alpha \bullet \beta : \alpha \in X,\ \beta \in Y, \text{ and } e\alpha = e\beta\}].$$

Example 2.2. Let $M = S^n$ be the round sphere of radius 1 in $\mathbb{R}^{n+1}$ Let $A, B, U \subset \Omega \subset \Lambda$ be as above. (But for degree reasons U is not the unit in the Chas-Sullivan ring, and $A^2 \neq B$.) Let C be the $(3n-2)-$ dimensional cycle in Λ consisting of all (parameterized) circles on S^n ("all circles great and small"), and E the $n-$ dimensional cycle in Λ consisting of all constant loops. We invite the reader to verify the following

(1) $[C] \bullet_{CS} [E] = [C]$

(2) $[E]$ is the identity element in the Chas-Sullivan ring.

(3) $[A] \bullet_{CS} [A] = 0$

(4) If X ,$Y \subset \Omega$, then $[X] \bullet_{CS} [Y] = 0$

(5) $[U] \bullet_{CS} [C] = [B]$

The Chas-Sullivan rings of spheres and projective spaces, which do not depend on the metric, were computed by [20], using somewhat more algebraic techniques. These rings are finitely generated (the generators listed above are almost enough) and the product is highly nontrivial; for example the element $[C]$ is nonnilpotent: $[C]^m \neq 0$, and with the standard metric on M the generator $[C]$ is level-nonnilpotent:

$$Cr\ [C]^m = mCr\,[C] = 2m\pi.$$

3. Poincaré duality

These cycles, and their Chas-Sullivan products, would have looked very familiar to Morse [55], who studied the topology of ΛS^n in the hope of finding closed geodesics. The cycles and products are also reminiscent of the work of of Bott-Samelson on manifolds all of whose geodesics are closed, which beautifully rounds out the Bott-Gromoll-Meyer-Vigué-Poirrier-Sullivan circle of ideas. When I first heard the definition of the Chas-Sullivan product (at the lunch table at the Institute for Advanced Study in 2005) I recognized it right away because I knew well these examples. I asked, "Where is the other product?"

There is a pervasive symmetry in the study of loop spaces and closed geodesics that can be thought of as Poincaré duality in the free loop space. If F is a Morse function on an oriented, compact manifold X of dimension N, then Poincaré duality can be thought of as "turning X upside down" like an hourglass: Following Milnor [54] we take the vertical axis to be the F-axis; thus turning the space X upside down is the same as replacing F with $-F$. The homology of X is computed by the cell complex of Morse-chains; for each critical point γ of index λ we have a disk of dimension λ that "hangs down" from γ and is attached below. The cohomology is computed by the cell complex of Morse cochains; for each critical point of coindex μ there is a a disk of dimension μ that "hangs up" from a critical point. The Kronecher product between homology and cohomology is given by the intersection pairing on Morse cycles and Morse cocycles. A homology class in dimension λ, when turned upside down, becomes the cohomology class of dimension $N - \lambda$ that is its Poincaré dual. As the free loop space is infinite dimensional, there is no duality map between homology and cohomology groups in complementary dimensions. However many things "work the same" if you "turn the free loop space upside down", that is if you do Morse theory on the free loop space with the function $-F$ instead of F. The guiding principle that every phenomenon in the free loop space has an dual counterpart has proven to be very powerful in a variety of contexts. We will present evidence of this duality principle and let you decide for yourself.

Mark Goresky and the author [32] looked for and found the product that is Poincaré dual to the Chas-Sullivan product, and investigated its properties. It was clear from the duality principle that the product should be of the form[1]

$$\circledast : H^j(\Lambda) \otimes H^k(\Lambda) \to H^{j+k+n-1}(\Lambda). \quad (*)$$

[1] In [32] the product is of the form

$$H^j(\Lambda, \Lambda^0) \otimes H^k(\Lambda, \Lambda^0) \to H^{j+k+n-1}(\Lambda, \Lambda^0)$$

but there is a way to extend the product to the form $(*)$.

The associated homology coproduct

$$\vee : H_i(\Lambda) \to \Sigma_{j+k=i+1-n} H_j(\Lambda) \otimes H_k(\Lambda)$$

had been previously introduced by Sullivan [62].

The "1" in the degree $(n-1)$ of the cohomology product is related to the index of the iterates of closed geodesics (see below), and to the observed fact that the duality principle works best not in the space Λ of *(parameterized)* $H^{2,1}$ loops, but in the space of *optimally parameterized* loops, the loops that are parameterized proportional to arclength. In this space F and $-F$ are on a more even footing, since we have thrown out all the nonoptimal parameterizations. These nonoptimal parameterizations are all directions in which F increases, for (arguably) no interesting reason if one is concerned with the geometry of loops. There is also a product on the based loops

$$\circledast_\Omega : H^j(\Omega) \otimes H^k(\Omega) \to H^{j+k+n-1}(\Omega).$$

whose relationship with the loop cohomology product $\circledast$ reflects the relationship [20] between the Chas-Sullivan and Pontryagin products. In [32] Goresky and the author showed that when M has a metric with all geodesics closed (for example if M is a sphere or projective space) and $n > 2$, the products $\circledast$ and $\circledast_\Omega$ are highly nontrivial; in particular the rings are finitely generated, as are the Pontryagin ring and the Chas-Sullivan rings computed by Cohen Jones and Yan [20]. Moreover the associated graded rings from the grading induced by the energy function (or F) in these cases can be computed by a general method based on Morse theory and geometry, and are also finitely generated and nontrivial. The complete ring structure is computed for spheres in [32]; they have the remarkable property that the rings are independent of the dimension n when n is odd, or when the coefficients are $\mathbb{Z}/2\mathbb{Z}$.

The *critical level of a cohomology class* is the reflected version of the critical level of a homology class:

$$Cr(x) = \sup\{a : x \text{ has support in } \Lambda^{\geq a}\}$$

where $\Lambda^{\geq a} = F^{-1}[a, \infty)$. The Chas-Sullivan product $\bullet$ and the loop cohomology product $\circledast$ satisfy the following dual basic inequalitites:

$$\begin{aligned} Cr(X \bullet Y) \leq & Cr(X) + Cr(Y) \quad \text{(homology)} \\ Cr(x \circledast y) \geq & Cr(x) + Cr(y) \quad \text{(cohomology)} \end{aligned}$$

On the based loop space, the Pontryagin product and the loop cohomology products satisfy the same inequalities. The cup-product does *not* satisfy such an inequality; see [32] 16.1. A cohomology class x is *level nilpotent* if for some m, $Cr(x^{\circledast m}) > mCr(x)$. The level nilpotence of a homology or cohomology product is related to the *index growth* of the critical point on which it lies hanging. Bott [11] proved, using a beautiful argument based on intersection theory in the symplectic group, that the index and nullity of the iterates γ^m of a closed geodesic γ satisfy the inequalities

$$\begin{aligned} m \cdot index(\gamma) - (m-1)(n-1) \leq & index(\gamma^m) \\ \leq & index + nullity(\gamma^m) \\ \leq & m \cdot index(\gamma) + (m-1)(n-1) \quad (**) \end{aligned}$$

If *equality*

$$m \cdot index(\gamma) - (m-1)(n-1) = index(\gamma^m)$$

holds for $m = m_0$, then if holds for $1 \leq m \leq m_0$, and we say the index growth is *minimal* up to $m = m_0$. If equality

$$index + nullity(\gamma^m) = m \cdot index(\gamma) + (m-1)(n-1)$$

holds for $m = m_0$, then if holds for $1 \leq m \leq m_0$, and we say the index growth is *maximal* up to $m = m_0$. *In the extreme cases the Chas-Sullivan powers, and the loop cohomology powers correspond to the iteration of closed geodesics*: When a homology class X lies hanging on a closed geodesic γ with minimal index growth, the Chas-Sullivan product X^{*m} lies hanging on the iterate γ^m; when a cohomology class x lies hanging on a closed geodesic γ with maximal index growth, the cohomology product x^{*m} lies hanging on the iterate γ^m.

As further evidence of Poincaré Duality here are some restatements of old theorems in terms of loop products. When these theorems were proved, the products had not been discovered. In retrospect it is clear that these theorems are naturally expressed in terms of products.

Bott [11]: *Let M be a compact Riemannian manifold. If all closed geodesics are non-degenerate (in the sense of Morse theory), then every homology class in $H_*(\Lambda)$ is level-nilpotent, and every cohomology class in $H^*(\Lambda)$ is level-nilpotent.*

Hingston [39]: *Let M be a compact Riemannian manifold. If there is a homology class in $H_*(\Lambda)$ that is not level nilpotent, then M has infinitely many closed geodesics. In particular, there is a closed geodesic of length L, $m_0 \in \mathbb{Z}^+$, and a sequence $\sigma_m \downarrow 0$ so that if $m \geq m_0$, M has a closed geodesic with length $\ell \in (mL, mL + \sigma_m)$.*

Hingston [40]:*Let M be a compact Riemannian manifold. If there is a cohomology class in $H^*(\Lambda)$ that is not level nilpotent, then M has infinitely many closed geodesics. In particular, there is a closed geodesic of length L, $m_0 \in \mathbb{Z}^+$, and a sequence $\sigma_m \downarrow 0$ so that if $m \geq m_0$, M has a closed geodesic with length $\ell \in (mL - \sigma_m, mL)$.*

The proofs in [39] and [40] are quite different, and the second is much more difficult. They are both variations on "Bangert's Lemma" [7]. There are many possibilities for the local geometry of a closed geodesic whose index for large m lies between the two bounds in $(**)$. But in the limiting cases the geometry is forced into a rigid mold which can be described exactly. The proof in [39] was discovered by accident; the guiding light of the Poincaré Duality principle then motivated the author to find the proof of [40].

Many of the early work on loop spaces was done not in the infinite dimensional setting, but in the finite dimensional approximation described by Morse [55] and refined by Bott [12] and Milnor [54]. The finite dimensional approximation space is a space of piecewise geodesic loops consisting of N minimal geodesic pieces, and parameterized by the vertices $\{(x_1, , , , , x_N)\} \subset M^N$. The finite dimensional approximation space is a finite dimensional manifold that for N large enough carries the topology and the Morse theory of $\Lambda^{\leq L}$ for L arbitrarily large. The Chas-Sulllivan product and the loop cohomology product are *almost* Poincaré dual in the finite dimensional approximation. The catch is that duality works best in the optimally parameterized loops, but the space of optimally parameterized piecewise geodesic loops (i.e. those for which the N pieces all have the same length) has singularities and (worse) spurious critical points. The loop cohomology product was originally defined by Goresky and the author using Poincaré duality in the finite dimansional approximation. When transformed to the infinite dimensional setting, the definition took it current form.

4. Applications to dynamics

In the search for periodic points it often turns out that the (necessarily degenerate) cases of minimal and maximal index growth for all m are precisely the cases not covered by other methods and thus the last cases to be proved. One example is the earlier mentioned Theorem [6, 8, 10, 27, 33, 39, 51]: Any Riemannian metric on S^2 has infinitely many closed geodesics. This was first proved by arguments of Lusternick-Schnirelmann/Ballmann/Grayson, Birkhoff, Bangert, and Franks. The last case to be proved was the case of extremal index growth. The author in [39] gave an alternative argument for the last step using the ideas outlined above. In his beautiful 2005 Annals paper [5] Angenent gives a new proof of the existence of infinitely many closed geodesics on S^2 except in the cases covered in [39]. Another example: The arguments in [39] and [40] are also valid for Finsler metrics. In 2010 Bangert and Long [9] proved the existence of at least two closed geodesics for any Finsler metric on S^2 by reducing the proof to the case of extremal growth.This result is sharp due to the wonderful examples of Katok [46, 69].

5. Related ideas in Floer / symplectic / contact theory

We mention briefly some related results and refer the reader to the references for detail [4, 22, 23, 26].

(1) Let M be a closed, symplectic manifold of dimension $2n$ with (for the sake of simplicity, though this is just the tip of the iceberg) $\pi_2 M = 0$. Let

$$H : S^1 \times M \to \mathbb{R}$$

be a periodic Hamiltonian. Following Arnold, Conley, Zehnder, Salamon, Floer, and many others, we look for periodic points of the Hamiltonian flow, which is given in local coordinates by

$$\dot{x} = J\nabla H(x,t).$$

These periodic points are critical points of the action function $\mathcal{A} : \Lambda M \to \mathbb{R}$. The critical points all have infinite index and coindex, but Floer theory was invented to circumvent this difficulty. When M is a torus, one can use a finite dimensional approximation. It was proved by Conley-Zehnder (in the case where M is a torus), and Salamon-Zehnder, that if all period 1 orbits are nondegenerate, then there are periodic orbits of arbitrarily high minimal integer period. The role of the nondegeneracy hypothesis is to ensure that the growth of the index (the Conley-Zehnder index in this case) is not extremal. An argument in the spirit of Bangert's Lemma, and in the spirit of [39, 40], applies in the case of extremal index growth, and was used by the author [41] (in the case where M is a torus) and by Ginzburg [28] to prove Conley's Conjecture: There are always periodic orbits of arbitrarily high minimal integer period. In [30] Ginzburg and Gürel state these results in terms of the pair-of-pants product on the Floer homology of the free loop space, and nonnilpotence of certain level homology classes occurs precisely when there is maximal or minimal index growth. One also has the exact analogs of the statements regarding the critical values: $\ell \in (mL, mL + \sigma_m)$ and $\ell \in (mL - \sigma_m, mL)$ in the cases of slow and fast growth.

(2) If M is a compact manifold, the cotangent bundle T^*M carries a natural symplectic structure. Let $H : S^1 \times T^*M \to \mathbb{R}$ be a periodic Hamiltonian of quadratic type. (The geodesic flow on T^*M is given by the Hamiltonian $H = |p|^2$.) There is an isomorphism between the Floer homology of the cotangent bundle of M and the homology of the free loopspace of M, in which the pair-of-pants product corresponds to the Chas-Sullivan product. [1, 2, 60, 64]. Abbondandolo and Schwarz [3] have described the product on the Floer side that corresponds to the loop coproduct.

(3) The contact setting. A contact form on M gives rise to an action function A on the free loop space ΛM, whose critical points are the closed Reeb orbits. Contact homology is the associated Morse homology, introduced using Floer theoretic tools by Eliashberg-Giventhal-Hofer in [25]. The iteration properties of local Floer homology were studied by Ginzburg-Gurel [30] and analogs of the theorem of Gromoll-Meyer were found in [45], McLean [1, 2, 17, 53, 60, 64, 65]. There are analogs of the theorem of Bangert-Long [9] mentioned above by reducing to the case of extremal growth: [31, 48]. See also [24, 29]. There are products in this context; see [17].

6. Critical levels of spheres

If M is compact and simply connected and carries a Riemannian metric, Gromov [35] (see also [56]) proved that the set of points

$$(C, d) = (Cr(X), \deg X) \in \mathbb{R}^2,$$

where $X \in H_d(\Lambda)$, $Cr(X)$ is the critical level of X, and $Cr(X) > 0$, lie between two lines: There are numbers $\mu, \nu > 0$ so that

$$\mu Cr(X) < \deg X < \nu Cr(X).$$

Note the critical levels have units of length. For simplicity all homology and cohomology will have rational coefficients. In [42] the author and Rademacher prove the

Theorem 6.1 (Resonance Theorem for Spheres). *If M is a sphere of dimension > 2, with a fixed Riemannian or Finsler metric g , then the points $(Cr(X), \deg X)$ lie at a finite distance from a line: there are constants$\overline{\alpha}$ and $\beta > 0$ so that*

$$\overline{\alpha} Cr(X) - \beta < \deg X < \overline{\alpha} Cr(X) + \beta.$$

The slope

$$\overline{\alpha} = \overline{\alpha}_g$$

is called the *global mean frequency* of of (M, g) and has units of conjugate points per unit length. While we have a proof of this theorem we still lack an explanation, and the theorem still seems quite surprising!

There is a spectral sequence bigraded by (length, degree), converging to $H_*(\Lambda)$, whose $\mathcal{E}^1$ page is a direct sum of the local level homology of the all the iterates of all the closed geodesics on M in the given metric. By a theorem of Bott [11] mentioned earlier $(**)$, the contributions of all the iterates of a single closed geodesic γ to the $\mathcal{E}^1$ page lie at a finite distance from the line

$$d = \overline{\alpha}_\gamma C$$

whose slope is the mean frequency

$$\overline{\alpha}_\gamma = \frac{\alpha_\gamma}{\ell(\gamma)},$$

where

$$\alpha_\gamma = \lim_{m\to\infty} \frac{index(\gamma^m)}{m}$$

is the *average index* of γ.

If the sectional (or, in the Finsler case, flag) curvature K of M is bounded between constants

$$K_1 < K < K_2$$

then the mean frequency is bounded as follows:

$$\frac{\sqrt{K_1}(n-1)}{\pi} < \overline{\alpha}_\gamma < \frac{\sqrt{K_2}(n-1)}{\pi}$$

For the round metric, and for the Katok metrics [46, 69] the curvature K is constant and thus the mean frequency of every closed geodesic satisfies

$$\overline{\alpha}_\gamma = \overline{\alpha}_g = \frac{\sqrt{K}(n-1)}{\pi},$$

though in general the closed geodesics in the Katok metrics have different lengths and different average indices. For these metrics all nonzero terms in the $\mathcal{E}^1$ page lie at a finite distance from the line

$$d = \frac{\sqrt{K}(n-1)}{\pi} C$$

and the theorem follows immediately. However an *open mapping theorem* [42] tells us that the average indices of geometrically distinct closed geodesics can be perturbed independently. Thus we expect that for a generic metric the $\mathcal{E}^1$ page has entries lying (approximately) along a union of lines, one line for each closed geodesic γ, with the spacing along each line determined by $\ell(\gamma)$. One proceeds from one page of the spectral sequence to the next by allowing certain generators to "cancel out" in pairs. Somehow in this process the generators that remain at the $\mathcal{E}^\infty$ page all lie with in a finite distance of the line $d = \overline{\alpha}C$. Unless a closed geodesic γ has mean frequency $\overline{\alpha}_\gamma$ *exactly* equal to the global mean frequency $\overline{\alpha}$, only a finite number of homology classes can lie hanging on the iterates of γ.

The Katok examples include nondegenerate Finsler metrics on spheres with only finitely many closed geodesics. If $M = S^n$ with $n > 2$ odd, it is proved in [42] :

Corollary 6.2. *For a metric g in a neighborhood of the Finsler metrics, and not too far from the round metric, at least one of the following holds:*

(1) *There are at least two closed geodesics γ with mean frequency $\overline{\alpha}_\gamma = \overline{\alpha}_g$.*

(2) *There is a sequence of closed geodesics $\{\gamma_j\}$ with mean frequencies $\overline{\alpha}_j \neq \overline{\alpha}_g$, satisfying*

$$\lim_{j\to\infty} \overline{\alpha}_j = \overline{\alpha}_g.$$

This is reminiscent of the conjecture of Hofer-Wysocki-Zehnder [44] to the effect that every Reeb flow for the tight 3-sphere has exactly two or infinitely many closed Reeb orbits. There is a conjecture that on S^2 a Finsler metric carries exactly two or infinitely many closed geodesics. This is proved in [37] near the standard metric. For $n > 2$ there is hope that the number "two" in the Corollary could be improved to the minimal number of geodesics for a Katok metric on S^n. A famous open problem is to prove the existence of infinitely many closed geodesics for any Riemannian metric on a sphere of dimension $n > 2$. As mentioned above, when $n = 2$ this statement has been proved for Riemannian metrics and is false for Finsler metrics by the Katok examples. An even more beautiful theorem would include the Finsler metrics and say that the only exceptions to the existence of infinitely many closed geodesics are very simple metrics in the Katok model.

Acknowledgements. The author is grateful to the Institute for Advanced Study, and especially to Helmut Hofer for the vibrant mathematical community they have fostered. Thanks to Umberto Hryniewicz for numerous discussions and for his help in putting together this paper.

The surface subgroup and the Ehrenepreis conjectures

Jeremy Kahn and Vladimir Markovic

Abstract. We survey our recent results including the surface subgroup theorem and the Ehrenpreis conjecture. applications and future direction are discussed.

Mathematics Subject Classification (2010). 20H10, 57M50.

Keywords. Surface subgroup theorem, Ehrenepreis.

1. Introduction

1.1. The surface subgroup theorem. One of the corollaries of the Geometrization Theorem is that most 3-manifolds admit hyperbolic structure. Therefore when studying topology of a 3-manifold one can often assume that the manifold is endowed with a hyperbolic structure. This greatly expands the tool-kit that is available bringing hyperbolic geometry, analysis and dynamics into play.

An essential step in the eventual proof of the Virtual Haken and the Virtual Fibering Conjectures is the Surface Subgroup Theorem:

Theorem 1.1 (Kahn-Markovic). *Every closed hyperbolic 3-manifold contains a quasifuchsian surface subgroup.*

Recall that every hyperbolic manifold $\mathbf{M}^3$ can be represented as the quotient $\mathbf{M}^3 = \mathbb{H}^3/\mathcal{G}$, where $\mathbb{H}^3$ is the hyperbolic 3-ball and $\mathcal{G}$ a Kleinian group. Using geometry and relying on fine statistical properties of the frame flow on hyperbolic manifolds we proved in [14] the following result which implies the Surface Subgroup Theorem:

Theorem 1.2 (Kahn-Markovic). *Let $\mathbf{M}^3 = \mathbb{H}^3/\mathcal{G}$ denote a closed hyperbolic 3-manifold. Given any $\epsilon > 0$, there exists a $(1+\epsilon)$-quasifuchsian group $G < \mathcal{G}$.*

(Recall that a group is K-quasifuchsian if it is K-quasiconformal deformation of a Fuchsian group.)

The nearly geodesic surfaces we constructed in [14] have large genus (it can be shown that the genus of S grows polynomially with $\frac{1}{\epsilon}$). Moreover, each such surface $f(S) \subset \mathbf{M}^3$ represents the trivial homology class in $H_2(\mathbf{M}^3, \mathbb{Z})$.

A three holed sphere with a hyperbolic metric and geodesic boundary is called a pair of pants (after Thurston). Given $R > 0$, the pair of pants whose all 3 cuffs have the same length

Proceedings of the International Congress of Mathematicians, Seoul, 2014

$2R$ is called the R-perfect pair of pants. Let $\mathbf{S}(R)$ denote a genus 2 Riemann surface that is obtained by gluing two R-perfect pairs of pants along their cuffs with the twist of $+1$. The induced orbifold is denoted by $\mathrm{Orb}(R)$.

Theorem 1.2 is proved by the showing that for a given closed hyperbolic 3-manifold $\mathbf{M}^3$ and for every $\epsilon > 0$ and every large enough R, there exists a Riemann surface $S = S(\epsilon, R)$ and a continuous map $f : S \to \mathbf{M}^3$ such that the induced map between universal covers $\partial f : \partial\mathbb{H}^2 \to \partial\mathbb{H}^3$ is $(1+\epsilon)$-quasisymmetric. Moreover, the surface S admits a decomposition into R-perfect pants that are glued to each other with the twist of $+1$. In particular, such a Riemann surface S is a regular holomorphic cover of the Model Orbifold $\mathrm{Orb}(R)$.

For fixed $\epsilon, R > 0$, a good pair of pants (in a given hyperbolic 3-manifold) is a pair of pants whose cuffs have complex half-length ϵ close to R (see Section 3). In order to find the map $f : S \to \mathbf{M}^3$ one is guided by the following principles:

1. Do not start by trying to specify the surface S.
2. Instead, consider the good pants $\mathbf{\Pi}$ immersed in $\mathbf{M}^3$ as the building blocks and eventually construct the surface $f(S) \subset \mathbf{M}^3$ by appropriately assembling together all the good pants from $\mathbf{\Pi}$.

Typically there are many ways in which one can assemble the pants and get an immersed surface.

Consider any finite formal sum $W \in \mathbb{N}\mathbf{\Pi}$. Taking two copies of each pair of pants (with opposite orientations) one obtains the new formal sum $2W \in \mathbb{N}\mathbf{\Pi}$. Then along every geodesic in $\mathbf{M}^3$ that appears as a boundary curve of some of the pants from $2W$ one can pair off the pairs of pants that contain that geodesic as a boundary component (there may be many ways in which one can pair off these pants and we choose one way of doing it for each such geodesic). One can now assemble these pairs of pants according to the instructions to construct a closed surface in $\mathbf{M}^3$.

So, we have constructed a closed surface S and a map $f : S \to \mathbf{M}^3$, but the induced map between fundamental groups is not necessarily injective. For example, if W denotes a single pair of good pants then the surface S is a genus two surface obtained by gluing together two pairs of pants. However, the corresponding map $f : S \to \mathbf{M}^3$ collapses one pair of pants onto the other and therefore the induced map between fundamental groups is not injective.

Observe that every such surface $f(S) \subset \mathbf{M}^3$ represents the trivial homology class in $H_2(\mathbf{M}^3, \mathbb{Z})$. This is because each pair of pants from W is used twice and with different orientations.

It is clear from the previous discussion that if one wants to glue pairs of good pants in $\mathbf{M}^3$ to get a nearly geodesic surface (and thus a quasifuchsian surface) then any two pairs of pants that are glued along a geodesic should meet at an angle that is close to π. It turns out that in order to assemble good pants and construct a nearly geodesic surface in $\mathbf{M}^3$, what is needed is that the good pants are equidistributed in $\mathbf{M}^3$, which follows from the exponential mixing of the frame flow. We will explain this in more details in the next section, but here we state the mixing principle:

Lemma 1.3 (Exponential Mixing). *Let $\mathbf{M}^3$ denote a closed hyperbolic manifold (in particular a hyperbolic surface). There exists $\mathbf{q} > 0$ that depends only on $\mathbf{M}^3$ such that the following holds. Let $\psi, \phi : \mathcal{F}(\mathbf{M}^3) \to \mathbb{R}$ be two C^1 functions (here $\mathcal{F}(\mathbf{M}^3)$ denotes the frame bundle, if $\mathbf{M}^3$ is a Riemann surface this is just the tangent bundle). Then assuming*

that the volume of the frame bundle $\mathcal{F}(\mathbf{M}^3)$ is equal to 1, for every $r \in \mathbb{R}$ the inequality

$$\left| \int_{\mathcal{F}(\mathbf{M}^3)} (\mathbf{g}_r^* \psi)(x)\phi(x)\, d\Lambda(x) - \int_{\mathcal{F}(\mathbf{M}^3)} \psi(x)\, d\Lambda(x) \int_{\mathcal{F}(\mathbf{M}^3)} \phi(x)\, d\Lambda(x) \right| \leq Ce^{-\mathbf{q}|r|},$$

holds, where $C > 0$ only depends on the C^∞ norm of ψ and ϕ.

2. The Ehrenpreis conjecture

The Ehrenpreis conjecture was an old conjecture in the theory of Riemann surfaces. The idea is that although two Riemann surfaces S and T do not have a common finite cover (all covers in this proposal are regular and unbranched) one should still be able to interpolate between certain finite covers of S and T respectively (according to Gromov this statement goes back to Riemann). The precise formulation of the conjecture is as follows:

Conjecture 2.1 (Ehrenpreis Conjecture). *Let S and T denote two closed Riemann surfaces of genus at least 2 and let $\epsilon > 0$. Then there exists finite covers S_1 and T_1 of S and T respectively, such that S_1 and T_1 are $(1+\epsilon)$ quasiconformal to each other (that is there exists $(1+\epsilon)$-quasiconformal map $f : S_1 \to T_1$).*

In [16] J. Kahn and I have announced a proof of this conjecture.

Remark 2.2. The Enhrenpreis Conjecture is harder to prove because there may be more pants on one side of a closed geodesic than the other. So we need to add in a signed sum of pants so that there are an equal number on both sides of every good geodesic. Computing this correction requires the "good pants homology", which we develop in [16].

In fact, we prove this conjecture by proving the statement that every closed hyperbolic Riemann surface has a virtual decomposition into good pairs of pants that are glued by a twist that is nearly equal to $+1$. Recall that (ϵ, R)-good pair of pants is a pair of pants whose cuffs have the length ϵ-close to R. We prove the following virtual decomposition type theorem:

Theorem 2.3 (Kahn-Markovic). *Let S be a hyperbolic surface and let $\epsilon > 0$. Then for every large enough $R > 0$, the surface S has a finite cover S_1 that can be decomposed into (ϵ, R)-good pants such that every two adjacent pairs of good pants are glued with the twist that is $\frac{\epsilon}{R}$ close to $+1$.*

We then show that this surface S_1 is quasiconformally close to a finite cover of the model orbifold $\mathrm{Orb}(R)$ (see above for the definition of the Model orbifold $\mathrm{Orb}(R)$):

Theorem 2.4 (Kahn-Markovic). *Let S be a closed hyperbolic Riemann surface. Then for every $K > 1$, and every large enough $R > 0$ there are finite covers S_1 and O_1 of the surface S and the model orbifold $\mathrm{Orb}(R)$ respectively, and a K-quasiconformal map $f : S_1 \to O_1$.*

The Ehrenpreis conjecture is an immediate corollary of this theorem.

Theorem 2.5 (Kahn-Markovic). *Let S and M denote two closed Riemann surfaces. For any $K > 1$, one can find finite degree covers S_1 and M_1 of S and M respectively, such that there exists a K-quasiconformal map $f : S_1 \to M_1$.*

The proof of the above Virtual Decomposition theorem follows from the equidistribution of the good pants (in much the same way as in the proof of the Surface Subgroup Theorem) and from the Correction theory that we will outline below.

3. The setup and main ideas

3.1. The feet of a pair of pants. A pair of pants is a compact hyperbolic Riemann surface with geodesic boundary that is homeomorphic to the sphere minus three disjoint round open disks. Any such pair of pants is determined by the lengths of the three boundary components, which are called cuffs. For reasons which will become clear in the next section, we will prefer to work with the half-lengths, which of course are half the lengths of the three cuffs. In particular, an R-perfect pair of pants is a pair of pants whose three half-lengths are equal to R (for a given $R > 0$).

An orthogeodesic for a compact hyperbolic surface S with geodesic boundary is a proper geodesic arc which is orthogonal to the boundary of S at both endpoints. The long orthogeodesics for a pair of pants are the three embedded orthogeodesics which divide S into two components—these are the embedded orthogeodesics from a cuff to itself. The short orthogeodesics are the three other embedded orthogeodesics (from one cuff to another); the three short orthogeodesics together divide S into two right-angled hexagons. Because a right-angled hexagon is determined by the lengths of three alternating sides, these two right-angled hexagons must be isometric. It follows that the six endpoints of the three short orthogeodesics divide the three cuffs into six segments such that each cuff is divided into two equal segments. At each endpoint of an orthogeodesic η, there is a unique normal vector to the boundary that generates η (via the geodesic flow); we call this normal vector the foot of η at that endpoint. We say that the feet of a pair of pants at a given cuff are the feet of the two short orthogeodesics from that cuff to the two other cuffs. Thus there are two feet of a pair of pants in the normal bundle of each cuff of the pants.

3.2. Good and perfect panted surfaces. Now suppose that we are given a closed hyperbolic Riemann surface S of genus $g > 1$, and a maximal collection $\mathcal{C}$ of disjoint curves on S. (By a *curve* we mean an (smooth) isotopy class of smoothly embedded closed curves). Each of these curves can be uniquely realized as a closed geodesic on S; together they divide S into $2g - 2$ pairs of pants. For each closed geodesic γ, there are two of these pairs of pants with γ as boundary (or γ appears as two boundaries of the same pair of pants). We can then find two pairs of feet, and holding up the (universal cover of the) cuff vertically, we see that the two feet on the right are a certain distance above the two feet on the left—except that this distance is only defined up to the half-length of the cuff. Therefore, to each cuff C, we have two invariants: the positive real half-length of the geodesic representative γ of C, and the shear, which is defined up to the half-length of γ. There is a natural topology on panted surfaces (of a given genus), for which these $6g - 6$ invariants provide local coordinates.

An R-perfect panted surface is one for which all of the cuffs of the pants have half-length R, and all of the shears are equal to 1. An R, ϵ-good pair of pants is one for which all three cuffs have half-length within ϵ of R, and an R, ϵ-good panted surface is one made of out of good pants, for which all of the shears are within ϵ/R of 1. (Sometimes we will write perfect for R-perfect, and good for R, ϵ-good). For any good panted surface $S, \mathcal{C}$, there is a path through good panted surfaces to a perfect panted panted surface $S', \mathcal{C}'$ and a homeomorphism

$h\colon S \to S'$ determined (up to isotopy) by that path. (The path is determined up to homotopy rel endpoints, and hence the homeomorphism is determined up to isotopy). We say that $S', \mathcal{C}'$ is the *perfect version* of $S, \mathcal{C}$, and that h is the *perfecting homeomorphism*.

We prove the following theorem which provides a criterion for two large genus surfaces to be close to each other in the corresponding Moduli space with respect to the Teichmüller metric.

Theorem 3.1. *There exists R_0, K_0, and $\epsilon_0 > 0$ such that the following holds. Suppose that $S, \mathcal{C}$ is an R, ϵ good panted surface, and $R > R_0$, $\epsilon < \epsilon_0$. Let $S', \mathcal{C}'$ be the perfect version of $S, \mathcal{C}$. Then there is a $K_0\epsilon$-quasiconformal diffeomorphism $h\colon S \to S'$ that is homotopic to the perfecting homeomorphism.*

The proof of this theorem is very delicate and we omit it here (the reader can see Section 2 in [14]). It should be stressed that the requirement that pants are glued with the twist by $+1$ plays a vital and subtle role and the criterion would not hold without it.

Theorem 2.5 follows if we can prove the following:

Theorem 3.2. *For every closed hyperbolic Riemann surface S we can find a finite cover $\hat{S}$ and a maximal set $\mathcal{C}$ of disjoint curves on $\hat{S}$ such that $\hat{S}, \mathcal{C}$ is a good panted surface.*

or, more precisely, if we can prove the following:

Theorem 3.3. *For every closed hyperbolic Riemann surface S, $\epsilon > 0$, and $R > R_0(S, \epsilon)$, we can find a finite cover $\hat{S}$ and a maximal set $\mathcal{C}$ of disjoint curves on $\hat{S}$ such that $\hat{S}, \mathcal{C}$ is an R, ϵ good panted surface.*

Let us briefly explain this implication. We glue two R-perfect pairs of pants together with a shear of 1 at each cuff to obtain an R-perfect surface S_R with an orientation-preserving isometry group of size 12. The model orbifold O_R is the quotient of S_R by this group of isometries; the three cuffs of half-length R on S_R map to a single segment η_R of length $R/2$ on O_R connecting two of the the order 2 points on O_R. *Any R-perfect panted surface S is a finite cover of O_R* in such a way that the R-cuffs of S are the components of the pre-image of η_R by the cover. It follows that any two R-perfect panted surfaces have a common finite cover. Then given two surfaces S and T, and $\epsilon > 0$, we find $R, \epsilon/2K_0$ good panted covers $\hat{S}$ and $\hat{T}$ (for any R sufficiently large). By Theorem 3.1, these are each $\epsilon/2$ close to perfect surfaces, which then have a common cover. Therefore $\hat{S}$ and $\hat{T}$ have common covers within ϵ of each other in the Teichmüller metric, and we are finished.

Recall that the Teichmüller metric on the moduli space of compact Riemann surfaces of genus g is defined so that the distance between S and S' is $\log K$, where K is the infimum of K for which there exists a K-quasiconformal diffeomorphism $h\colon S \to S'$. We will often write $1 + \epsilon$-quasiconfomal when we should really be writing e^{ϵ}-quasiconformal, and so forth—the reader can make the necessary modifications.

3.3. Building a good cover. We can now begin to describe how we prove Theorem 3.3. Recall that S is our given closed hyperbolic Riemann surface. A good curve for S (really an R, ϵ good curve) will be a closed geodesic γ (or the associated free homotopy class) whose half-length $\mathbf{hl}(\gamma)$ is within ϵ of R. We will denote the set of R, ϵ good curves by $\Gamma_{\epsilon,R}$; it is a finite set, with size asymptotic to $4\epsilon e^{2R}/2R$ when R is large.

Now let Π be a topological pair of pants, and let $f\colon \Pi \to S$ be a π_1 injective immersion. Then there is a unique hyperbolic metric on Π (up to pullback by a diffeomorphism isotopic

to the identity) such that Π becomes a geometric pair of pants (with geodesic boundary) and f is isotopic to an isometric immersion. If Π is then a good pair of pants (for some R, ϵ), then we say that f represents an immersed good pair of pants in S. For any R and ϵ, there is a finite set $\Pi_{\epsilon,R} \equiv \Pi_{\epsilon,R}(S)$ of good pairs of pants in S. Using the exponential mixing of the geodesic flow on S, and the consequent estimates on the number of long orthogeodesic segments connecting a pair of geodesic segments on S, we prove that the feet of good pants are evenly distributed in the normal bundle of every good geodesic:

Theorem 3.4. *Suppose that $\gamma \in \Gamma_{\epsilon,R}$, and let I be an interval in the (square root of the) normal bundle for γ. The number $n(\gamma, I)$ of feet of pants in $\Pi_{\epsilon,R}$ that lie in I is estimated by*

$$n(\gamma, I) = \frac{n(\gamma)|I|}{2\mathbf{l}(\gamma)} + O(e^{(1-\alpha)R}),$$

where $n(\gamma)$ is the total number of pairs of feet on both sides on γ, and $\alpha \equiv \alpha(S)$. Moreover,

$$n(\gamma) \sim 2\epsilon^2 R e^R / \operatorname{Area}(S),$$

for R large given S and ϵ.

What is important in this statement is that the error term for $n(\gamma, I)$ is exponentially small (in R) compared to $n(\gamma)$. Up to this error term, the feet of the pants with γ as a boundary are evenly distributed on the normal bundle of γ. Let us suppose, by some miracle, that the distribution of feet is also *balanced*: that there are exactly as many feet on one side of γ as the other. (By the two sides of γ we mean the two components of the unit normal bundle for γ). Then it is a simple and elementary exercise to show that there is a bijection $\sigma\colon \Pi_\gamma^+ \to \Pi_\gamma^-$ (where Π_γ^+ and Π_γ^- are the pants with feet on the left and right sides of the unit normal bundle of the oriented geodesic γ) such that for any pair of pants $\pi \in \Pi_\gamma^+$, the feet of $\sigma(\pi)$ on γ are $1 + O(e^{-\alpha R})$ above the feet of π on γ. We then use this bijection to glue the pants in Π_γ^- to the pants of Π_γ^+ (along the cuffs that map to γ), and doing this with every $\gamma \in \Gamma_{\epsilon,R}$, we obtain a closed surface, made of the pants in $\Pi_{\epsilon,R}$, that is a finite cover of S. Because the shears are exponentially close to 1, and an exponentially small number is less than ϵ/R when R is large, we have obtained a good panted cover of S, and have thereby proven Theorem 3.3.

Of course, we have no reason to believe that there are exactly the same number of pants on the two sides of γ. We will describe in a few paragraphs how to correct this imbalance, but first we will describe the analogous construction in a closed hyperbolic three-manifold M, and we will see that in three dimensions, the work is a bit easier, because there is no imbalance to correct.

3.4. Working in three dimensions. Suppose that $f\colon \Pi \to M$ is a π_1-injective map from a topological pair of pants Π to M. We are interested in describing f up to homotopy. We can assume that f maps the boundaries of Π to closed geodesics $\gamma_0, \gamma_1, \gamma_2$ in M. We can also assume that f maps three disjoint arcs in Π (connecting the three boundary components) into three geodesic segments η_0, η_1, η_2 such that η_0 connects γ_1 and γ_2 and meets both geodesics orthogonally (and similarly for η_1 and η_2). These three arcs will divide Π into two (filled) hexagons, and f will map the boundary of each of these hexagons into skew right-angled hexagons.

Skew right-angled hexagons in $\mathbb{H}^3$ are very much like right-angled hexagons in $\mathbb{H}^2$, with $\mathbb{R}$ replaced by $\mathbb{C}$. That is, a skew right-angled hexagon is determined by the complex length

of three alternating sides. The real part of the complex length is the real length, and the imaginary part, which is defined up to multiples of $2\pi i$, is the amount of rotation from one adjacent side to the other adjacent side, after one adjacent side has been translated along the given side to meet the other adjacent side. Because the complex lengths of the η_i are the same in both skew right-angled hexagons, the two hexagons are isometric, and hence each γ_i is divided into two segments by the endpoints of $\eta_{i\pm1}$, and these two segments have equal complex length (with respect to the $\eta_{i\pm1}$). We call this complex length the complex half-length $\mathbf{hl}(\gamma)$ of γ. The *feet* or initial vectors of the orthogeodesics $\eta_{i\pm1}$ are elements of the unit normal bundle $N^1(\gamma)$, which is a torsor for $\mathbb{C}/(2\pi i\mathbb{Z} + 2\mathbf{hl}(\gamma)\mathbb{Z})$, and the difference of between the two feet is exactly $\mathbf{hl}(\gamma)$. Thus we can think of the unordered pair of feet as living in $N^1(\sqrt{\gamma})$, the set of unordered pairs that differ by $\mathbf{hl}(\gamma)$; it is a torsor for $\mathbb{C}/(2\pi\mathbb{Z} + \mathbf{hl}(\gamma)\mathbb{Z})$.

We let $\Gamma_{\epsilon,R}$ be the good closed geodesics in M (so $\gamma \in \Gamma_{\epsilon,R}$ if the complex length $\mathbf{l}(\gamma)$ satisfies $|\mathbf{l}(\gamma) - 2R| < 2\epsilon$), and we let $\mathbf{\Pi}_{\epsilon,R}$ be the good pants in M (so $f\colon \Pi \to M$ is in $\mathbf{\Pi}_{\epsilon,R}$ if for each $\gamma \in f(\partial\Pi)$ we have $|\mathbf{hl}(\gamma) - R| < \epsilon$).

We can then prove the analogue of Theorem 3.4 for distribution of the feet of good pants:

Theorem 3.5. *Suppose that $\gamma \in \Gamma_{\epsilon,R}$, and let $I \times J$ be a rectangle in the (square root of the) normal bundle for γ. The number $n(\gamma, I)$ of feet of pants in $\mathbf{\Pi}_{\epsilon,R}$ that lie in I is estimated by*

$$n(\gamma, I) = \frac{n(\gamma)|I \times J|}{2\pi\Re(\mathbf{hl}(\gamma))} + O(e^{(1-\alpha)R}),$$

where $n(\gamma)$ is the total number of pairs of feet in $N^1(\sqrt{\gamma})$, and $\alpha \equiv \alpha(M)$. Moreover,

$$n(\gamma) \sim 8\epsilon^4 R e^{2R}/\mathrm{Vol}(M)$$

for R large given M and ϵ.

It then follows that if $A_\gamma \subset N^1(\sqrt{\gamma})$ is the set of pairs of feet of good pants on γ, then we can find a permutation $\sigma\colon A_\gamma \to A_\gamma$ such that

$$|\sigma(x) - x - \pi i - 1| < \epsilon/R$$

for every $x \in A$.

Then we can assemble the pants of $\mathbf{\Pi}_{\epsilon,R}$ into a "good panted surface group representation" using the "doubling trick". We take two copies of every pair of pants in $\mathbf{\Pi}_{\epsilon,R}$, and give them the two possible orientations. Then for any $\gamma \in \Gamma_{\epsilon,R}$, we have two sets, Π^+_γ and Π^-_γ, of oriented pants with γ as boundary, where each pair of pants in Π^+_γ induces a "positive" orientation on γ (arbitrarily chosen), and the opposite holds for Π^-_γ. We then find $\hat{\sigma}\colon \Pi^+_\gamma \to \Pi^-_\gamma$ such that the pair of feet of $\hat{\sigma}(\Pi)$ on γ is σ applied to the pair of feet of Π on γ. In this way we pair off all of the boundary components of the two copies of the good pants.

We then obtain an immersed panted surface $f\colon S \to M$ (with a maximal set $\mathcal{C}$ of curves on S). It is an ϵ, R good panted surface group representation in the following sense: the restriction of f to every component of $S - \bigcup\mathcal{C}$ is a pair of good pants, and for every $C \in \mathcal{C}$, the complex shear coordinates—the difference (in $N^1(\sqrt{\gamma})$) between the feet of the pants on one side of C and the other—is within ϵ of $i\pi + 1$.

It follows that f is essential by the following theorem (closely analogous to Theorem 3.1), which gives a way to certify the injectivity of the induced homomorphism $\rho\colon \pi_1(S) \to \mathrm{Isom}(\mathbb{H}^3)$.

Theorem 3.6. *There exists R_0, K_0, and $\epsilon_0 > 0$ such that the following holds. Suppose that $\rho\colon \pi_1(S) \to \mathrm{Isom}(\mathbb{H}^3)$ is an R, ϵ good panted surface group representation, and $R > R_0$, $\epsilon < \epsilon_0$. Then we can find an R-perfect panted Fuchsian group (which we then think of as acting on $\mathbb{H}^3$), and an equivariant map $h\colon \mathbb{H}^3 \to \mathbb{H}^3$ that extends to be $K_0\epsilon$-quasiconformal on the boundary. In particular, ρ is a faithful, discrete, and quasifuchsian representation.*

3.5. The good pants homology and the Ehrenpreis conjecture. We now return the the problem of proving Theorem 3.3, which implies the Ehrenpreis conjecture. We will let $\Gamma_{\epsilon,R}$ denote the set of *oriented* geodesics, and we will let $\mathbb{Z}\Gamma_{\epsilon,R}$ denote the set of integral formal sums of elements of $\Gamma_{\epsilon,R}$, where we will think of opposite orientations of the same geodesic as summing to zero. Let $\partial\colon \Pi_{\epsilon,R} \to \mathbb{Z}\Gamma_{\epsilon,R}$ be the obvious boundary map. We prove that when R is large given S and ϵ, there is a map $q\colon \mathbb{Q}\Gamma_{\epsilon,R} \to \mathbb{Q}\Pi_{300\epsilon,R}$ such that, for any $\alpha \in \mathbb{Q}\Pi_{\epsilon,R}$,

1. $\partial q(\partial\alpha) = \partial\alpha$, and
2. $||q(\alpha)||_\infty \leq e^{-R}P(R)||\alpha||_\infty$ for any weighted sum α of good curves.

(Where $P(R)$ is a polynomial in R that depends only on S and ϵ). Letting $\alpha \equiv \Sigma\Pi_{\epsilon,R}$ be the formal sum of the good pants, we replace α with $\alpha' = \alpha - q(\partial\alpha)$ to obtain a "balanced" sum of pants ($\partial\alpha' = 0$) with the same equidistribution properties[1] as in Theorem 3.4 (because $q(\partial\alpha)$ is small compared to α). We can then pair these pants across every good geodesic to obtain an immersed (or covering) panted surface which, by Theorem 3.1, is $1+\epsilon$ quasiconformally equivalent to the corresponding perfect surface, thus proving the Ehrenpreis conjecture.

We will briefly outline the construction of the map q and the demonstration of the estimate (2). We define the "good pants homology" as $\mathbb{Q}\Gamma_{\epsilon,R}/\partial\mathbb{Q}\mathbf{\Pi}_{\epsilon,R}$; if two sums of good curves differ by an element of $\partial\mathbb{Q}\mathbf{\Pi}_{\epsilon,R}$, we will say that they are $\mathbf{\Pi}_{\epsilon,R}$ homologous. We prove that, if A_i, B_j, U, V $(i,j = 0,1)$ are elements of $\pi_1(S,*)$ such that the broken closed geodesic $[\cdot A_i \cdot U \cdot B_j \cdot V \cdot]$ has "bounded inefficiency" and the geodesic segments $\cdot U \cdot$ and $\cdot V \cdot$ are sufficiently long, then

$$\sum_{i,j=0,1} (-1)^{i+j}[A_iUB_jV] \equiv 0$$

in $\mathbf{\Pi}_{\epsilon,R}$ (really $\Pi_{300\epsilon,R}$) homology, provided, of course, that the $[A_iUB_jV]$ are the free homotopy classes (or, if you like, conjugacy classes in $\pi_1(S,*)$) of good curves.

This then permits us to define, for $A, T \in \pi_1(S,*)$,

$$A_T \equiv \frac{1}{2}\left([TAT^{-1}U] - [TA^{-1}T^{-1}U]\right),$$

where U is fairly arbitrary. Then A_T in good pants homology is independent of the choice of U. We can show through a series of lemmas (see [16]) that $(XY)_T \equiv X_T + Y_T$ in good pants homology; this then implies that any element of $\mathbb{Q}\mathbf{\Pi}_{\epsilon,R}$ that is zero in $H_1(S)$ is zero in $\mathbf{\Pi}_{\epsilon,R}$ homology.

We have not yet said anything about the function q. The idea is that whenever we prove that two formal sums of curves are equal in good pants homology, we produce a sum of good

[1]We should observe as well that α' is positive!

pants (the "witness" to the homology) whose boundary is equal to the difference of the two formal sums. When we make an arbitrary choice in determining the sum of good pants, we take the average of the results of our choices as our witness. When one identity in good pants homology is proved using another one, the witness for the latter is used to build the witness for the former. In this way, when we prove that

$$(XY)_T \equiv X_T + Y_T$$

in good pants homology, we can explicitly produce a function $g\colon \pi_1(S) \times \pi_1(S) \to \mathbb{Q}\mathbf{\Pi}_{\epsilon,R}$ such that $(XY)_T - X_T - Y_T = \partial g(X, Y)$.

We then let $g_1, \dots g_{2n}$ be a standard set of generators for $\pi_1(S, *)$; then $[g_1], \dots, [g_{2n}]$ also form a basis for $H_1(S)$, and so does $\mathfrak{g} = \{(g_1)_T, \dots, (g_{2n})_T\}$, because $X \equiv X_T$ in H_1. For any $\gamma \in \Gamma_{\epsilon,R}$, we can find a unique $\hat{\gamma} \in \mathbb{Z}\mathfrak{g}$ that is equal to γ in $H_1(S)$. Then in the course of proving that $\gamma \equiv \hat{\gamma}$ in $\mathbf{\Pi}_{\epsilon,R}$ homology, we produce $q\colon \mathbb{Q}\Gamma_{\epsilon,R} \to \mathbb{Q}\mathbf{\Pi}_{\epsilon,R}$ such that

$$\partial q(\gamma) = \gamma - \hat{\gamma}.$$

The identity (1) then follows for q, because $\widehat{\partial\alpha} = 0$ (because $\partial\alpha \equiv 0$ in H_1) for any $\alpha \in \mathbb{Q}\mathbf{\Pi}_{\epsilon,R}$ (where we have extended $\gamma \mapsto \hat{\gamma}$ to $\mathbb{Q}\mathbf{\Pi}_{\epsilon,R}$).

It remains only to show the estimate (2) for this q. Again, for each identity that we prove in [16], and each resulting implicit definition of a witness, we produce a corresponding estimate for the "witness function", using the previous estimates. Is this manner we produce the desired inequality.

4. Applications

4.1. Virtual classification of 3-Manifolds. A subsurface $S \subset \mathbf{M}^3$ (here S is a compact surface, possibly with boundary) is **essential** if the induced map between fundamental groups is an injection. The surface is **incompressible** in $\mathbf{M}^3$ if it is embedded in $\mathbf{M}^3$ and if every homotopically non-trivial simple loop on S is mapped onto a homotopically non-trivial closed curve in $\mathbf{M}^3$. Every essential embedded surface is incompressible, and the converse is a well-known theorem.

Machinery has been developed to study hyperbolic 3-manifolds that are Haken. A manifold is Haken if it contains an incompressible surface. If $\mathbf{M}^3$ is Haken, one can cut $\mathbf{M}^3$ along its incompressible surface to obtain a 3-manifold with boundary (which may be disconnected). Furthermore, hyperbolic 3-manifolds with boundary are known to be Haken so one can continue to cut until arriving at indecomposable pieces. This is known as the Haken hierarchy and it is a cornerstone of 3-dimensional topology. Although many 3-manifolds are not Haken it was conjectured by Thurston that every such manifold has a finite degree cover that is. This was known as the Virtual Haken Conjecture.

Thurston made an even stronger conjecture called the Virtual Fibering Conjecture. Let $\mathbb{S}_g$ denote a closed surface of genus $g \geq 2$. Given a homeomorphism $f : \mathbb{S}_g \to \mathbb{S}_g$, let $\mathbf{M}^3_f$ denote the corresponding mapping torus. Then $\mathbf{M}^3_f$ is a closed 3-manifold that fibers over the circle. Thurston proved that $\mathbf{M}^3_f$ is hyperbolic if and only if f is homotopic to a pseudo-Anosov homeomorphism of $\mathbb{S}_g$. The Virtual Fibering Conjecture Thurston stated that every hyperbolic 3-manifold has a finite degree cover that fibers over the circle.

These two conjectures were major driving forces behind the research in three dimensional topology in recent decades. Building on the Surface Subgroup Theorem of Kahn-Markovic and the work by Wise [23] and Haglund-Wise [12], Agol [2] completed the proofs of both conjectures. Below we state the main steps in the proof.

A group is cubulated if it is acting properly and co-compactly on a CAT(0) cube complex. It turns out that each cubulated hyperbolic group has a rich (hidden) underlying stucture. Wise developed this theory [23], although in his work he used an additional assumption that cubulated hyperbolic groups have a certain Haken hierarchy. Under this assumption he, and in collaboration with Haglund, Hruska, Hsu and others, showed that such groups can be embedded in Right Angled Artin groups which implies that such cubulated hyperbolic groups have many deep properties like being linear, LERF (that is, finitely generated subroups are separable), etc. In particular, if the fundamental group of a hyperbolic 3-manifold satisfies these assumption, it follows from Wise's theory that this 3-manifold is Virtually Haken. Moreover, using the Agol's criterion for virtual fibering [1], it also follows that such a 3-manifold virtually fibers over the circle.

In order for Wise's theory to be applied to hyperbolic 3-manifolds it has to be shown that 3-manifold groups are cubulated and that Wise's assumption on the Haken hierarchy can be dropped.

In the course of proving the Surface Subgroup Theorem we proved that given any two points on the 2-sphere there is a surface subgroup whose limit set separates these two points. Combining this fact and the Sageev construction [22], Bergeron-Wise showed:

Theorem 4.1 (Bergeron-Wise). *The fundamental group of a closed hyperbolic 3-manifold is cubulated.*

Finally, Agol [1] proved Wise's conjecture that cubulated hyperbolic groups are virtually special (which in particular means that Wise's assumption on the Haken hierarchy is not needed for his theory to work), and thus he was able to prove the Virtual Haken Theorem and the Virtual Fibering Theorem:

Theorem 4.2 (Agol). *Every closed hyperbolic 3-manifold has a finite cover that fibers over the circle. In particular, every hyperbolic 3-manifold has a finite cover that is Haken.*

The reader may want to consult the comprehensive survey article [3] by Aschenbrenner-Friedl-Wilton for a complete overview of these theories.

4.2. Counting Problems for Essential Surfaces and Moduli spaces. Counting closed geo-desics in negatively curved manifold is an old and profound subject. Standard results (that are essentially corollaries of the mixing properties of geodesic flows on negatively curved manifolds) state that the number of closed geodesics of length at most L grows exponentially with L. For hyperbolic manifolds (and in particular for Riemann surfaces) this asymptotic is precisely known (Margulis [19]) with excellent bounds on error terms.

Analogously, in a given hyperbolic 3-manifold $\mathbf{M}^3$ one can count the number of essential surfaces (up to homotopy) live inside $\mathbf{M}^3$. Let $s(\mathbf{M}^3, g)$ denote the number (up to homotopy) of genus g incompressible surfaces of $\mathbf{M}^3$. The following counting result was proved in [15]:

Theorem 4.3 (Kahn-Markovic). *Let $\mathbf{M}^3$ be a closed hyperbolic 3-manifold. There exist constants $0 < c_1 \leq c_2$, such that the inequality $(c_1 g)^{2g} \leq s(\mathbf{M}^3, g) \leq (c_2 g)^{2g}$, holds for every large g.*

- A difficult (and perhaps deep) conjecture is to prove that for some constant $c = c(\mathbf{M}^3) > 0$ the formula
$$\lim_{g\to\infty} \frac{\sqrt[2g]{s(\mathbf{M}^3, g)}}{g} = c$$
holds. A positive answer to this conjecture would represent a kind of the Prime Number Theorem for counting essential surfaces in 3-manifolds analogous to the Margulis' Prime Number Theorem for counting closed geodesics [19].
- Another important question is: What does a random essential surface of genus g (for some large g) inside $\mathbf{M}^3$ look like? Is this a quasifuchsian surface or is it a geometrically infinite surface (according to Thurston, Bonahon and Canary a geometrically infinite closed surface in $\mathbf{M}^3$ is a virtual fiber)?

4.3. Homology Of curves And surfaces in hyperbolic 3-Manifolds. In manifolds of negative curvature each homotopy class of closed curves can be realized by a unique geodesic. Given that closed curves have such nice geometric representatives, Thurston recently asked if one can represent each homology class in $H_2(\mathbf{M}^3, \mathbb{Z})$ by a nearly geodesic representative. The following theorem is proved using the methods from [14].

Theorem 4.4 (Liu-Markovic). *Every rational second homology class of a closed hyperbolic 3-manifold has a positive integral multiple represented by an oriented connected closed quasi-Fuchsian subsurface.*

It is well known that every homology class in $H_2(\mathbf{M}^3, \mathbb{Z})$ can be represented as a sum (with integer coefficients) of connected incompressible surfaces in $\mathbf{M}^3$. Such an incompressible surface may be quasifuchsian but it also can be a non-geometrically finite (and thus non quasifuchsian) incompressible surface. At any rate, this result shows that we can replace any such sum of incompressible surfaces with a connected quasifuchsian surface without changing the homology class.

Let γ_1 and γ_2 denote two oriented closed curves inside a closed hyperbolic 3-manifold $\mathbf{M}^3$. Moving into a general position one can show that if γ_1 and γ_2 are homologous in $\mathbf{M}^3$ then γ_1 and $-\gamma_2$ bound an immersed surface in $\mathbf{M}^3$. Topologically it is much more significant when two homologous closed curves γ_1 and $-\gamma_2$ bound an essential surface inside $\mathbf{M}^3$ (a surface, possibly with boundary, is essential in $\mathbf{M}^3$ if its fundamental group injects into the fundamental group of $\mathbf{M}^3$). The following claim asserts that this property is always true in the rational homology $H_1(\mathbf{M}^3, \mathbb{Q})$. In particular, every closed homologically trivial curve in a closed hyperbolic 3-manifold $\mathbf{M}^3$ rationally bounds an essential surface in $\mathbf{M}^3$. This answers a question of D. Calegari in the case of hyperbolic 3-manifolds (this problem is wide open for hyperbolic groups for example).

Theorem 4.5 (Liu-Markovic). *Every rationally null-homologous, π_1 injectively immersed oriented closed 1-submanifold in a closed hyperbolic 3-manifold has an equidegree finite cover which bounds an oriented connected compact immersed quasi-Fuchsian subsurface.*

The following two very recent results by Hongbin Sun are heavily dependent on the Virtual Haken Theorem and Theorem 4.5.

Theorem 4.6 (Sun). *Let A be a finite Abelian group. Then every closed hyperbolic 3-manifold $\mathbf{M}^3$ has a finite degree cover $\mathbf{M}^3_1$ such that A is a direct summand in $\mathrm{Tor}\big(H_1(\mathbf{M}^3, \mathbb{Z})\big)$.*

Theorem 4.7 (Sun). *For any closed oriented hyperbolic 3-manifold* $\mathbf{M}^3$*, and any closed oriented 3-manifold* $\mathbf{N}^3$*, there exists a finite cover* $\mathbf{M}^3_1$ *of* $\mathbf{M}^3$*, and a degree-2 map* $f : \mathbf{M}^3_1 \to \mathbf{N}^3$*, i.e.* $\mathbf{M}^3$ *virtually 2-dominates* $\mathbf{N}^3$.

Very recently, Ursula Hamenstead (see [13]) showed that most closed, rank-one locally symmetric spaces contain surface subgroups. In particular, she proves that every closed complex hyperbolic contains a surface subgroup.

The Geometry of Ricci Curvature

Aaron Naber

Abstract. This is an overview of recent developments in geometry and analysis of Riemannian manifolds with lower and bounded Ricci curvature.

Mathematics Subject Classification (2010). Primary 53-02.

Keywords. ricci, curvature, regularity, path space,

1. Introduction

This paper overviews various recent developments in analysis and geometry related to Ricci curvature. To begin with, if one were to consider a Riemannian manifold (M^n, g) then its curvature operator Rm may best be interpreted as the *hessian* of the metric. This is of course not literal, the actual hessian of the metric vanishes, but in many ways one can expect from a Riemannian manifold with bounded sectional curvature the same type of control one expects from a function with a C^2 bound. It is therefore not surprising a fairly complete understanding of such spaces exists.

The Ricci curvature Ric of the Riemannian manifold is the trace of the curvature. If we therefore interpret the curvature as the hessian of the metric, we should then interpret the Ricci curvature as the laplacian of the metric. Ricci curvature is a prevalent concept in geometric analysis, and by this interpretation one can understand why. Everywhere in analysis one deals with the laplacians of functions, it is therefore not surprising that one would want to deal with the laplacian of the metric. This intuition only goes so far, but it makes for a good starting point.

Though much of this paper will describe recent results in the development of Ricci curvature, we will see that many of the themes and ideas have applications to a broader class of equations, geometric and not. For good reviews on older developments in Ricci curvature we refer the reader to [6],[36].

Let us begin by breaking down the layout of this overview. Section 2 begins with a brief background and overview of Ricci curvature. This includes basic definitions and previous results in the literature which are of importance. Section 3 discusses recent results for spaces with bounded Ricci curvature. In particular, new analytic estimates are discussed which are equivalent to the corresponding bounds on Ricci curvature. Section 4 discusses recent advances in the structure of spaces with lower Ricci curvature bounds. This includes an outline of the constant dimension conjecture, and Hölder continuity of tangent cones. Section 5 discusses a recent technique in the proving of *a priori* estimates for solutions of nonlinear equations. The notion is that of quantitative stratification, and though the primary

Proceedings of International Congress of Mathematicians, 2014, Seoul

application discussed is to prove *a priori* curvature estimates for Einstein manifolds, there have since been applications in many unrelated areas, for instance minimal surfaces, mean curvature flow, harmonic maps between Riemannian manifolds, and critical sets of elliptic equations. Section 6 ends the paper with a list of some open problems and conjectures from the area of Ricci curvature.

2. Background and Overview of Ricci Curvature

There are many ways in which the Ricci tensor arises in both geometry and physics, but the primary interest of this article is in how Ric is tied in with the analysis and geometric structure of M. In this section we review some results, new and old, which help to give the appropriate intuition for the Ricci curvature.

2.1. Lower Ricci Curvature and The Heat Flow. In this section we review the results of Bakry-Emery-Ledoux on characterizing lower Ricci curvature bounds in terms of the behavior of the heat flow. These estimates, and related estimates, not only play a crucial role in the structure theory of sections 2.3 and 4, but are also the first motivation for related estimates for bounded Ricci curvature given in section 3.

Recall first that given a Riemannian manifold (M^n, g) we have associated to it the laplace operator Δ. From this we have the heat flow operator $H_t : L^2(M) \to L^2(M)$ induced by $\frac{1}{2}\Delta$, and the corresponding heat kernel $\rho_t(x, dy) = \rho_t(x, y)dv_g(y)$ defined by

$$H_t u(x) = \int_M u(y)\rho_t(x, dy)\,. \tag{2.1}$$

To understand the role of the Ricci curvature tensor on the analysis of M one begins with a simple computation with the laplacian and gradient to obtain the Bochner formula

$$\Delta|\nabla u|^2 = \langle \nabla u, \nabla \Delta u\rangle + 2|\nabla^2 u|^2 + 2\mathrm{Ric}(\nabla u, \nabla u)\,, \tag{2.2}$$

from which if we assume the lower Ricci bound $\mathrm{Ric} \geq -\kappa g$ we get the Bochner inequality

$$\Delta|\nabla u|^2 \geq \langle \nabla u, \nabla \Delta u\rangle - 2\kappa|\nabla u|^2\,. \tag{2.3}$$

These inequalities are equivalent to the lower bounds on the Ricci curvature, and are the basis for the definition of lower Ricci curvature given by Bakry-Emery [4]. It should be pointed out that their precise condition applies to a much broader situation.

From the Bochner formula many important estimates on the heat flow H_t can be proved, which themselves turn out to be equivalent to the lower Ricci bound. We summarize the results of [4],[5] in the following theorem.

Theorem 2.1 (Bakry-Emery-Ledoux). *Let (M^n, g) be a smooth Riemannian manifold, then the following are equivalent:*

(1) *Ric* $\geq -\kappa g$.
(2) $|\nabla H_t u| \leq e^{\frac{\kappa}{2}t} H_t|\nabla u|$.
(3) $|\nabla H_t u|^2 \leq e^{\kappa t} H_t|\nabla u|^2$.

(4) $\lambda_1(-\Delta_{x,t}) \geq \kappa(e^{\kappa t}-1)^{-1}$.

(5) $\int_M u^2 \ln u^2 \rho_t(x,dy) \leq 2\kappa^{-1}\,(e^{\kappa t}-1)\int_M |\nabla u|^2 \rho_t(x,dy)$ *if* $\int_M u^2\,\rho_t = 1$.

In condition (4) above we are using the heat kernel laplacian, defined as the laplace operator associated to the metric measure space $(M^n, g, \rho_t(x,dy))$. Explicitly, we have that

$$\Delta_{x,t} u = \Delta u - \langle \nabla_y \rho_t(x,y), \nabla u\rangle\,. \tag{2.4}$$

There are various consequences of Theorem 2.1, the most important of which is that a solution of the heat flow has a priori gradient estimates. There are dimensional versions of Theorem 2.1 which give rise to laplacian bounds as well.

2.2. Rigidity Theorems for Lower Ricci Curvature. In the previous subsection we discussed the relationship between lower Ricci curvature and the heat flow. This will eventually give the analytic control needed in the structure theory. However, as for many areas, structure theories for lower Ricci curvature also require a notion of rigidity. In this subsection we briefly review the two main such rigidities that play a role for lower Ricci curvature, namely volume monotonicity and the splitting theorem. Throughout the paper various generalizations of these rigidity theorems will be presented, and in essence we will see that each time one can improve on the rigidity it allows one to prove stronger structure theorems.

We begin with the Bishop-Gromov volume monotonicity and the associated rigidity statement. Throughout let us consider a manifold (M^n, g) with the lower Ricci bound $\mathrm{Ric} \geq (n-1)\kappa$. Then we denote by M^n_κ the space form of curvature κ. That is, M^n_κ is the unique simply connected n-manifold whose sectional curvatures are all κ. We denote by $\mathrm{Vol}_\kappa(B_r)$ the volume of a ball of radius $r>0$ in M^n_κ.

To explain the result in its full strength let us discuss the notion of a metric cone space. Namely, let Y be a compact Riemannian manifold, and let $C_\kappa(Y) \equiv Y\times[0,\infty)/\{Y\times\{0\}\}$ be the topological cone of Y. We can equipped $C_\kappa(Y)$ with a natural metric given by $g_\kappa \equiv dr\otimes dr + sn_\kappa(r)^2 g_Y$, where

$$sn_\kappa(r) \equiv \begin{cases} |\kappa|^{-1/2} sinh(\sqrt{|\kappa|}r), & \text{if } \kappa<0\\ r, & \text{if } \kappa = 0\\ |\kappa|^{-1/2} sin(\sqrt{|\kappa|}r), & \text{if } \kappa>0 \end{cases} \tag{2.5}$$

When $\kappa\equiv 0$ we will sometimes just write $C(Y) = C_0(Y)$ as the cone space. It is not so hard to generalize this construction when Y is an arbitrary metric space. Let us now state the Bishop-Gromov volume monotonicity, and the rigidity statement associated to it:

Theorem 2.2 (Bishop-Gromov). *Let (M^n,g) be complete with Ric $\geq (n-1)\kappa$. Then for each $x\in M$ if we consider the volume ratio $V_r(x) \equiv \frac{Vol(B_r(x))}{Vol_\kappa(B_r)}$, then we have that $\frac{d}{dr}V_r(x)\leq 0$. Further, if there exists $0<r_0<r_1$ such that $V_{r_0}(x) = V_{r_1}(x)$, then the annulus $A_{r_0,r_1}(x)$ is isometric to an annulus $A_{r_0,r_1}(0_\kappa)$ in M^n_κ.*

A quantitative version of the above is the basis for the stratification theory of the next section, as well as the starting point for the quantitative stratification and curvature estimates for Einstein manifolds of section 5.

To exploit the volume monotonicity and its associated rigidity of Theorem 2.2, one will need to be in the noncollapsed setting. That is, if (M^n,g,p) is a pointed Riemannian manifold with a lower Ricci bound, the estimates and structure of sections 2.3 and 5 depend on

a lower volume bound $\mathrm{Vol}(B_1(p)) > v > 0$ of the unit ball around p. On the other hand, there is another form of rigidity which will allow one to prove structure theorems even in the collapsed setting. The Cheeger-Gromoll splitting theorem is the starting point for this point of view:

Theorem 2.3 (Cheeger-Gromoll). *Let (M^n, g) be a complete Riemannian manifold with $\mathrm{Ric} \geq 0$. Assume there exists a line $\gamma : (-\infty, \infty) \to M$, that is, γ is a minimizing geodesic satisfying $d(\gamma(s), \gamma(t)) = |t - s|$ for all $s, t \in (-\infty, \infty)$. Then there exists a smooth manifold N with $\mathrm{Ric} \geq 0$ such that M is isometric to the product space $\mathbb{R} \times N$.*

The first structure theorems for spaces with lower Ricci curvature bounds follow in [7] by first proving an effective version of the splitting theorem, see section 2.3. The proofs of several conjectures remaining in [7] are proved by first building further refinements of the splitting theorem, see section 4 for more on this. Recently the splitting theorem has been proved in [22] for general metric-measure spaces which satisfy a nonnegative Ricci curvature assumption in the weak sense. In the paper [29], this is used to prove a structure theory for such spaces which extends the results of section 2.3 and 4.

2.3. Limit Spaces and Basic Structure Theory of Lower Ricci Curvature. In this section we review the basic structure of spaces with lower Ricci curvature bounds. If one wants to study the structure of such spaces, then it is equally important to study limits of sequences of such spaces. The right notion of limit here is given by Gromov-Hausdorff convergence. That is, let $(X, d_X, p), (Y, d_Y, q)$ be pointed metric spaces. We call a mapping $f : B_{\epsilon^{-1}}(p) \to B_{\epsilon^{-1}}(q)$ an ϵ-isometry if

(1) $f\big(B_{\epsilon^{-1}}(p)\big)$ is ϵ-dense in $B_{\epsilon^{-1}}(q)$

(2) $|d_X(x, y) - d_Y(f(x), f(y))| < \epsilon$ for all $x, y \in B_{\epsilon^{-1}}(p)$.

Then we say

$$d_{GH}(X, Y) \leq \epsilon\,, \tag{2.6}$$

if there exists ϵ-isometries $f : B_{\epsilon^{-1}}(p) \to B_{\epsilon^{-1}}(q)$ and $h : B_{\epsilon^{-1}}(q) \to B_{\epsilon^{-1}}(p)$. See [31] for a good introduction to the subject. The importance of the Gromov-Hausdorff convergence in the subject begins with the following classical compactness theorem by Gromov:

Theorem 2.4 (Gromov). *Let (M_j^n, g_j, p_j) be a sequence of complete, pointed Riemannian manifolds with $\mathrm{Ric}_j \geq -(n-1)$, then there exists a subsequence and a pointed metric space (X, d, p) such that*

$$(M_j^n, g_j, p_j) \to (X, d, p)\,, \tag{2.7}$$

where the convergence is in the (pointed) Gromov-Hausdorff sense.

In the above theorem X is a priori just an arbitrary metric space. The regularity and structure theory of spaces with lower Ricci curvature bounds comes down to the ability to say more about X. The beginning point is the following result by Cheeger and Colding [7], which gives quantitative refinements of Theorems 2.2 and 2.3, which in particular allow one to conclude the results for limit spaces.

Theorem 2.5 (Cheeger-Colding). *Let (M^n, g) be a complete manifold. Then for each $\epsilon > 0$ there exists $\delta(n, \epsilon) > 0$ such that if $\mathrm{Ric} \geq -\delta$ with $x \in M$, then the following hold:*

(1) *(Almost Volume Cone) If* $|V_{\delta^{-1}}(x) - V_{\delta}(x)| < \delta$, *then there exists a metric space* Y *with diam* $\leq \pi$ *such that* $d_{GH}\left(B_{\epsilon^{-1}}(x), B_{\epsilon^{-1}}(0_y)\right) < \epsilon$, *where* $0_y \in C(Y)$ *is the cone point.*

(2) *(Almost Splitting Theorem) If* $\gamma : (-\delta^{-1}, \delta^{-1}) \to M$ *is a minimizing geodesic with* $\gamma(0) = x$, *then there exists a metric space* Y *such that* $d_{GH}\left(B_{\epsilon^{-1}}(x), B_{\epsilon^{-1}}(y)\right) < \epsilon$, *where* $y \in \mathbb{R} \times Y$.

When combined with some geometric measure theory there are many applications to the above statement. To discuss them let us separate into cases, the collapsed and noncollapsed:

2.3.1. Noncollapsed Limit Spaces. In this subsection we consider a limit space $(M^n_j,g_j,p_j) \to (X, d, p)$ where $\mathrm{Ric}_j \geq -(n-1)$ and $\mathrm{Vol}(B_1(p_j)) > v > 0$. We call such a limit space noncollapsed. This is the scenario in which the strongest regularity results are available. The regularity theorems of [7] take two forms. The first is about the stratification of the singular set of X, and the second is about regular part of X. The results of sections 4 and 5 will generalize these, so we will discuss both.

Stratifying a limit space is based on the classical idea of blow up. Namely:

Definition 2.6. Given a metric space (X_x, d_x, x), we call X_x a tangent cone for X at $x \in X$ if there exists a sequence $r_j \to 0$ such that $(X, r_j^{-1}d, x) \to (X_x, d_x, x)$.

By Gromov's theorem we have that for every sequence $r_j \to 0$ there exists a convergent subsequence. In particular, tangent cones exist at every point. Unfortunately, they may be highly non-unique, which is to say the we can get different tangent cones at the same point by taking different blow up sequences. For instance, in [14] examples of limit spaces are constructed where the tangent cones at a fixed point are not only not isometric, they are not homeomorphic and the dimension of the singular set varies, see section 4.1. However, the following is an important structural theorem for noncollapsed spaces, and it follows immediately from theorem 2.5 and the volume monotonicity:

Theorem 2.7. *In a noncollapsed limit* X *every tangent cone* X_x *is a metric cone. That is, there exists a compact metric space* Y_x *such that* $X_x = C(Y_x)$.

This is the starting point for the notion of a stratification. The idea of a stratification is a pretty standard one in the study of geometric nonlinear equations. In spirit, the idea is to separate points of X based on how singular the points are. To make this more precise we define the notion of k-symmetric:

Definition 2.8. Consider the following definitions:

(1) We call a metric space Y k-symmetric for $k \geq 0$ if there exists a metric space Z such that $Y = C(Z) \times \mathbb{R}^k$.

(2) Given a metric space X, we define for each $k \in \mathbb{N}$ the closed strata

$$S^k(X) \equiv \{x \in X : \text{ no tangent cone at } x \text{ is k-symmetric}\}. \tag{2.8}$$

Note then that theorem 2.7 is the statement that every tangent cone is 0-symmetric. Standard blow up techniques from geometric measure theory can now be used to prove the following:

Theorem 2.9 ([7]). *If $(M^n_j, g_j, p_j) \to (X, d, p)$ where $\mathrm{Ric}_j \geq -(n-1)$ and $\mathrm{Vol}(B_1(p_j)) > v > 0$, then we have the following Hausdorff dimension estimate:*

$$\dim_H S^k(X) \leq k\,. \tag{2.9}$$

In section 5 an entirely new proof of theorem 2.9 will be described which will allow for a quantitative refinement. This quantitative refinement is crucial in the proof of L^p-curvature estimates for Einstein manifolds.

Let us end this section with the following regularity statement from [7]. By generalizing an argument of Reifenberg, combined with volume convergence and theorem 2.5 one obtains:

Theorem 2.10 ([7]). *If $(M^n_j, g_j, p_j) \to (X, d, p)$ where $\mathrm{Ric}_j \geq -(n-1)$ and $\mathrm{Vol}(B_1(p_j)) > v > 0$, then there exists an open dense subset $X_0 \subseteq X$ which is a topological manifold.*

2.3.2. Collapsed Limit Spaces. The case of collapsed limits is much worse. In the noncollapsed scenario one focused on theorem 2.5.1 and the volume monotonicity. For collapsed limits the only rigidity theorem one can exploit is the almost splitting of theorem 2.5.2. Now we are considering a sequence $(M^n_j, g_j, p_j) \to (X, d, p)$ satisfying $\mathrm{Ric}_j \geq -(n-1)$. Now in the case when $\mathrm{Vol}(B_1(p_j)) \to 0$, it is better to consider the normalized measure $\nu_j \equiv \mathrm{Vol}(B_1(p_j))^{-1} dv_{g_j}$ on M. In this case the notion of Gromov-Hausdorff convergence can be extended to measured Gromov-Hausdorff convergence to give us a limit (after possible passing to a subsequence)

$$(M^n_j, g_j, \nu_j, p_j) \to (X, d, \nu, p)\,, \tag{2.10}$$

where ν is a measure on X with the property that if $f_j : B_{\epsilon_j^{-1}}(p_j) \to B_{\epsilon_j^{-1}}(p)$ is the sequence of Gromov Hausdorff maps with $\epsilon_j \to 0$, then

$$f_{j,*}\nu_j \to \nu\,. \tag{2.11}$$

To prove structural theorems on X one begins by showing that almost every point of x lies in the interior of a minimizing geodesic. Note then that by theorem 2.5.2 this implies that every tangent cone at such points split an $\mathbb{R}$-factor. Then one starts to iterate this construction by applying it to the tangent cone itself to see that almost every double tangent cone splits $\mathbb{R}^2$. By repeating this process one can prove the following:

Theorem 2.11 ([7]). *If X is a potentially collapsed limit, then for ν-a.e. $x \in X$ we have that the tangent cone at x is unique and isometric to $\mathbb{R}^{k_x}$.*

It was conjectured that k_x could be taken independent of x in the above. In section 4 we will explain how this conjecture is proved.

3. Bounded Ricci Curvature and Analysis on Path Space

In this section we overview recent results of [30] concerned with a new class of estimates for spaces with bounded Ricci curvature. Recall from Section 2.1 the results of Bakry-Emery-Ledoux, which showed that lower bounds on the Ricci curvature are equivalent to

certain estimates on the heat flow on M. These estimates took several forms, but all were essentially concerned with the gradient behavior of functions on M. These estimates, and similar such estimates, play a hugely important role in the structure theory of spaces with lower Ricci curvature bounds. These estimates may also be used to make sense of lower Ricci curvature bounds on general metric measure spaces, see [3] in particular.

Using the results of Bakry-Emery-Ledoux as a moral starting point, the goal of this section is to explain how to generalize these estimates to the context of two sided bounds on the Ricci curvature. That is, we want estimates of an analytical nature, which are not only implied by bounds on the Ricci curvature, but are sufficiently strong that they are equivalent to bounds on the Ricci curvature. It will turn out that for each of the estimates of Theorem 2.1, there will be a corresponding stronger estimate which is equivalent to bounded Ricci curvature. In particular, we see how bounded Ricci curvature on M controls the analysis of path space $P(M)$ in a manner analogous to how lower Ricci curvature controls the analysis on M. Though we will not discuss it, we refer the reader to [30] to see how these ideas may be used to make sense of a notion of bounded Ricci curvature on metric-measure spaces.

In more detail, in this section we see that bounded Ricci curvature can be characterized in terms of the metric-measure geometry of path space $P(M)$. The correct notion of geometry on path space is one induced by what we call the parallel gradient, and the measures on path space of interest are the classical Wiener measures. Our first such characterization is in section 3.2 and shows that bounds on the Ricci curvature are equivalent to certain parallel gradient estimates on path space. These turn out to be infinite dimensional analogues of the Bakry-Emery gradient estimates, which are the finite dimensional gradient estimates on the heat flow well known to characterize lower Ricci bounds. Our second characterization is in section 3.3 and relates bounded Ricci curvature to the stochastic analysis of path space. In particular, we see that bounds on the Ricci curvature are equivalent to the appropriate $C^{\frac{1}{2}}$-time regularity of martingales on $P(M)$. Our final characterization of bounded Ricci curvature relates Ricci curvature to the analysis on path space. Specifically, in section 3.4 we study the Ornstein-Uhlenbeck operator L_x, a form of infinite dimensional laplacian on path space, and prove sharp spectral gap and log-sobolev estimates under the assumption of bounded Ricci curvature. Further we show these estimates on L_x are again equivalent to bounds on the Ricci curvature. For analogous results for d-dimensional bounded Ricci curvature see [30].

3.1. Basics of Path Space. Given a Riemannian manifold (M^n, g) we have associated to it the laplace operator Δ. From this we have the heat flow operator $H_t : L^2(M) \to L^2(M)$ induced by $\frac{1}{2}\Delta$, and the corresponding heat kernel $\rho_t(x, dy) = \rho_t(x, y)dv_g(y)$ defined by

$$H_t u(x) = \int_M u(y)\rho_t(x, dy)\,. \tag{3.1}$$

Now recall that path space

$$P(M) \equiv C^0([0, \infty), M)\,, \tag{3.2}$$

comes equipped with a canonical collection of mappings. Namely, for each partition $\mathbf{t} \equiv \{0 \le t_1 < t_2 < \cdots < t_k < \infty\}$ we have an induced mapping $e_{\mathbf{t}} : P(M) \to M^k$ given by

$$e_{\mathbf{t}}(\gamma) = (\gamma(t_1), \ldots, \gamma(t_k))\,. \tag{3.3}$$

These evaluation maps play two important roles. The first is to define a class of functions on $P(M)$ that one can work with to do analysis, the cylinder functions. That is, given $u : M^k \to \mathbb{R}$ and a partition $\mathbf{t}$ we define the cylinder function $U : P(M) \to \mathbb{R}$ by the formula $U(\gamma) \equiv e_{\mathbf{t}}^* u(\gamma) \equiv u(\gamma(t_1), \dots, \gamma(t_k))$.

The second role of the evaluation maps is in the construction of the Wiener measure. Namely, for each $x \in M$ it is possible to prove the existence of a measure Γ_x on path space $P(M)$ which is uniquely determined by the pushforwards

$$e_{\vec{t},*}\Gamma_x = \rho_{t_1}(x, dy_1)\rho_{t_2-t_1}(y_1, dy_2)\cdots\rho_{t_k-t_{k-1}}(y_{k-1}, dy_k)\,. \tag{3.4}$$

The complicated aspect of this theorem is that the measure Γ_x does in fact concentrate on the continuous curves, however it turns out this may be proved in vast generality, see [21].

Finally, let us recall that if we consider the L^2 functions on path space $L^2(P_x(M), \Gamma_x)$, then this Hilbert space comes canonically equipped with a weakly continuous, nested, 1-parameter family of closed subspaces $L^2_t(P_x(M)) \subseteq L^2(P_x(M))$ defined by $F \in L^2_t$ iff $F(\gamma) = F(\sigma)$ whenever $\gamma(s) = \sigma(s)$ for $s \leq t$. We may equivalently describe the subspaces $L^2_t(P_x(M))$ in the following manner. Note that path space comes equipped with a one parameter family of σ-algebras $\mathcal{F}^t$, where $\mathcal{F}^t$ is the weak σ-algebra generated by the valuation maps $e_{\mathbf{t}}$ with $\mathbf{t}$ a partition of $[0, t]$. Then $L^2_t(P_x(M))$ is the closed subspace of $L^2(P_x(M))$ of $\mathcal{F}^t$-measurable functions. With this in mind, we say a one parameter family of functions $F^t \in L^2(P(M))$ is a martingale iff for each $s < t$ we have that F_s is the projection of F^t to L^2_s. One can often view a martingale as the appropriate generalization of the heat flow on path space.

3.2. The Gradient Estimate.

3.2.1. The Parallel Gradient. In order to explain the estimates in [30] we have to define the right notion of geometry on path space. More specifically, we need to define the right notion of gradient. As in any situation, a gradient requires two pieces of information. First we need a notion of a directional derivative. However since $P(M)$ is a Banach manifold whose tangent space at γ may be identified with the continuous vector fields at γ, the notion of a directional derivative is well defined. Additionally, to define a gradient we need a restricted class of vectors, for instance those of norm 1 in some sense or another, in order to turn the directional derivative into a gradient.

The notion introduced in [30], and the one relevant to Ricci curvature, is that of the parallel gradient. In fact, there are a 1-parameter family of such gradients. In essence, each is a gradient which depends on only a finite dimensional amount of information. However, the whole family can be used to recover some more standard infinite dimensional notions of gradient. More specifically, given a cylinder function $F : P(M) \to \mathbb{R}$ we define the norm of its 0-parallel gradient $|\nabla_0 F| : P(M) \to \mathbb{R}^+$ by

$$|\nabla_0 F|(\gamma) \equiv \sup_V \{D_V F : \dot{V} = 0\,, |V|(0) = 1\}\,. \tag{3.5}$$

That is, we are looking at all parallel translation invariant vector fields along γ of norm 1, and taking the supremum of the directional derivatives. This is a n-dimensional space of directions. Though we will not discuss this point, it should be pointed out that there is a subtlety in the above definition. Namely, the curves γ are continuous, and thus it may not be clear what is meant by a parallel translation invariant vector field. This issue can be

resolved, though it requires the notion of the stochastic parallel translation map, which we will not discuss here.

Similarly, let us introduce the notion of the t-parallel gradient. We call a left continuous vector field V along γ a t-parallel vector field if $V(s) = 0$ if $s < t$, and if $\dot{V}(s) = 0$ for $s \geq t$. Note that for a cylinder function F the directional derivative $D_V F$ is still well defined. Then we define

$$|\nabla_t F|(\gamma) \equiv \sup_V \{D_V F : V \text{ is } t\text{-parallel}\,, |V|(t) = 1\}\,. \tag{3.6}$$

Note that though we have only defined the norm, it is easy to see that this supremem is obtained for some t-parallel translation invariant vector field, which we may define as being *the* t-parallel gradient $\nabla_t F$. It is not so hard to check that these all extend to closed linear operators on $L^2(P(M), \Gamma_x)$, see [30] for more on the parallel gradient.

3.2.2. The Estimate. Now we are in a position to discuss our first characterization of bounded Ricci curvature on M. Let us begin by recalling the classic gradient estimates of Bakry-Emery on the heat flow. Their estimates tell us that the lower Ricci curvature bound $\text{Ric} \geq -\kappa$ is equivalent to the gradient estimate on the heat flow given by

$$|\nabla H_t u| \leq e^{\frac{\kappa}{2}t} H_t |\nabla u|\,, \tag{3.7}$$

where H_t is the heat flow associated to the operator $\frac{1}{2}\Delta$ on M. The first characterization of bounded Ricci curvature will be a path space version of this estimate. In fact, one may recover (3.7) by applying the path space estimate to essentially the simplest type of function on path space.

To describe the characterization let $F \in C^0(P(M))$ be a continuous function on path space, for instance a smooth cylinder function. In section 3.1 we described for each $x \in M$ the construction of the Wiener measure Γ_x on path space. Let us observe that by letting the measures Γ_x act on F we can construct a continuous function on M by considering

$$\int_{P(M)} F\, d\Gamma_x\,, \tag{3.8}$$

as a function of x. This method takes continuous functions on $P(M)$ to continuous functions on M, and it is reasonable to ask what else we know about $\int F\, d\Gamma_x$ as a function on M in terms of F as a function on $P(M)$. In particular, when is it a lipschitz function on M, and can we control the gradient of $\int F\, d\Gamma_x$ as a function on M in terms of the gradient of F as a function on $P(M)$. In this case it of course matters a great deal what we mean by *gradient* of F on $P(M)$. It turns out that if we mean the parallel gradient as defined in section 3.2.1, then the estimate

$$|\nabla \int_{P(M)} F\, d\Gamma_x| \leq \int_{P(M)} |\nabla_0 F|\, d\Gamma_x\,, \tag{3.9}$$

is equivalent to the smooth metric measure space being Ricci flat. That is, we have that (3.9) holds if and only if $\text{Ric} \equiv 0$. More generally, we have that $|\text{Ric}| \leq \kappa$ if and only if

$$|\nabla \int_{P(M)} F\, d\Gamma_x| \leq \int_{P(M)} |\nabla_0 F| + \int_0^\infty \frac{\kappa}{2} e^{\frac{\kappa}{2}s} |\nabla_s F|\, ds \cdot d\Gamma_x\,. \tag{3.10}$$

As a first application, it is a worthwhile computation to see what happens when we apply the above estimate to the simplest function on path space, namely a cylinder function $F(\gamma) \equiv u(\gamma(t))$ where u is a smooth function on M and $t > 0$ is fixed. In this case we see that we exactly recover (3.7), see [30].

3.3. The $C^{1/2}$-Martingale Estimate. Our second characterization of bounded Ricci curvature relates the bounds on the Ricci curvature to the stochastic analysis on M. Recall from section 3.1 that a family of functions $F^t : P_x(M) \to \mathbb{R}$ on based path space $P_x(M) \equiv \{\gamma \in P(M) : \gamma(0) = x\}$ is a martingale if for each $s < t$ we have that F^s is the projection of F^t to the $\mathcal{F}^s$-measurable functions. Again, one should view this as an appropriate extension of the heat flow on M to path space.

A particularly natural construction of a martingale is to begin with an L^2 function $F : P_x(M) \to \mathbb{R}$ and let F^t be the projection of F to $L^2_t(P_x(M)$. The martingale F^t is then a measurement of how much of F, as a function on path space, depends only on first $[0, t]$ of a curve. As a family of functions F^t is highly nondifferentiable. To see this note that for any partition $\mathbf{t} = \{0 \leq t_1 < \cdots < t_{|\mathbf{t}|} < \infty\}$ we have the identity

$$||F||^2_{L^2} = \sum ||F^{t_{k+1}} - F^{t_k}||^2_{L^2} \,. \tag{3.11}$$

From this it is clear that not only is the family F^t not differentiable in the t-variable, but what we may hope to converge is the quadratic limit

$$\lim_{s\to 0} \frac{\left(F^{t+s} - F^t\right)^2}{s} = [dF^t] \,, \tag{3.12}$$

for at least $a.e.\ t > 0$ in L^1. One should be very careful that this is not a pointwise limit. One may rephrase this for a martingale as follows. If we consider the quadratic variation

$$[F^t] \equiv \lim_{\mathbf{t}} \sum \left(F^{t_{j+1}} - F^{t_j}\right)^2 , \tag{3.13}$$

where the limit is taken over partitions of $[0, t]$, then for a martingale $[F^t]$ is of bounded variation and is $\mathcal{F}^t$-measurable. In particular, its time derivative $[dF^t]$ exists for almost every time. This is highly nontrue for general stochastic processes.

The infinitesmal quadratic variation $[dF^t]$ is the correct replacement for the time derivative of F^t. A reasonable question then is what properties of F control the quadratic variation $[F^t]$ and its infinitesmal $[dF^t]$. The main estimate of this section is that the estimate

$$\int_{P(M)} [dF^t] \, d\Gamma_x \leq \int_{P(M)} |\nabla_t F|^2 \, d\Gamma_x \,, \tag{3.14}$$

is equivalent to M being Ricci flat $\mathrm{Rc} \equiv 0$. More generally, the estimate

$$\int_{P(M)} \sqrt{[dF^t]} \, d\Gamma_x \leq \int_{P(M)} |\nabla_t F| + \int_t^T \frac{\kappa}{2} e^{\frac{\kappa}{2}(s-t)} |\nabla_s F| \, d\Gamma_x \,, \tag{3.15}$$

$$\int_{P(M)} [dF^t] \, d\Gamma_x \leq e^{\frac{\kappa}{2}(T-t)} \int_{P(M)} |\nabla_t F|^2 + \int_t^T \frac{\kappa}{2} e^{\frac{\kappa}{2}(s-t)} |\nabla_s F|^2 \, d\Gamma_x \,, \tag{3.16}$$

is equivalent to the bound $-\kappa g \leq \text{Ric} \leq \kappa g$ on the Ricci curvature. There are several stronger versions of this estimate, but we refer the reader to [30] for more on this.

As a last remark let us compare these estimates to the lower Ricci curvature context, and in particular let us note that (3.16) implies a generalization of the Bakry-Emery gradient estimate when applied to the simplest functions on path space. Specifically, when we apply (3.16) to the functions of the form $F(\gamma) \equiv u(\gamma(t))$, where u is a smooth function on M and t is fixed, then we will get the estimate

$$H_t|\nabla H_{T-t}u|^2(x) \leq e^{\kappa(T-t)}H_T|\nabla u|^2(x)\,, \tag{3.17}$$

for every smooth u and all times $0 \leq t \leq T$. It is not hard to see that (3.17) is equivalent to (3.7), and in particular is itself equivalent to the Ricci curvature lower bound $Rc \geq -\kappa g$.

3.4. Spectral Gap and Log-Sobolev Estimates on the Ornstein-Uhlenbeck Operator. The third characterization of bounded Ricci curvature shows how to equate bounds on the Ricci curvature of a smooth manifold with the analysis on path space. Specifically, we will recall below how to define the Ornstein-Uhlenbeck operators $L_x : L^2(P_x(M), \Gamma_x) \to L^2(P_x(M), \Gamma_x)$, which are infinite dimensional laplacians on path space, and see how the spectral properties of L_x are equivalent to bounds on the Ricci tensor.

Spectral gap and log-Sobolev inequalities for the Ornstein-Uhlenbeck operator on path space have a long history. In the context of path space on $\mathbb{R}^n$ they were first proved by Gross [23]. In this case one can approximate in a very strong sense the Ornstein-Uhlenbeck operator by finite dimensional operators and thus prove the estimate rather directly by more classical arguments. In the case of path space on a smooth Riemannian manifold the Ornstein-Uhlenbeck operator was first defined in [17], and its spectral gap and log-sobolev properties were first studied in [18, 24] and [1]. In [1] it was proven that such estimates existed for an arbitrary compact Riemannian manifold. To prove the result the manifold was isometrically embedded in Euclidean space, and therefore the spectral gap itself depended on the embedding. In [18, 24] it was first understood that Ricci curvature could also be used to control the spectral gap and log-Sobolev inequalities. The proof in [18] was based on a clever manipulation of the martingale representation formula for manifolds, which itself was based on a combination of the classic Clark-Ocone-Haussmann formula and Driver's integration by parts formula for the Malliavin gradient. The proof in [24] is based on a more inductive procedure. We refer the reader to the useful book [25] for a more complete reference.

In this section we will discuss the estimates of [30], which give sharp spectral gap and log-sobolev estimates, and show these estimates are equivalent to Ricci curvature bounds. To explain all of this more carefully let us briefly discuss the H^1_x-gradient on path space, which was first introduced by Malliavin. We will be interested in what's to come in studying functions F which are defined on based path space $P_x(M)$. Normally it is easier to consider the constructions on smooth cylinder functions first, and then to extend more arbitrarily. Classically, one defines the H^1_x-gradient on based path space in a manner similar to the parallel gradient of section 3.2.1 by

$$|\nabla F|_{H^1_x}(\gamma) \equiv \sup\left\{D_V F : \int_\gamma |\dot{V}|^2 = 1, V(0) = 0\right\}. \tag{3.18}$$

Now on based path space $P_x(M)$ we have introduced both a natural geometry given by the H^1_x-gradient, and we have a canonical measure given by the Wiener measure Γ_x. This allows us to define a Dirichlet form, from which the Ornstein-Uhlenbeck operator will be

defined. Namely, we define the closed symmetric bilinear form on $L^2(P_x(M),\Gamma_x)$ by the formula

$$E[F] \equiv \frac{1}{2}\int_{P_x(M)} |\nabla F|^2_{H^1_x} d\Gamma_x \,. \tag{3.19}$$

In fact, we have that the energy functional $E[F]$ on a smooth manifold is a Dirichlet form, see [17]. In particular, by the standard theory of Dirichlet forms [28], there exists a unique, closed, nonnegative, self-adjoint operator

$$L_x : L^2(P_x(M),\Gamma_x) \to L^2(P_x(M),\Gamma_x)\,, \tag{3.20}$$

such that

$$E[F] = \int_{P_x(M)} \langle F, L_x F\rangle \, d\Gamma_x \,. \tag{3.21}$$

The operator L_x is the Ornstein-Uhlenbeck operator on $P_x(M)$. Let us remark that it is not hard to show that L_x preserves $\mathcal{F}^T$-measurable functions F on $P_x(M)$. One can rephrase this by saying that L_x restricts to a well defined operator on time restricted based path space

$$P^T_x(M) \equiv \{\gamma \in C^0([0,T],M) : \gamma(0) = x\}\,. \tag{3.22}$$

It is clear from the definition that $L_x 1 = 0$, and since L_x is a self-adjoint operator it has a well defined spectral theory. It is then reasonable to ask about the behavior of this spectrum, and in particular whether or not there exists a spectral gap for the operator. It is shown in [30] that M satisfies the Ricci curvature bound $|\mathrm{Ric}| \leq \kappa$ if and only if the Ornstein-Uhlenbeck operator L_x on time restricted path space $P^T_x(M)$ satisfies the spectral gap

$$\lambda_1(L_x) \geq 2\left(e^{\kappa T}+1\right)^{-1}. \tag{3.23}$$

In fact, it turns out to also be the case that a smooth metric measure space satisfies the Ricci curvature eigenvalue bound $|\mathrm{Ric}| \leq \kappa$ if and only if we have the seemingly stronger log-Sobolev estimate

$$\int_{P_x(M)} F^2 \ln F^2 \, d\Gamma_x \leq \left(e^{\kappa T}+1\right)\int_{P_x(M)} |\nabla F|^2_{H^1_x}\, d\Gamma_x \,, \tag{3.24}$$

where F is any $\mathcal{F}^T$-measurable function on path space such that $\int_{P_x(M)} F^2\, d\Gamma_x = 1$. It is fairly standard that a log-Sobolev estimate of the form (3.24) implies the spectral gap (3.23). A consequence of Theorem 3.1 is the converse statement.

We end the section by discussing the relationship between this estimate and the lower Ricci curvature version. As in the previous estimates, the goal is to apply the estimates (3.23) and (3.24) to a function $F(\gamma) \equiv u(\gamma(t))$, where u is a fixed function on M and t is fixed. In this case we recover the spectral gap

$$\lambda_1(-\Delta_{x,t}) \geq \kappa\left(e^{\kappa t}-1\right)^{-1}\,, \tag{3.25}$$

on the heat kernel laplacian, as well as the log-Sobolev estimate

$$\int_M u^2 \ln u^2 \rho_t(x, dy) \leq 2\kappa^{-1} \left(e^{\kappa t} - 1\right) \int_M |\nabla u|^2 \rho_t(x, dy)\,, \tag{3.26}$$

where u is any function such that $\int_M u^2(y)\rho_t(x, dy) = 1$. A consequence of [5] is that these estimates are themselves equivalent to the lower Ricci bound $Rc \geq -\kappa g$, and therefore we have again easily recovered the lower Ricci curvature from the path space estimate.

3.5. Summary of Main Results. In this section we simply summarize the results of the previous sections. Let us remark that the results of [30] are more general in several directions. To begin with, in [30] it is seen that the results hold for metric-measure spaces, not just Riemannian manifolds. Additionally, a dimensional version of the inequalities is proved. However, for simplicity sake we restrict ourselves to the context of a Riemannian manifold for the next statement:

Theorem 3.1. *Let (M^n, g) be a smooth complete metric measure space, then the following are equivalent:*

(R1) *The Ricci curvature satisfies the bound*

$$-\kappa g \leq Ric \leq \kappa g\,. \tag{3.27}$$

(R2) *For any function $F \in L^2(P(M), \Gamma_g)$ on the total path space $P(M)$ we have the estimate*

$$\left|\nabla \int_{P(M)} F\, d\Gamma_x\right| \leq \int_{P(M)} \left(|\nabla_0 F| + \int_0^\infty \frac{\kappa}{2} e^{\frac{\kappa}{2}s} |\nabla_s F|\, ds\right) d\Gamma_x\,, \tag{3.28}$$

(R3) *For any function $F \in L^2(P(M), \Gamma_g)$ on the total path space $P(M)$ which is $\mathcal{F}^T$-measurable we have the estimate*

$$\left|\nabla \int_{P(M)} F\, d\Gamma_x\right|^2 \leq e^{\frac{\kappa}{2}T} \int_{P(M)} |\nabla_0 F|^2 + \int_0^T \frac{\kappa}{2} e^{\frac{\kappa}{2}s} |\nabla_s F|^2\, ds \cdot d\Gamma_x\,. \tag{3.29}$$

(R4) *For any function $F \in L^2(P(M), \Gamma_x)$ on based path space $P_x(M)$ we have the estimate*

$$\int_{P(M)} \sqrt{[dF^t]}\, d\Gamma_x \leq \int_{P(M)} |\nabla_t F| + \int_t^T \frac{\kappa}{2} e^{\frac{\kappa}{2}(s-t)} |\nabla_s F|\, d\Gamma_x\,, \tag{3.30}$$

(R5) *For any function $F \in L^2(P(M), \Gamma_x)$ on based path space $P_x(M)$ which is $\mathcal{F}^T$-measurable we have the estimate*

$$\int_{P(M)} [dF^t]\, d\Gamma_x \leq e^{\frac{\kappa}{2}(T-t)} \int_{P(M)} |\nabla_t F|^2 + \int_t^T \frac{\kappa}{2} e^{\frac{\kappa}{2}(s-t)} |\nabla_s F|^2\, d\Gamma_x\,, \tag{3.31}$$

(R6) *The Ornstein-Uhlenbeck operator* $L_x : L^2(P_x^T(M),\Gamma_x) \to L^2(P_x^T(M),\Gamma_x)$ *on based path space* $P_x^T(M)$ *satisfies the spectral gap estimate*

$$\lambda_1(L_x) \geq 2\left(e^{\kappa T}+1\right)^{-1}. \tag{3.32}$$

(R7) *On based path space* $P_x(M)$*, equipped with the Wiener measure* Γ_x *and the* H_x^1*-gradient, if* F *is a* $\mathcal{F}^T$ *measurable function then we have the log-Sobolev inequality*

$$\begin{aligned}\int_{P_x(M)} F^2\ln F^2\,d\Gamma_x &\leq 2e^{\frac{\kappa}{2}T}\int_{P(M)}\left(\int_0^T \cosh(\frac{\kappa}{2}t)|\nabla_t F|^2\,dt\right)d\Gamma_x \\ &\leq \left(e^{\kappa T}+1\right)\int_{P_x(M)}|\nabla F|^2_{H_x^1}\,d\Gamma_x\,,\end{aligned} \tag{3.33}$$

whenever F *satisfies* $\int_{P_x(M)} F^2\,d\Gamma_x = 1$.

An obvious but interesting corollary of the above is the following characterization of Ricci flat manifolds.

Corollary 3.2. *Let* $(M^n,g,e^{-f}dv_g)$ *be a smooth complete metric measure space, then the following are equivalent:*

(1) *The space is Ricci flat, that is,* $Ric+\nabla^2 f = 0$

(2) *For any function* F *on the total path space* $P(M)$ *we have the estimate*

$$\left|\nabla\int_{P(M)} F\,d\Gamma_x\right| \leq \int_{P(M)}|\nabla_0 F|\,d\Gamma_x.$$

(3) *For any function* F *on based path space* $P_x(M)$ *we have the estimate*

$$\int_{P(M)}\sqrt{[dF^t]}\,d\Gamma_x \leq \int_{P(M)}|\nabla_t F|\,d\Gamma_x.$$

(4) *The Ornstein-Uhlenbeck operator* $L_x : L^2(P_x(M),\Gamma_x)\to L^2(P_x(M),\Gamma_x)$ *on based path space satisfies the spectral gap estimate* $\lambda_1(L_x)\geq 1$.

(5) *For any function* $F\in L^2(P_x(M),\Gamma_x)$ *with* $\int_{P_x(M)}F^2\,d\Gamma_x = 1$ *on based path space we have the estimate*

$$\int_{P_x(M)} F^2\ln F^2\,d\Gamma_x \leq 2\int_{P_x(M)}|\nabla F|^2_{H_x^1}\,d\Gamma_x.$$

Remark 3.3. By twisting the Wiener measure one can find versions of the above estimates which characterize general Einstein manifolds.

4. Structure of Lower Ricci Curvature

In this section we discuss some recent results of [15] which prove various conjectures from [7, 20] on the structure of limit spaces with lower Ricci curvature bounds. In particular, we discuss how such limits have a well defined dimension and have isometry groups which are lie groups. The proofs revolve around new estimates, which in short state that the geometry of metric balls can only change at a Holder rate along minimizing geodesics. In particular, tangent cones *at the same scale* change along a geodesic at most at a Hölder rate. This Hölder rate turns out to be sharp. The following is the main estimate of [15].

Theorem 4.1 ([15]). *Let (M^n, g) be a Riemannian manifold which satisfies Ric $\geq -(n-1)$ with $\gamma : [0, \ell] \to M$ a minimizing geodesic. There there exists $C(n), \alpha(n) > 0$ such that for any $s, t \in (\delta, (1-\delta)\ell)$ and $r \leq r(n)\ell$ we have that*

$$d_{GH}(B_r(\gamma(s)), B_r(\gamma(t))) < \frac{C}{\delta \ell}\, r\, |s-t|^{\alpha(n)}\,. \tag{4.1}$$

Remark 4.2. The most direct application of the above is to see that tangent cones at the same scale along minimizing geodesics in limit spaces X must change at a continuous rate, see [15].

In fact the Hölder exponent $\alpha(n)$ is *effectively* $\frac{1}{2}$, and examples are constructed to show that the result fails for $\alpha > \frac{1}{2}$, see Theorem 4.10. The proof of Theorem 4.1 involves many new estimates which we will not discuss here and we refer the reader to [15] for more on this.

Theorem 4.1 can be compared to an important theorem of Petrunin in [32], where it is shown that on Alexandrov spaces (i.e. spaces with lower sectional bounds), tangent cones on minimizing geodesics are unique. Here we see that we can't expect uniqueness under only a lower Ricci assumption, but that at least tangent cones do change at a continuous rate along a minimizing geodesics. Let us state the main applications of this estimate. The following was a conjecture from [7], which informally states that limit spaces have a well defined dimension.

Theorem 4.3 ([15]). *Let $M_i^n \to X$ be a limit of manifolds satisfying Ric $\geq -(n-1)$. Let $\mathcal{R}^k \subseteq X$ be defined by $x \in \mathcal{R}^k$ iff the tangent cone at x is unique and equal to $\mathbb{R}^k$. Then there exists a unique constant $k \leq n$ such that $X \setminus \mathcal{R}^k$ has measure zero.*

Remark 4.4. More precisely, the measure μ_X in the above theorem is the canonical limit measure on X gotten by limiting the normalized volume forms on M_i, see [CoNa1].

Proof. Instead of giving the full proof let us consider a simple example. The moral of the construction gives the idea for the general proof without the necessary technical complications needed for the general case. Thus let X be a trumpet space. That is, let $X \equiv (-\infty, 0] \cup_{(0,0_c)} C(S^1)$, where we have identified the end of the interval $(-\infty, 0]$ with the cone point 0_c of $C(S^1)$. So X is a connected space with a one dimensional part and a two dimensional part. Let us see why X cannot arise as a limit of spaces with lower Ricci bounds by using Theorem 4.1. Indeed, assume it is, and let $x_0 \in (-\infty, 0)$ be a point in the one dimensional part and $x_1 \in C(S^1)/0_c$ be a point in the two dimensional part. Let γ be a minimizing geodesic connecting x_0 to x_1. Now part of γ lives in $(-\infty, 0)$ and the other part in $C(S^1)$, hence there is t_0 such that $\gamma(t) \in (-\infty, 0)$ for $t < t_0$ and $\gamma(t) \in C(S^1)/\{0_c\}$

for $t > t_0$. In particular, for $t < t_0$ we have the tangent cone at $\gamma(t)$ is unique and isometric to $\mathbb{R}$, and for $t > t_0$ the tangent cone at $\gamma(t)$ is unique and isometric to $\mathbb{R}^2$. However, by Theorem 4.1, and the remark following it, the tangent cones of $\gamma(t)$ must be changing continuously along γ, which is a contradiction. □

Now that we have seen that limit spaces X have a well defined regular set $\mathcal{R}^k$, the structure of this regular set is of interest. It is known that if X is a limit space of manifolds with bounded sectional then the regular set $\mathcal{R}$ is totally convex. Under only a lower Ricci curvature assumption we prove that $\mathcal{R}$ is weakly convex (see [15] for a precise definition). Under the additional assumptions of bounded Ricci curvature and noncollapsing we can improve this to the statement that $\mathcal{R}$ is totally convex.

Theorem 4.5 ([15]). *Let $M_i^n \to X$ be a limit of manifolds satisfying $|Ric| \leq n-1$ and $Vol(B_1(p)) > v > 0$. Then the regular set $\mathcal{R}^n$ is totally geodesic. That is, if $p, q \in \mathcal{R}$ and γ is a minimizing geodesic connecting p and q, then $\gamma \subseteq \mathcal{R}$.*

Finally, we state one last application of Theorem 4.1. Namely, it is conjectured in [20] and [7] that the isometry group of a limit space X is a Lie group. This conjecture is based on the proof in [20] of this statement when X is Alexandrov, and the proof in [7] of this statement when X is a noncollapsed limit of manifolds with a lower Ricci bound. Using Theorem 4.1 we can prove this conjecture. Essentially, it is a consequence of the weak convexity of the regular set which was alluded to before:

Theorem 4.6 ([15]). *Let $M_i^n \to X$ be a limit of manifolds satisfying $Ric \geq -(n-1)$. Then the isometry group of X is a Lie group.*

4.1. Examples with Lower Ricci Curvature. Throughout this section we let $M_i^n \to Y$ be a limit of manifolds satisfying the lower Ricci bound $\mathrm{Ric} \geq -(n-1)$ and the noncollapsing assumption $\mathrm{Vol}(B_1(p)) > v > 0$.

In a different direction than the previous subsection we want to understand to what extent examples of limit spaces Y can be as degenerate as possible. Unlike the Alexandrov case, e.g. limits with lower sectional curvature, it is not the case that tangent cones even need to be unique anymore, though it is always an open question as to what extent this nonuniqueness can be pushed. In [14] we give a *characterization* for the families of tangent cones which may appear at a point in a noncollapsed limit. To make this precise note that it does hold that every tangent cone Y_p at $p \in Y$ in a noncollapsed limit is a metric cone, so $Y_p = C(X_p)$ where $X_p \in \mathcal{M}_{GH}$ is a compact metric space. Given this we let

$$\overline{\Omega}_{Y,p} \equiv \{X \in \mathcal{M}_{GH} : \text{ some tangent cone } Y_p \text{ at } p \text{ satisfies } Y_p = C(X)\}, \tag{4.2}$$

be the space of all such cross sections. It is easy to check that $\overline{\Omega}_{Y,p}$ is closed and path connected in $\mathcal{M}_{GH}$ with respect to the Gromov-Hausdorff topology. It also holds that if $X \in \overline{\Omega}_{Y,p}$ then

$$\mathrm{Ric}(X) \geq n-1, \tag{4.3}$$

and that

$$\mathrm{Vol}(X) = V(p), \tag{4.4}$$

is independent of $X \in \bar{\Omega}_{Y,p}$. The second statement is a consequence of the Bishop-Gromov monotonicity. In fact, we see in [14] that this almost characterizes subsets of $\mathcal{M}_{GH}$ which can appear as $\overline{\Omega}_{Y,p}$ for some limit space Y. All that is missing is what we call Ricci closability. We will not give a precise definition here, but essentially this is nothing more than a form of geometric cobordism statement. The precise characterization is the following.

Theorem 4.7 ([14]). *Let Ω be an open connected manifold, our parameter space. Let $\{(X^{n-1}, g_s)\}_{s\in\Omega} \subseteq \mathcal{M}_{GH}$, with $n \geq 3$, be a smooth family of closed manifolds such that (4.3) and (4.4) hold and such that for some s_0 we have that X_{s_0} is Ricci closable. Then there exists a sequence of complete manifolds $(M^n_\alpha, g_\alpha, p_\alpha) \overset{GH}{\to} (Y, d_Y, p)$ which satisfy $Ric_\alpha \geq 0$ and $Vol(B_1(p)) > v > 0$ for which $\overline{\{X_s\}} = \overline{\Omega}_{Y,p}$, where $\overline{\{X_s\}}$ is the closure of the set $\{X_s\}$ in the Gromov-Hausdorff topology.*

We have two primary applications of this. First, we construct limit spaces whose tangent cones at a point have singular sets of varying dimensions. In particular, this rules out the possibility of stratifying limit spaces based on tangent cones. Secondly, we construct examples where differing tangent cones at a point may not even be homeomorphic. Specifically we have

Theorem 4.8 ([14]). *For every $n \geq 3$, there exists a limit space $(M^n_\alpha, g_\alpha, p_\alpha) \overset{GH}{\to} (Y, d_Y, p)$ where each M_α satisfies $Ric \geq 0$ and $Vol(B_1(p_\alpha)) > v > 0$, and such that for each $0 \leq k \leq n-2$ there exists a tangent cone at p which is isometric to $\mathbb{R}^k \times C(X)$, where X is a smooth closed manifold not isometric to the standard sphere.*

This example tells us that stratifying limit spaces Y by the singular behavior of tangent cones is not possible. The next example gives even more degenerate behavior.

Theorem 4.9 ([14]). *There exists a limit space $(M^5_\alpha, g_\alpha, p_\alpha) \overset{GH}{\to} (Y^5, d_Y, p)$ of a sequence M_α satisfying $Ric \geq 0$ and $Vol(B_1(p_\alpha)) > v > 0$, and such that there exists distinct tangent cones $C(X_0)$, $C(X_1)$ at $p \in Y$ with X_0 homeomorphic to $\mathbb{C}P^2 \sharp \overline{\mathbb{C}P}^2$ and X_1 homeomorphic to S^4.*

The final example shows that Theorem 4.1 is sharp.

Theorem 4.10 ([15]). *For every $\epsilon > 0$ there exists a noncollapsed limit space Y_ϵ with a minimizing geodesic $\gamma \subseteq Y_\epsilon$ such that*

(1) *The tangent cones $Y_{\gamma(s)}$ at each of the points $\gamma(s)$ are unique.*

(2) *The path $B_1 Y_{\gamma(s)}$ in the set of compact metric spaces $\mathcal{M}_{GH}$ with the Gromov Hausdorff topology is $C^{1/2}$-Hölder continuous.*

(3) *The path $B_1 Y_{\gamma(s)}$ in the set of compact metric spaces $\mathcal{M}_{GH}$ with the Gromov Hausdorff topology is not $C^{1/2+\epsilon}$-Hölder continuous.*

5. Quantitative Stratification and Regularity of Nonlinear PDE's

In this section we will outline new methods for proving L^p-estimates on the solutions of nonlinear equations. The method originated in [12] with the proving of *a priori* curvature

estimates for Einstein manifolds, however the technique is very general and has since been applied to minimal surfaces [11], harmonic maps between Riemannian manifolds [11], mean curvature flow [9], harmonic map flow, and the study of critical sets of elliptic equations [10]. In spirit, the new ideas involve improvements on the idea of stratification, and combining these improvments with ϵ-regularity theorems that exploit the symmetry produced by the stratification.

In the study of nonlinear partial differential equations, and in particular the study of geometric pde's, a very common tool is that of a stratification. We saw an example of this in section 2.3, and the general philosophy remains the same in other cases. That is, typically solutions of such nonlinear equations are not smooth and there is some singular set Sing of the solution. However, as a general principle it is helpful to not only separate out the smooth points from the singular points, but also to separate points based on the *degree* of the singularity. Thus, one usually has a stratification $S^0 \subseteq S^1 \subseteq \cdots \subseteq S^{n-1} \equiv \text{Sing}$ of the singular set where S^k is defined as the set of points which are not of degree $k+1$. The precise meaning of this varies from situation to situation, see section 2.3 for an example of this in the context of lower Ricci curvature.

The typical result of a stratification theory of a nonlinear pde is to prove an estimate of the form

$$\dim S^k \leq k\,, \tag{5.1}$$

where almost always the meaning of dimension is in the Hausdorff sense. As powerful as such results are, there is an underlying weakness to them. Fundamentally, this stems from the simple fact that the rationals are a dense subset of Euclidean space which have Hausdorff dimension zero. In particular, (5.1) cannot prevent the singular set from being dense, or from being arbitrarily dense. Thus, despite the many applications of (5.1), any questions which involve control of a more effective nature cannot be answered with (5.1).

In particular, what one typically would like to prove for solutions of differential equations are Schauder type estimates. In the context of Ricci curvature this means one would like to conclude *a priori* L^p curvature bounds for Einstein manifolds, for minimal surfaces this means showing L^p bounds on the second fundamental form, and for harmonic maps between Riemannian manifolds this means proving *a priori* L^p estimates on the gradient or hessian of such a map. We will see how to prove such estimates in this section. In the spirit of this article we will focus on the proof for Einstein manifolds, however the basic outline is the same in each situation (even if the details vary).

The outline of this section is the follows. In section 5.1 we give the rigorous definition of the quantitative stratification, and a statement of the main results concerning it. In section 5.2 we outline the proof of these estimates. The ideas involved turn out to be different from the standard proof of (5.1) by dimension reduction, and interestingly enough can be used to give a new proof of (5.1). In section 5.3 we apply these results to Einstein manifolds to conclude *apriori* L^p estimates on the curvature. In fact, we will see that the results are significantly stronger than this, and actually give estimates for the regularity scale. Finally in section 5.4 we outline the proof of the estimates of section 5.3.

5.1. Quantitative Stratification and Statement of Main Results. The goal of the quantitative stratification is to see that under reasonable circumstances, most points have balls of some definite size around them which contain a lot of symmetries. Of course we will make this more precise. The standard notion of stratification, which is reviewed in section 2.3, is

based on the idea of grouping points of a limit space X by the number of symmetries of its tangent cones. This is an infinitesmal notion which depends on the blow up behavior at a point. In particular, on a smooth manifold the stratification is always trivial as every tangent cone is $\mathbb{R}^n$ and thus has maximal symmetry. On the other hand, the quantitative stratification introduced in this section is based on grouping points based on the number of *almost* symmetries of balls of definite size. In particular, this stratification is not based on infinitesmal behavior, and even for a smooth manifold the quantitative stratification is nontrivial. The applications of section 5.3 depend on this.

To define the quantitative stratification we proceed by making rigorous the notion of *almost* symmetries:

Definition 5.1. Let (X, d) be a metric space, we make the following definitions:

(1) Given $x \in X$ we say X is k-symmetric at x if there exists a compact metric space Y such that $X \equiv C(Y) \times \mathbb{R}^k$ is isometric to a cone space over Y cross $\mathbb{R}^k$, and if x is the cone tip under this isometry.

(2) Given $x \in X$ and $0 < r \leq 1$ and $\epsilon > 0$ we say that X is (k, ϵ, r)-symmetric at x if there exists a metric space Z which is k-symmetric at $z \in Z$ such that

$$d_{GH}\left(B_{\epsilon^{-1}r}(x), B_{\epsilon^{-1}r}(z)\right) < \epsilon r\,. \tag{5.2}$$

To state the second definition in words, we say that X is (k, ϵ, r)-symmetric if the ball $B_r(x)$ looks very close to having k-symmetries. The quantitative stratification is then defined as follows:

Definition 5.2. Given a metric space X with $\epsilon, r > 0$ fixed and $k \in \mathbb{N}$, we define the closed (k, ϵ, r)-strata $S^k_{\epsilon,r}(X)$ by

$$S^k_{\epsilon,r}(X) \equiv \{x \in X : \text{ for no } r \leq s \leq 1 \text{ is } X \ \ (k+1, \epsilon, s) - \text{symmetric at } x\}\,. \tag{5.3}$$

Thus, the strata $S^k_{\epsilon,r}(X)$ is the collection of points such that no ball of size at least r is almost $k+1$-symmetric. The first main result of [12] is to show that for manifolds which are noncollapsed and have lower Ricci curvature bounds, the set $S^k_{\epsilon,r}(X)$ is small in a very strong sense. To say this a little more carefully, if one imagines the k-strata as being a well behaved k-dimensional submanifold (for simplicity sake), then one would expect the volume of the r-tube around the set to behave like r^{n-k}. We show this almost holds:

Theorem 5.3 ([12]). *Let (M^n, g, p) be a complete manifold with $Rc \geq -(n-1)$ and $Vol(B_1(p)) > v > 0$. Then for every $\epsilon > 0$ there exists $C(n, v, \epsilon)$ such that*

$$Vol(B_r(S^k_{\epsilon,r}(M)) \cap B_1(p)) \leq C r^{n-k-\epsilon}\,. \tag{5.4}$$

Remark 5.4. Though one can take $\epsilon > 0$ to be arbitrarily small, there is an ϵ loss in the power $r^{n-k-\epsilon}$ beyond what one might hope for. In fact, some loss is necessary as if one only assumes a lower bound on the Ricci curvature then the result fails for r^{n-k}. Under a full bound on the Ricci curvature it is conceivable the result may be improved however.

5.2. Outline of Proof of Theorem 5.3. We now give an outline of the proof of Theorem 5.3. The classical dimension estimates on the singular set (5.1) are given by a dimension reduction argument. Such an argument cannot be quantified. Morally, this is because the basis for the argument is to take multiple tangent cones. The quantification of such an argument leads to the comparison of scales which are not comparible, and a loss of effective control. Instead, we give an entirely new proof of (5.1) which is more adaptable to being made quantitative. The next subsections will outline the proof and the main ideas involved.

5.2.1. Cone Splitting. The essence of any stratification is symmetry. A stratification is a measurement of how many points (and scales) do not have a lot of symmetry. To provide estimates on such things one needs a way of producing symmetry. The basic idea in [12] is that of cone splitting.

To explain this, recall that a metric space X is 0-symmetric if $X = C(Y)$ is a cone space over another metric space. More generally X is 0-symmetric with respect to $x \in X$ if $X = C(Y)$ such that x is the cone point of $C(Y)$. Imagine now that X is 0-symmetric with respect to two distinct points $x_0, x_1 \in X$. In fact, it is not a hard exercise that this is only possible if $X \equiv \mathbb{R} \times C(Y')$ is 1-symmetric with x_0 and x_1 cone points lying on the same $\mathbb{R}$-factor. Said more simply, two 0-symmetries imply a 1-symmetry. This may be generalized simply into a process we call cone splitting:

Cone Splitting: Let $X = \mathbb{R}^k \times C(Y)$ be k-symmetric, and assume there exists $x_0 \notin \mathbb{R}^k \times \{0_y\}$, where 0_y is the cone point of $C(Y)$, such that X is 0-symmetric with respect to x_0. Then X is $k+1$-symmetric.

Thus the key step in producing symmetry of a metric space is simply to produce lots of 0-symmetry. More simply, k independent 0-symmetries imply a k-symmetry. We will see in the next subsection how to do this. Let us end this subsection with the effective version of the above cone splitting for spaces with lower Ricci curvature bounds:

Theorem 5.5 ([12]). *Let (M^n, g) be a Riemannian manifold with Ric $\geq -(n-1)$. For every $\epsilon, \tau > 0$ there exists $\delta(n, \epsilon, \tau) > 0$ such that the following holds. If M is $(10r, k, \delta)$-symmetric at $x \in M$ with Gromov-Hausdorff map $\phi : B_{10r}(x) \to \mathbb{R}^k \times C(Y)$, and if there exists $x_0 \in B_r(x)$ such that $\phi(x_0) \notin B_\tau(\mathbb{R}^k \times \{0_y\})$ with M being $(10r, 0, \delta)$-symmetric at x_0, then M is $(5r, k+1, \epsilon)$-symmetric at x.*

5.2.2. Energy Decomposition. In this last subsection we saw the key to forcing k-symmetries was to construct k indepedent 0-symmetries. To begin this process we want to consider the case of just finding which scales are 0-symmetric. The key ingredient here is the existence of a monotone quantity. Namely, if M satisfies Ric $\geq -(n-1)$ then for each $x \in M$ we have the monotone quantity

$$V_r(x) = -\ln \frac{\text{Vol}(B_r(x))}{\text{Vol}_{-1}(B_r)}\,, \tag{5.5}$$

where B_r is a ball of radius r in hyperbolic space. One can rephrase theorem 2.5.2 in the following manner:

A consequence of the Cheeger-Colding theory is the following quantitative form of the rigidity of theorem 2.2:

Theorem 5.6. *Let (M^n, g) be a Riemannian manifold with Ric $\geq -(n-1)$, then for each $\epsilon > 0$ there exists $\delta(n, \epsilon) > 0$ such that if for $r < \delta$ we have that $|V_r(x) - V_{\delta r}(x)| < \delta$, then M is $(r, 0, \epsilon)$-symmetric at x.*

Now let us denote by $r_\alpha = 2^{-\alpha}$ the sequence of scales which drop by a factor of $\frac{1}{2}$. For a given point $x \in M$ we will call the scale r_α a *good* scale if x is $(r_\alpha, 0, \epsilon)$-symmetric at scale r_α, and a *bad* scale otherwise. Now let us check the following easy, but highly important, consequence of the monotone quantity:

Theorem 5.7 ([12]). *Let (M^n, g, p) be a Riemannian manifold with Ric $\geq -(n-1)$ and Vol$(B_1(p)) > v > 0$. Then for each $\epsilon > 0$ there exists $N(n, \epsilon, v) > 0$ such that for every $x \in B_1(p)$ we have that there are at most N bad scales at x.*

Proof. Note first that if Vol$(B_1(p)) > v > 0$, then the doubling property of the volume tells us that Vol$(B_1(x)) > C(n)^{-1}v > 0$ for each $x \in B_1(p)$. Now it follows from theorem 5.6 that for r_α to be a good scale it suffices that $V_{r_\alpha}(x) - V_{r_{\alpha+\beta}}(x) < \delta$, where $\beta(n, \epsilon)$ and $\delta(n, \epsilon)$ are fixed constants. But now let us observe that

$$\sum |V_{r_\alpha}(x) - V_{r_{\alpha+1}}(x)| = \sum V_{r_\alpha}(x) - V_{r_{\alpha+1}}(x) = V_1(x) - V_0(x) \leq -\log(C^{-1}v)\,. \tag{5.6}$$

On the other hand imagine there are at least N scales for which $V_{r_\alpha}(x) - V_{r_{\alpha+\beta}}(x) > \delta$. Then we get that

$$\sum |V_{r_\alpha}(x) - V_{r_{\alpha+1}}(x)| \geq \frac{N\delta}{\beta}\,. \tag{5.7}$$

Combining the last two inequalities gives the required upper bound on N. □

The last Theorem tells us that at every point most scales are almost 0-symmetric. What we want to see now is that at most points and scales there are other points nearby which are also *good* scales. By the cone-splitting this would give us our desired symmetries.

We begin with the following, for each $x \in B_1(p)$ let us associate to x the infinite $\mathbb{Z}_2$-tuple given by

$$T_\alpha(x) = \begin{cases} 0, & \text{if } x \text{ is } (r_\alpha, 0, \epsilon) - \text{symmetric} \\ 1, & \text{otherwise} \end{cases} \tag{5.8}$$

The content of the last Theorem is that

$$\sum T_\alpha(x) \leq N(n, v, \epsilon)\,. \tag{5.9}$$

Now the energy decomposition of M is as follows. Let us fix $\beta \in \mathbb{N}$, and for each β-tuple of $\mathbb{Z}_2$, $T \in \mathbb{Z}_2^\beta$, let us define

$$M_T \equiv \{x \in B_1(p) : T_\alpha(x) = T_\alpha \text{ for all } 0 \leq \alpha \leq \beta\}\,. \tag{5.10}$$

That is, we are grouping points of M by which scales they are good and bad on. Now the key result is the following:

Theorem 5.8 ([12]). *Let (M^n, g, p) be a Riemannian manifold with Ric $\geq -(n-1)$ and Vol$(B_1(p)) > v > 0$. Then for each $\epsilon, \epsilon' > 0$ and $T \in \mathbb{Z}_2^\beta$ there exists $C(n, \epsilon) > 0$ such that*

$$\text{Vol}(B_r(S^k_{\epsilon,r} \cap M_T)) < Cr^{n-k-\epsilon'}, \tag{5.11}$$

for $r \geq r_\beta$.

The proof is involved, and based on an induction on β. The key idea which brings the energy decomposition into play is that by only comparing points which are good on the same scales, either we can locally cover M_T by a sufficiently small number of balls for the estimate, or if we cannot then this forces splitting by the cone-splitting principle.

5.2.3. Proof of Theorem 5.3. The proof of Theorem 5.3 now follows almost immediately from Theorem 5.8. There is no harm in assuming $r = r_\beta$ for some β, otherwise there exists a unique r_β such that $r_\beta \leq r < r_{\beta-1}$ and by volume doubling we can still use the r_β covering.

Now for each β-tuple $T \in \mathbb{Z}_2^\beta$ we have the desired estimate

$$\text{Vol}(B_{r_\beta}(S^k_{\epsilon,r_\beta} \cap M_T)) < Cr_\beta^{n-k-\epsilon'}, \tag{5.12}$$

from Theorem 5.8. In general, to estimate Vol$(B_r(S^k_{\epsilon,r} \cap B_1(p)))$ we would then need to multiply this estimate by the number of β-tuples T, which is $2^\beta = r_\beta^{-1}$. Of course this is too large a loss. However, by Theorem 5.7 we only need to consider those β-tuples T for which $\sum T_\alpha \leq N$, which is on the order of $\approx \beta^N \approx C \log r_\beta$. Thus if we let $\epsilon' = \epsilon/2$ we have that

$$\text{Vol}(B_{r_\beta}(S^k_{\epsilon,r_\beta} \cap B_1(p))) \leq \sum_T \text{Vol}(B_{r_\beta}(S^k_{\epsilon,r_\beta} \cap M_T)) < Cr_\beta^{n-k-\epsilon/2} \log r_\beta \leq Cr_\beta^{n-k-\epsilon}, \tag{5.13}$$

which proves Theorem 5.3.

5.3. Application to Einstein Manifolds. Now let us outline how Theorem 5.3 may be used to prove *a priori* L^p bounds on the curvature, and in fact for the regularity scale, for Einstein manifolds. As was discussed, the same moral works in many other areas to provide the first Schauder estimates for various nonlinear pde's.

To begin with, so that we may state the result in its full strength, let us define the notion of regularity scale:

Definition 5.9. Given a smooth Riemannian manifold (M^n, g), for each point $x \in M$ let us define the regularity scale $r_{|Rm|}(x)$ as

$$r_x = r_{|\text{Rm}|}(x) \equiv \max\left\{0 < r \leq 1 : \sup_{B_r(x)} |\text{Rm}| \leq r^{-2}\right\}. \tag{5.14}$$

Let us begin with some remarks on the regularity scale. For starters, note the easy estimate $|\text{Rm}|(x) \leq r_x^{-2}$, and thus lower bounds on the regularity scale correspond to upper bounds on the curvature. However, control over the curvature at a single point gives no a priori control of the geometry in a neighborhood of that point. On the other hand, the regularity scale bounds the curvature in a definite size neighborhood, which tells us everything about

the possible geometries. In particular, if M is Einstein we can immediately conclude that on a ball of half the size we have control over all derivatives of the curvature, that is:

$$\sup_{B_{r_x/2}(x)} |\nabla^{(k)}\mathrm{Rm}| \leq C_k r_x^{-k}\,. \tag{5.15}$$

Additionally it is worth remarking that the definition of the regularity scale is chosen to be scale invariant. That is, if we rescale the geometry by r_x^{-1}, so that $B_{r_x}(x) \to B_1(x)$, then we have that the curvature $|\mathrm{Rm}| \leq 1$ is bounded by one on the ball $B_1(x)$ of radius one.

Now the main result of this section and the main application of the quantitative stratification is the following:

Theorem 5.10 ([12]). *Let (M^n, g, p) be an Einstein manifold with $|Ric| \leq n-1$ and $Vol(B_1(p)) > v > 0$. Then the following hold:*

(1) *For each $p < 1$ we have that*

$$\int_{B_1(p)} |Rm|^p \leq \int_{B_1(p)} r^{-2p} < C(n, v, p)\,, \tag{5.16}$$

and in particular we have the Minkowski estimate

$$Vol(B_r(\{x : r_x \leq r\})) < C(n, v, p) r^{2p}\,. \tag{5.17}$$

(2) *If M is Kähler, then for each $p < 2$ we have that*

$$\int_{B_1(p)} |Rm|^p \leq \int_{B_1(p)} r^{-2p} < C(n, v, p)\,, \tag{5.18}$$

and in particular we have the Minkowski estimate

$$Vol(B_r(\{x : r_x \leq r\})) < C(n, v, p) r^{2p}\,. \tag{5.19}$$

(3) *Finally if we assume $\int |Rm|^p \equiv \Lambda < \infty$, then we can conclude the much stronger estimate*

$$Vol(B_r(\{x : r_x \leq r\})) < C(n, \Lambda, p) r^{2p}\,. \tag{5.20}$$

Theorem 5.10.3 is particularly useful for Kähler Einstein manifolds, where one has the L^2 bound based on topological assumptions.

5.4. Outline of Proof of the Quantitative Estimates. Now we end this section by outlining the proof of Theorem 5.10. In particular we focus on Theorem 5.10.2, the proofs of the other statements are similar up to technical details. The idea is very straightforward given the quantitative stratification of Theorem 5.3 and the ϵ-regularity of Cheeger-Tian. Namely, let us state their theorem in the following manner: If M^n is Kähler Einstein with $|\mathrm{Rc}| \leq n-1$ and $\mathrm{Vol}(B_1(p)) > v > 0$, then there exists $\epsilon(n, v) > 0$ such that if p is $(n-3, \epsilon, 2r)$-symmetric, then $r_x \geq r$.

Now let us fix $r > 0$ and $\epsilon > 0$ from the above statement and $\delta > 0$ aribitrarily. Then Theorem 5.3 tells us in particular that

$$\mathrm{Vol}(B_r(S^{n-4}_{\epsilon,2r}(M) \cap B_1(p))) < C(n, \epsilon, \delta) r^{4-\delta}\,. \tag{5.21}$$

However, if $x \notin S^{n-4}_{\epsilon,2r}$ then this is exactly the statement that there exists $s \geq 2r$ such that x is $(n-3,\epsilon,s)$-symmetric. In particular, by the ϵ-regularity theorem this immediately gives $r_x \geq r$. Combining this with the volume estimate (5.21) immediately gives the estimate (5.19), as claimed.

6. Open Problems and Conjectures

We end this write up with a small list of open problems and conjectures involving spaces with lower Ricci curvature bounds. Some of these are old and some are new. Let us begin with the basic issue of regularity of spaces with lower Ricci curvature bounds:

Open Question. *Let X be a Gromov-Hasudorff limit of manifolds M^n_j satisfying Ric $\geq -(n-1)$. More generally let X be a metric-measure space satisfying a lower Ricci curvature bound in the generalized sense, for instance X could be a $RCD(n,K)$-space as in [3]. Then is X a topological manifold on an open dense subset?*

In a recent paper [29] it has been shown that such a $RCD(n,K)$ space is rectifiable, which is roughly the statement that X may be obtained from gluing together subsets of Euclidean space. The statement of manifold roughly requires these subsets to be *open*. This is still unknown, and one of the more interesting problems in the area.

In another direction it has been discussed that even for noncollapsed limit spaces the tangent cones need not be unique, and in fact by [15] pretty much any subset which could be the collection of tangent cones at a point in some limit is. However, it would be of interest to understand how big a subset of a limit space does have unique tangent cones. One might hope for the following:

Conjecture 6.1. *Let (X,d,p) be a Gromov-Hasudorff limit of manifolds (M^n_j,g_j,p_j) satisfying Ric$_j \geq -(n-1)$ and Vol$(B_1(p_j)) > v > 0$. Then the set of points of X which have nonunique tangent cones has dimension $\leq n-3$.*

It is a corollary of [7] that away from a set of dimension $\leq n-2$ the tangent cones are unique and $\mathbb{R}^n$. It is also known that away from a set of dimension $\leq n-3$ that there exists *some* tangent cone which is $\mathbb{R}^{n-2}\times C(S^1(r))$, where $S^1(r)$ is the circle of radius $r \leq 1$. An equivalent version of the above conjecture is therefore the following

Conjecture 6.2. *Let (X,d,p) be a Gromov-Hasudroff limit of manifolds (M^n_j,g_j,p_j) satisfying Ric$_j \geq -(n-1)$ and Vol$(B_1(p_j)) > v > 0$. Then away from a set of Hausdorff dimension $\leq n-3$ the tangent cone is unique and isometric to $\mathbb{R}^{n-2}\times C(S^1(r))$ for some $r \leq 1$.*

A corollary of the above would be the $n-2$-rectifiability of the singular set.

Instead of considering just spaces with a lower Ricci curvature bound we could consider Einstein manifolds, and in particular noncollapsed Einstein manifolds. There are many structural conjectures out there at the moment, and the following is a strengthened version which would imply many of them:

Conjecture 6.3. *Let (M^n,g,p) be an Einstein manifold satisfying $|$Ric$| \leq n-1$ and*

Vol$(B_1(p)) > v > 0$. *Then there exists* $C(n, v) > 0$ *such that*

$$\int_{B_1(p)} |Rm|^2 < C\,. \tag{6.1}$$

Note that if M^n is Kähler then the conjecture is known if we further assume topological restrictions on M. Without any such topological restrictions it has been proved in Theorem 5.10 that $\int_{B_1(p)} |\mathrm{Rm}|^{2-\epsilon} < C_\epsilon$ for any $\epsilon > 0$. On the other hand, for four dimensional Einstein manifolds the conjecture is again known to hold under topological restrictions (in this case the L^2 norm of the curvature is equivalent to the Euler characteristic). Finally, if M^4 is Kähler and four dimensional, then the above conjecture can be shown to hold in full.

We end with the following structural conjecture for noncollapsed limits of Einstein manifolds:

Conjecture 6.4. *Let* (X, d, p) *be a Gromov-Hasudorff limit of Einstein manifolds* (M^n_j, g_j, p_j) *satisfying* $|Ric_j| \leq n - 1$ *and Vol*$(B_1(p_j)) > v > 0$. *Then* X *is homeomorphic to a real-analytic variety.*

A great deal of progress has been made recently in the above conjecture, in particular it has been proven for compact Kähler manifolds with positive first chern class, see [35],[16].

New applications of Min-max Theory

André Neves

Abstract. I will talk about my recent work with Fernando Marques where we used Almgren–Pitts Min-max Theory to settle some open questions in Geometry: The Willmore conjecture, the Freedman–He–Wang conjecture for links (jointly with Ian Agol), and the existence of infinitely many minimal hypersurfaces in manifolds of positive Ricci curvature.

Mathematics Subject Classification (2010). Primary 53C42; Secondary 49Q05.

Keywords. Minimal surfaces, Willmore energy, conformal geometry, Min-max Theory.

1. Introduction

I will start by introducing three problems in Geometry which, while quite distinct, have in common the fact that their solution comes from understanding unstable critical points in the space of all embedded hypersurfaces on a given manifold. A panoramic overview of variational methods in Geometry can be found in the contribution of Fernando C. Marques [36].

1.1. Willmore Conjecture. A central question in Mathematics has been the search for the "optimal" representative within a certain class of objects. Partially motivated by this principle, Thomas Willmore started in the 60's the quest for the "optimal" immersion of a surface in space.

With that in mind, he associated to every compact surface $\Sigma \subset \mathbb{R}^3$ the quantity (now known as the *Willmore energy*),

$$\mathcal{W}(\Sigma) = \int_\Sigma \left(\frac{k_1 + k_2}{2}\right)^2 d\mu,$$

where k_1, k_2 are the principal curvatures of Σ.

The Willmore energy is invariant under rigid motions, scaling, and is large when the surface contains long thin tubes or long thin holes thus detecting how "bended" the surface Σ is in space. Less obvious, is the fact that the Willmore energy is also invariant under the inversion $x \mapsto x/|x|^2$ and thus invariant under conformal transformations. Willmore himself only found this some years later but, as we explain soon, this was know already since the twenties.

It is worthwhile to remark that in applied sciences the Willmore energy had already made its appearance a long time ago, under the name of *bending energy*, in order to study vibrating

Proceedings of the International Congress of Mathematicians, Seoul, 2014

properties of thin plates. In 1810's, Marie-Sophie Germain proposed, as the bending energy of a thin plate, the integral with respect to the surface area of an even, symmetric function of the principal curvatures, in which case the Willmore energy is the simplest possible example (excluding the area). Similar quantities were also considered by Poisson around the same time.

Moreover, the Willmore energy had also appeared in Mathematics through the work of Thomsen [52] and Blaschke [7] in the 1920's but their findings were forgotten and only brought to light after the interest in the Willmore energy increased. In particular, Thomsen and Blaschke were already aware of the conformal invariance of the Willmore energy.

Back to Willmore's quest for the "best" possible immersion, he showed that round spheres have the least possible Willmore energy among all compact surfaces in space. More precisely, ever compact surface $\Sigma \subset \mathbb{R}^3$ has

$$\mathcal{W}(\Sigma) \geq 4\pi$$

with equality only for round spheres.

Having found the compact surface with least possible energy, he tried to find the torus in space with smaller energy than any other tori. It is interesting to note that, just by looking at the shape of tori in space, no obvious candidate stands out. Hence, Willmore fixed a circle on a plane and considered tubes Σ_r of a constant radius r around that circle. When r is very small, Σ_r is a thin tube around the planar circle and thus its energy $\mathcal{W}(\Sigma_r)$ will be very large. If we keep increasing the value of r, the "hole" centered at the axis of revolution of the torus decreases and eventually disappears for some r_0. Thus $\mathcal{W}(\Sigma_r)$ will be arbitrarily large for r close to r_0. Therefore $\mathcal{W}(\Sigma_r)$ must have an absolute minimum as r ranges from 0 to r_0, which Willmore computed to be $2\pi^2$.

Up to scaling, the "optimal" torus that Willmore found has generating circle with radius 1 and center at distance $\sqrt{2}$ from the axis of revolution:

$$(u, v) \mapsto \big((\sqrt{2} + \cos\, u) \cos\, v, (\sqrt{2} + \cos\, u) \sin\, v, \sin\, u\big) \in \mathbb{R}^3.$$

In light of his findings, Willmore conjectured [55]:

Willmore Conjecture (1965). *Every compact surface Σ of genus one has*

$$\int_\Sigma \left(\frac{k_1 + k_2}{2}\right)^2 d\mu \geq 2\pi^2.$$

It seems at first rather daring to make such conjecture after having tested it only on a very particular one parameter family of tori. On the other hand, the torus Willmore found is special and had already appeared in Geometry: Inside the unit 3-sphere S^3 in $\mathbb{R}^4$ there is a highly symmetric torus, the Clifford torus, which is given by $S^1(\frac{1}{\sqrt{2}}) \times S^1(\frac{1}{\sqrt{2}})$. There is a stereographic projection from the 3-sphere onto space that sends the Clifford torus to the "optimal" torus found by Willmore.

The richness of the Willmore conjecture derives partially from the fact that the Willmore energy is invariant under conformal maps. One immediate consequence is that the conjecture can be restated for surfaces in the unit 3-sphere S^3. Indeed, if Σ is a compact surface in S^3 and $\tilde{\Sigma}$ its image in $\mathbb{R}^3$ under stereographic projection, then one has

$$\mathcal{W}(\tilde{\Sigma}) = \int_\Sigma 1 + \left(\frac{k_1 + k_2}{2}\right)^2 d\mu,$$

where k_1, k_2 are the principal curvatures of Σ *with respect* to the standard metric on S^3. For this reason, one calls the left-hand side of the above equation the *Willmore energy* $\mathcal{W}(\Sigma)$ of $\Sigma \subset S^3$.

The conjecture had been verified in many special cases borrowing inspiration from several distinct areas such as integral geometry, algebraic geometry, minimal surfaces, analysis or conformal geometry. We refer the reader to [38] for the history of partial results and mention simply the ones relevant to our work.

In 1982 it was proven by Li and Yau [33] that the Willmore energy of any non-embedded surface must be at least 8π (which is strictly bigger than $2\pi^2$. In particular, it suffices to check the Willmore conjecture for embedded tori.

Ros [46] proved in 1999 the Willmore conjecture for tori in S^3 that are preserved by the antipodal map and his method motivated our approach.

Curiously, two biologists, Bensimon and Mutz [40], verified the Willmore conjecture with the aide of a microscope while studying the physics of membranes! They produced toroidal vesicles in a laboratory and observed that they assumed the shape, which according to the Helfrich model [23] should be the minimizer for the Willmore energy, of the Clifford torus or its conformal images (called Dupin cyclides).

Jointly with Fernando Marques [38] we showed that

Theorem 1.1. *Every embedded compact surface Σ of S^3 with positive genus has*

$$\mathcal{W}(\Sigma) \geq 2\pi^2.$$

Equality only holds, up to rigid motions, for stereographic projections of the Clifford torus.

The rigidity statement characterizing the equality case in Theorem 1.1 is optimal because, as we have mentioned, the Willmore energy is conformal invariant.

Using the Li–Yau result previously mentioned we obtain

Corollary. *The Willmore conjecture holds.*

1.2. Energy of links. The second application comes from the theory of links in $\mathbb{R}^3$. Let $\gamma_i : S^1 \to \mathbb{R}^3$, $i = 1, 2$, be a 2-component link, i.e., a pair of closed curves in Euclidean three-space with $\gamma_1(S^1) \cap \gamma_2(S^1) = \emptyset$.

A 2-component link is said to be *nontrivial* if it cannot be deformed without intersecting itself into two curves contained in disjoint balls. To every link (γ_1, γ_2) one associates an integer invariant, called the linking number $\mathrm{lk}(\gamma_1, \gamma_2)$, that intuitively measures how many times each curve winds around the other.

To every 2-component link (γ_1, γ_2), O'Hara [44] associated an energy, called the *Möbius cross energy*. Its definition is reminiscent of the electrostatic potential energy and is given by ([15, 44]):

$$E(\gamma_1, \gamma_2) = \int_{S^1 \times S^1} \frac{|\gamma_1'(s)||\gamma_2'(t)|}{|\gamma_1(s) - \gamma_2(t)|^2}\, ds\, dt.$$

Freedman, He, and Wang studied this energy in detail and found that it has the remarkable property of being invariant under conformal transformations of $\mathbb{R}^3$ [15], just like the Willmore energy.

Using Gauss formula for the linking number, one can see that

$$E(\gamma_1, \gamma_2) \geq 4\pi |\mathrm{lk}(\gamma_1, \gamma_2)|$$

and so it is then natural to search for optimal configurations, i.e., minimizers of the Möbius energy. This question can be given the following nice physical interpretation (see [44]). Assuming that each curve in the link is non-conductive, charged uniformly and subject to a Coulomb's repulsive force, the equilibrium configuration the link will assume should minimize the Möbius energy.

Freedman, He and Wang [15] considered this question and after looking at the particular the case where one of the link components is a planar circle, they made the following conjecture.

Freedman–He–Wang Conjecture (1994). *The Möbius energy is minimized, among the class of all nontrivial links in $\mathbb{R}^3$, by the stereographic projection of the standard Hopf link in S^3.*

The standard Hopf link $(\hat{\gamma}_1, \hat{\gamma}_2)$ in S^3 is described by

$$\hat{\gamma}_1(s) = (\cos s, \sin s, 0, 0) \in S^3 \quad \text{and} \quad \hat{\gamma}_2(t) = (0, 0, \cos t, \sin t) \in S^3,$$

and it is simple to check that $E(\hat{\gamma}_1, \hat{\gamma}_2) = 2\pi^2$.

In a joint work with Ian Agol and Fernando Marques [1] we showed that:

Theorem 1.2. *Let (γ_1, γ_2) be a 2-component link in $\mathbb{R}^3$ with $|\mathrm{lk}(\gamma_1, \gamma_2)| = 1$. Then $E(\gamma_1, \gamma_2) \geq 2\pi^2$.*

Equality only holds, up to rigid motions and orientation, for stereographic projections of the Hopf link.

It follows from a result of He [22] that it suffices to prove the conjecture for links (γ_1, γ_2) with linking number $\mathrm{lk}(\gamma_1, \gamma_2) = \pm 1$. Thus, we obtained the following corollary

Corollary. *The conjecture made by Freedman, He, and Wang holds.*

1.3. Existence of embedded minimal hypersurfaces. A question lying at the core of Differential Geometry, asked Poincaré [41] in 1905, is whether every closed Riemann surface always admits a closed geodesic.

If the surface is not simply connected then we can minimize length in a nontrivial homotopy class and produce a closed geodesic. Therefore the question becomes considerably more interesting on a two-sphere, and the first breakthrough was in 1917, due to Birkhoff [6], who found a closed geodesic for any metric on a two-sphere.

Later, in a remarkable work, Lusternik and Schnirelmann [35] showed that every metric on a 2-sphere admits three simple (embedded) closed geodesics (see also [4, 17, 27, 30, 34, 51]). This result is optimal because there are ellipsoids which admit no more than three simple closed geodesics.

This suggests the question of whether we can find an infinite number of geometrically distinct closed geodesics in any closed surface. It is not hard to find infinitely many closed geodesics when the genus of the surface is positive.

The case of the sphere was finally settled in 1992 by Franks [14] and Bangert [5]. Their works combined imply that every metric on a two-sphere admits an infinite number of closed geodesics. Later, Hingston [24] estimated the number of closed geodesics of length at most L when L is very large.

Likewise, one can ask whether every closed Riemannian manifold admits a closed minimal hypersurface. When the ambient manifold has topology one can find minimal hypersurfaces by minimization and so, like in the surface case, the question is more challenging

when every hypersurface is homologically trivial. Using min-max methods, and building on earlier work of Almgren, Pitts [42] in 1981 proved that every compact Riemannian $(n+1)$-manifold with $n \leq 5$ contains a smooth, closed, embedded minimal hypersurface. One year later, Schoen and Simon [48] extended this result to any dimension, proving the existence of a closed, embedded minimal hypersurface with a singular set of Hausdorff codimension at least 7.

When M is diffeomorphic to a 3-sphere, Simon–Smith [49] showed the existence of a minimal embedded sphere using min-max methods (see also [8]).

Motivated by these results, Yau made the following conjecture [58] (first problem in the Minimal Surfaces section):

Yau's Conjecture (1982). *Every compact 3-manifold (M, g) admits an infinite number of smooth, closed, immersed minimal surfaces.*

Lawson [32] showed in 1970 that the round 3-sphere admits embedded minimal surfaces of every possible genus.

When M is a compact hyperbolic 3-manifold, Khan and Markovic [28] found an infinite number of incompressible surfaces in M of arbitrarily high genus. One can then minimize energy in their homotopy class and obtain an infinite number of smooth, closed, immersed minimal surfaces.

Jointly with Fernando Marques [39] we showed

Theorem 1.3. *Let (M^{n+1}, g) be a compact Riemannian manifold with $2 \leq n \leq 6$ and a metric of positive Ricci curvature.*

Then M contains an infinite number of distinct, smooth, embedded, minimal hypersurfaces.

Until Theorem 1.3 was proven, it was not even known whether metrics on the 3-sphere arbitrarily close to the round metric also admit an infinite number of minimal surfaces.

I find a fascinating problem to shed some light into the asymptotic behaviour of the minimal surfaces given by Theorem 1.3.

2. Almgren–Pitts Min-max Theory

As mentioned in the Introduction, Theorem 1.1, Theorem 1.2, and Theorem 1.3, follow from understanding the topology of the space of all embedded hypersurfaces.

In very general terms, the guiding principle of Morse Theory is that given a space and a function defined on that space, the topology of the space forces the function to have certain critical points. For instance, if the space has a k-dimensional nontrivial cycle, then the function should have a critical point of index at most k.

The space we are interested is $\mathcal{Z}_n(M)$, the space of all orientable compact hypersurfaces with possible multiplicities in a compact Riemannian $(n+1)$-manifold (M, g) with $n \geq 2$. If we allow for non-orientable hypersurfaces as well, the space is denoted by $\mathcal{Z}_n(M; \mathbb{Z}_2)$.

These spaces are studied in the context of Geometric Measure Theory and come with a well understood topology (flat topology) and equipped with a natural functional which associates to every element in $\mathcal{Z}_n(M)$ (or $\mathcal{Z}_n(M; \mathbb{Z}_2)$) its n-dimensional volume.

I will try to keep the discussion with as little technical jargon as possible in order to convey the main ideas and thus ignore almost all technical issues.

Critical points of the volume functional are called *minimal hypersurfaces* and their index is the number of independent deformations that decrease the area. For instance, on the 3-torus with the flat metric, there is a natural flat 2-torus which minimizes area in its homology class and thus it is a minimal surface of index zero. Likewise, on the 3-sphere with the round metric, the equator (which has area 4π) is a minimal sphere and has the property that if we "push" it up into the northern hemisphere then its area is decreased. Hence, its index is at least one. On the other hand, one can check that a deformation of the equator that preserves the enclosed volume is never area decreasing. Thus the equator has index one.

Almgren [3] started in the 60's the study of Morse Theory for the volume functional on $\mathcal{Z}_n(M)$ (or $\mathcal{Z}_n(M;\mathbb{Z}_2)$) and that continued through the 70's jointly with Pitts, his Phd student. I present now the basic principles of Almgren–Pitts Min-max Theory.

Suppose X is a topological space and $\Phi : X \to \mathcal{Z}_n(M)$ a continuous function. Consider

$$[\Phi] = \{\Psi : X \to \mathcal{Z}_n(M) : \ \Psi \text{ homotopic to } \Phi \text{ relative to } \partial X\}.$$

Note that if $\Psi \in [\Phi]$ then $\Phi = \Psi$ on ∂X. To the homotopy class $[\Phi]$ we associate the number, called the *width*,

$$\mathbf{L}([\Phi]) = \inf_{\Psi\in[\Phi]} \sup_{x\in X} \mathrm{vol}(\Psi(x)).$$

The Almgren-Pitts Min-max Theorem [42] can be stated as

Theorem 2.1 (Min-max Theorem). *Assume that* $\mathbf{L}([\Phi]) > \sup_{x\in\partial X} \mathrm{vol}(\Phi(x))$.

There is a compact embedded minimal hypersurface Σ *(with possible multiplicities) such that*

$$\mathbf{L}([\Phi]) = \mathrm{vol}(\Sigma).$$

The theorem also holds for $\mathcal{Z}_n(M;\mathbb{Z}_2)$ with no modifications.

The support of Σ is smooth outside a set of codimension 7 and thus smooth if $n \geq 6$ (for $n \geq 5$ the regularity theory was done by Schoen and Simon [48]). The Min-max Theorem allows for Σ to be a union of disjoint hypersurfaces, each with some multiplicity. More precisely

$$\Sigma = n_1\Sigma_1 + \ldots + n_k\Sigma_k,$$

where $n_i \in \mathbb{N}$, $i = 1, \ldots, k$, and $\{\Sigma_1, \ldots, \Sigma_k\}$ are embedded minimal surfaces with disjoint supports.

Naturally, if the space of parameters X is a k-dimensional, we expect the index of Σ to be at most k but this fact has not been proven.

The condition $\mathbf{L}([\Phi]) > \sup_{x\in\partial X} \mathrm{vol}(\Phi(x))$ means that $[\Phi]$ is capturing some nontrivial topology of $\mathcal{Z}_n(M)$. The guiding philosophy behind Min-max Theory consists in finding examples of homotopy classes satisfying this condition and then use the Min-max Theorem to deduce geometric consequences.

The next example illustrates well this methodology. Given $f : M \to [0,1]$ a Morse function, consider the continuous map

$$\Phi : [0,1] \to \mathcal{Z}_n(M), \quad \Phi(t) = \partial\{x \in M : f(x) < t\}.$$

We have $\Phi(0) = \Phi(1) = 0$ because all elements in $\mathcal{Z}_n(M)$ with zero volume are identified to be the same and Almgren showed in [2] that $L([\Phi]) > 0$, i.e., $[\Phi]$ is a nontrivial element of $\pi_1(\mathcal{Z}_n(M), \{0\})$. Using Min-max Theorem one obtains the existence of a minimal

hypersurface in (M, g) whose volume realizes $L([\Phi])$ and thus (M, g) admits a minimal embedded hypersurface which is smooth outside a set of codimension 7. This application was one of the motivations for Almgren and Pitts to develop their Min-max Theory.

3. The $2\pi^2$ Theorem

Let I^k denote a closed k-dimensional cube and $B_r(p)$ denote the geodesic ball in S^3 of radius r centered at p.

We present a criteria due to Marques and myself [38] to ensures that a map $\Phi : I^5 \to \mathcal{Z}_2(S^3)$ determines a nontrivial 5-dimensional homotopy class in $\mathcal{Z}_\in(\mathcal{S}^\ni)$.

Let $\mathcal{G}_o$ be the set of all oriented geodesic spheres in $\mathcal{Z}_2(S^3)$. Each nonzero element in $\mathcal{G}_o$ is determined by its center and radius. Thus this space is homeomorphic to $S^3 \times [-\pi, \pi]$ with an equivalence relation that identifies $S^3 \times \{-\pi\}$ and $S^3 \times \{\pi\}$ all with the zero in $\mathcal{Z}_2(S^3)$.

The maps Φ we consider have the property that

$$\Phi(I^4 \times \{1\}) = \Phi(I^4 \times \{0\}) = \{0\} \quad \text{and} \quad \Phi(I^4 \times I) \subset \mathcal{G}_o.$$

Hence $\Phi(I^5)$ can be thought of a 5-cycle in $\mathcal{Z}_2(S^3)$ whose boundary lies in $\mathcal{G}_o$ and thus $[\Phi]$ can be seen as an element of $\pi_5(\mathcal{Z}_2(S^3), \mathcal{G}_o)$. The next theorem gives a condition under which $[\Phi] \neq 0$ in $\pi_5(\mathcal{Z}_2(S^3), \mathcal{G}_o)$, i.e., the image of Φ cannot be homotoped into the set of all geodesic spheres.

Theorem 3.1. *Let $\Phi : I^5 \to \mathcal{Z}_2(S^3)$ be a continuous map such that:*

(1) $\Phi(x, 0) = \Phi(x, 1) = 0$ *for any* $x \in I^4$*;*

(2) *for any $x \in \partial I^4$ fixed we can find $Q(x) \in S^3$ such that*

$$\Phi(x, t) = \partial B_{\pi t}(Q(x)), \quad 0 \leq t \leq 1.$$

In particular, $\Phi(I^5) \subset \mathcal{G}_o$.

(3) *the center map $Q : \partial I^4 \to S^3$ has* $\deg(Q) \neq 0$.

Then

$$\mathbf{L}([\Phi]) > 4\pi = \sup_{x \in \partial I^5} \mathbf{M}(\Phi(x)).$$

Condition (3) is crucial, as the next example shows. Consider

$$\Phi : I^5 \to \mathcal{Z}_2(S^3), \quad \Phi(x, t) = \partial B_{\pi t}(p),$$

where p is a fixed point in S^3. Conditions (1) and (2) of Theorem 3.1 are satisfied but $\mathbf{L}([\Phi]) = 4\pi$ because $\Phi(I^5) \subset \mathcal{G}_o$.

Sketch of proof. The idea for the proof is, in very general terms, the following. Let $\mathcal{R} \subset \mathcal{G}_o$ denote the space of all oriented great spheres (which is homeomorphic to S^3). With this notation, note that from condition (2) we have that

$$\Phi(\partial I^5 \times \{1/2\}) \subset \mathcal{R}.$$

Moreover, the map $\Phi : \partial I^5 \times \{1/2\} \to \mathcal{R} \approx S^3$ has degree equal to $\deg(Q)$ and thus nonzero by condition (3). For simplicity, suppose we can find $\Psi \in [\Phi]$ so that

$$\mathbf{L}([\Phi]) = 4\pi = \sup_{x \in I^5} \text{area}(\Psi(x)).$$

Then $S = \Psi^{-1}(\mathcal{R})$ should be a 4-dimensional cycle in I^5 with $\partial S = \partial I^4 \times \{1/2\}$. Thus

$$\Psi_*[\partial S] = \partial[\Psi(S)] = \partial[\mathcal{R}] = 0 \text{ in } H_3(\mathcal{R}, \mathbb{Z}).$$

On the other hand, $\Phi = \Psi$ on $\partial S = \partial I^4 \times \{1/2\}$ and so

$$\Psi_*[\partial S] = \Phi_*[\partial I^4 \times \{1/2\}] = \deg(Q)[\mathcal{R}] \neq 0$$

and this is a contradiction. □

Suppose now that Φ is a map satisfying the hypothesis of Theorem 3.1. From the Min-max Theorem we obtain the existence of Σ, an embedded minimal surface, such that $\mathbf{L}([\Phi]) = \text{area}(\Sigma) > 4\pi$. Moreover, it is natural to expect that Σ has index at most 5 because we are dealing with a 5-parameter family of surfaces.

Urbano [54] in 1990 classified minimal surface of S^3 with low index and he gave a rather elegant and short proof of

Theorem 3.2 (Urbano's Theorem). *Assume S is a closed embedded minimal surface in S^3 having* $\text{index}(S) \leq 5$.

Then, up to ambient isometries, S is either a great sphere (index one) or the Clifford torus (index five) up to ambient isometries.

Remark 3.3. We already argued that the great sphere has index one. The Clifford torus has index five because unit speed normal deformations decreases area, the four parameter space of conformal dilations (to be seen later) also decrease area, and these five deformations are linearly independent.

Going back to our discussion, we see that Σ cannot be a great sphere because its area is $\mathbf{L}([\Phi]) > 4\pi$ and so it has to be a Clifford torus with area $2\pi^2$. This heuristic discussion motivates the

Theorem 3.4 ($2\pi^2$ Theorem). *Assume that Φ satisfied the hypothesis of Theorem 3.1. Then*

$$\sup_{x \in I^5} \text{area}(\Phi(x)) \geq 2\pi^2.$$

A proof can be found in [38]. Because the Almgren–Pitts theory does not provide us with the fact that the index of Σ is at most 5, we had to use a new set of arguments to prove the index estimate in the case we were interested.

4. Strategy to prove Theorem 1.1

We sketch the proof of the inequality in Theorem 1.1. The complete argument can be found in [38].

The conformal maps of S^3 (modulo isometries) can be parametrized by the open unit 4-ball B^4, where to each nonzero $v \in B^4$ we consider the conformal dilation F_v centered at $\frac{v}{|v|}$ and $-\frac{v}{|v|}$. Composing with the stereographic projection $\pi : S^3 \setminus \{-\frac{v}{|v|}\} \to \mathbb{R}^3$, the map

$$\pi \circ F_v \circ \pi^{-1} : \mathbb{R}^3 \to \mathbb{R}^3$$

corresponds to a dilation in space centered at the origin, where the dilation factor tends to infinity as $|v|$ tends to one.

Given a compact embedded surface $S \subset S^3$ and $-\pi \leq t \leq \pi$, we denote by S_t the surface at distance $|t|$ from S, where S_t lies in the exterior (interior) of S if $t \geq 0$ ($t \leq 0$). Naturally, S_t might not be a smooth embedded surface due to the existence of possible focal points but it will always be well defined in the context of Geometric Measure Theory.

We can now define the following 5-parameter family $\{\Sigma_{(v,t)}\}_{(v,t)\in B^4\times[\pi,\pi]}$ of surfaces in S^3 given by

$$\Sigma_{(v,t)} = (F_v(\Sigma))_t \in \mathcal{Z}_2(S^3).$$

One crucial property of this 5-parameter family is the following.

Theorem 4.1 (Heintze–Karcher Inequality). *For every $(v,t) \in B^4 \times [\pi,\pi]$ we have*

$$\operatorname{area}(\Sigma_{(v,t)}) \leq \mathcal{W}(\Sigma).$$

A related result was proven by Ros in [46].

In order to apply the $2\pi^2$ Theorem it is important that we understand the behaviour $\Sigma_{(v,t)}$ as (v,t) approaches the boundary of $B^4 \times [\pi,\pi]$. The fact that the diameter of S^3 is π implies that $\Sigma_{(v,\pm\pi)} = 0$ for all $v \in B^4$ and so we are left to analyze what happens when v approaches S^3.

Assume v in the 4-ball tends to $p \in S^3$. If p does not belong to Σ, then $F_v(\Sigma)$ is "pushed" into $\{-p\}$ as v tends to p and so $\operatorname{area}(F_v(\Sigma))$ tends to zero. When p lies in Σ the situation is considerably more subtle. Indeed, if v approaches p radially, i.e., $v = sp$ with $0 < s < 1$, then $F_{sp}(\Sigma)$ converges, as s tends to 1, to the unique great sphere tangent to Σ at p. Thus the continuous function in S^3 given by $p \mapsto \operatorname{area}(\Sigma_{sp})$ tends, as $s \to 1$, to a discontinuous function that is zero outside Σ and 4π along Σ. Hence, for any $0 < \alpha < 4\pi$, there must exist a sequence $\{v_i\}_{i\in\mathbb{N}}$ in B^4 tending to Σ so that $\operatorname{area}(\Sigma_{v_i})$ tends to α and so it is natural to expect that the convergence of $F_v(\Sigma)$ depends on how v approaches $p \in \Sigma$. A careful analysis revealed that, depending on the angle at which v tends to p, $F_v(\Sigma)$ tends to a geodesic sphere tangent to Σ at p, with radius and center depending on the angle of convergence.

Initially this behaviour was a source of perplexity but then we realized that, even if the parametrization was becoming discontinuous near the boundary of the parameter space, the closure of the family $\{\Sigma_{(v,t)}\}_{(v,t)\in B^4\times[\pi,\pi]}$ in $\mathcal{Z}_2(S^3)$ was a "nice" continuous 5-cycle in $\mathcal{Z}_2(S^3)$. Hence, we were able to reparametrize this family and obtain a continuous map $\Phi : I^5 \to \mathcal{Z}_2(S^3)$ with $\Phi(I^5)$ equal to the closure of $\{\Sigma_{(v,t)}\}_{(v,t)\in B^4\times[\pi,\pi]}$ in $\mathcal{Z}_2(S^3)$ and satisfying conditions (1) and (2) of Theorem 3.1.

Finally, and most important of all, we showed that the degree of the center map Q in condition (2) of Theorem 3.1 is exactly the genus of Σ. This point is absolutely crucial because it showed us that the map Φ "remembers" the genus of the surface Σ. Thus, when the genus is positive, condition (3) of Theorem 3.1 is also satisfied and we obtain from the $2\pi^2$ Theorem that

$$2\pi^2 \leq \sup_{x\in I^5} \operatorname{area}((\Phi(x)).$$

On the other hand, because $\Phi(I^5)$ is equal to the closure of $\{\Sigma_{(v,t)}\}_{(v,t)\in B^4\times[\pi,\pi]}$ in $\mathcal{Z}_2(S^3)$, we obtain from the Heintze–Karcher Inequality that

$$\sup_{x\in I^5} \operatorname{area}(\Phi(x)) \leq \mathcal{W}(\Sigma).$$

This means that $\mathcal{W}(\Sigma) \geq 2\pi^2$, which is the statement we wanted to prove.

5. Strategy to prove Theorem 1.2

The approach to prove Theorem 1.2 is similar to the one used in Theorem 1.1. The conformal invariance of the energy implies that it suffices to consider links (γ_1, γ_2) in S^3. For each link (γ_1, γ_2) in S^3 we construct a suitable family $\Phi : I^5 \to \mathcal{Z}_2(S^3)$ that satisfies conditions (1) and (2) of Theorem 3.1. Moreover, we will also show that if $|\mathrm{lk}(\gamma_1, \gamma_2)| = 1$ then condition (3) of Theorem 3.1 is will also be satisfied. Hence we can apply the $2\pi^2$ Theorem and conclude that

$$\sup_{x\in I^5} \operatorname{area}(\Phi(x)) \geq 2\pi^2.$$

On the other hand, the map Φ is constructed so that $\operatorname{area}(\Phi(x)) \leq E(\gamma_1, \gamma_2)$ for each $x \in I^5$ and this implies the inequality in Theorem 1.2.

We give a brief indication of how the map Φ is constructed.

To every pair of curves in $\mathbb{R}^4$ there is a natural way to construct a "torus" in S^3. More precisely, given two curves (γ_1, γ_2) in $\mathbb{R}^4$, the *Gauss map* is denoted by

$$G(\gamma_1, \gamma_2) : S^1 \times S^1 \to S^3, \quad (s,t) \mapsto \frac{\gamma_1(s) - \gamma_2(t)}{|\gamma_1(s) - \gamma_2(t)|}$$

and we consider $G(\gamma_1, \gamma_2)_\#(S^1 \times S^1)$ in $\mathcal{Z}_2(S^3)$. Furthermore, one can check that

$$\operatorname{area}(G(\gamma_1, \gamma_2)_\#(S^1 \times S^1)) \leq E(\gamma_1, \gamma_2).$$

For instance, if (γ_1, γ_2) is the Hopf link then $G(\gamma_1, \gamma_2)_\#(S^1 \times S^1)$ is the Clifford torus and the inequality above becomes an equality.

Given $v \in B^4$, we consider the conformal map F_v of $\mathbb{R}^4$ given by an inversion centered at v. The conformal map F_v sends the unit 4-ball B^4 to some other ball centered at $c(v) = \frac{v}{1-|v|^2}$. We consider

$$g : B^4 \times (0, +\infty) \to \mathcal{Z}_2(S^3)$$

given by

$$g(v,z) = G\left(F_v \circ \gamma_1, \lambda(F_v \circ \gamma_2 - c(v)) + c(v)\right)_\# (S^1 \times S^1).$$

Intuitively, $g(v,z)$ is the image of the Gauss map of the link obtained by applying the conformal transformation F_v to (γ_1, γ_2) and then dilating the curve $F_v \circ \gamma_2$ with respect to the center $c(v)$ by a factor of λ. Note that both curves $F_v \circ \gamma_1$ and $\lambda(F_v \circ \gamma_2 - c(v)) + c(v)$ are contained in spheres centered at $c(v)$.

The 5-parameter family we just described also enjoys a Heintze–Karcher type-inequality, meaning that for all $(v, \lambda) \in B^4 \times (0, +\infty)$ we have

$$\operatorname{area}(g(v,z)) \leq E(\gamma_1, \gamma_2).$$

The map Φ is constructed via a reparametrization of g.

6. Gromov–Guth families

In order to apply the Min-max Theorem on a general manifold M, it is important that one understands the homotopy groups of the space $\mathcal{Z}_n(M;\mathbb{Z}_2)$. This was done by Almgren [2] in 1962 and he showed that

$$\pi_1(\mathcal{Z}_n(M;\mathbb{Z}_2)) = \mathbb{Z}_2 \quad \text{and} \quad \pi_i(\mathcal{Z}_n(M;\mathbb{Z}_2)) = 0 \quad \text{if } i > 1.$$

Thus $\mathcal{Z}_n(M;\mathbb{Z}_2)$ is weakly homotopic equivalent to $\mathbb{RP}^\infty$ and so we should expect that $\mathcal{Z}_n(M,\mathbb{Z}_2)$ contains, for every $p \in \mathbb{N}$, an homotopically nontrivial p-dimensional projective space.

From the weak homotopy equivalence with $\mathbb{RP}^\infty$, we have that

$$H^k(\mathcal{Z}_n(M;\mathbb{Z}_2)) = \mathbb{Z}_2 \quad \text{for all } k \in \mathbb{N} \text{ with generator } \bar{\lambda}^k.$$

We are interested in studying maps $\Phi : X \to \mathcal{Z}_n(M;\mathbb{Z}_2)$ whose image detects $\bar{\lambda}^p$ for some $p \in \mathbb{N}$.

Given a simplicial complex X, a continuous map $\Phi : X \to \mathcal{Z}_n(M;\mathbb{Z}_2)$ is called a *p-sweepout* if $\Phi^*(\bar{\lambda}^p) \neq 0$ in $H^p(X;\mathbb{Z}_2)$. Heuristically, a continuous map $\Phi : X \to \mathcal{Z}_n(M;\mathbb{Z}_2)$ is called a *p-sweepout* if for every set $\{x_1,\dots,x_p\} \subset M$, there is $\theta \in X$ so that $\{x_1,\dots,x_p\} \subset \Phi(\theta)$.

Gromov [18–20] and Guth [21] studied p-sweepouts of M.

We now check that p-sweepouts exists for all $p \in M$. Let $f \in C^\infty(M)$ be a Morse function and consider the map

$$\Phi : \mathbb{RP}^p \to \mathcal{Z}_n(M;\mathbb{Z}_2),$$

given by

$$\Phi([a_0,\dots,a_p]) = \partial\left\{x \in M : a_0 + a_1 f(x) + \ldots + a_p f^p(x) < 0\right\}.$$

Note that the map Φ is well defined because opposite orientations on the same hypersurface determine the same element in $\mathcal{Z}_n(M;\mathbb{Z}_2)$. A typical element of $\Phi([a_0,\dots,a_p])$ will be $f^{-1}(r_1) \cup \ldots \cup f^{-1}(r_j)$ where $r_1,\dots,r_j$ are the real roots of the polynomial $p(t) = a_0 + a_1 t + \ldots + a_p t^p$. It easy to see that Φ satisfies the heuristic definition of a p-sweepout given above and in [39] we check that the map is indeed a p-sweepout.

Denoting the set of all p-sweepouts of M by $\mathcal{P}_p$, the *p-width* of M is defined as

$$\omega_p(M) = \inf_{\Phi \in \mathcal{P}_p} \sup\{\mathrm{vol}(\Phi(x)) : x \in \mathrm{dmn}(\Phi)\},$$

where $\mathrm{dmn}(\Phi)$ is the domain of Φ.

It is interesting to compare the p-width with the min-max definition of the p^{th}-eigenvalue of (M,g). Set $V = W^{1,2}(M) \setminus \{0\}$ and recall that

$$\lambda_p = \inf_{(p+1)-\text{plane } P \subset V} \max\left\{\frac{\int_M |\nabla f|^2 dV_g}{\int_M f^2 dV_g} : f \in P\right\}.$$

Hence one can see $\{\omega_p(M)\}_{p\in\mathbb{N}}$ as a nonlinear analogue of the Laplace spectrum of M, as proposed by Gromov [18].

The asymptotic behaviour of $w_p(M)$ is governed by the following result proven by Gromov [18] and Guth [21].

Theorem 6.1 (Gromov and Guth's Theorem). *There exists a positive constant $C = C(M, g)$ so that, for every $p \in \mathbb{N}$,*

$$C^{-1} p^{\frac{1}{n+1}} \leq \omega_p(M) \leq C p^{\frac{1}{n+1}}.$$

The idea to prove the lower bound is, roughly speaking, the following. Choose p disjoint geodesic balls $B_1, \dots, B_p$ with radius proportional to $p^{-\frac{1}{n+1}}$. For every p-sweepout Φ one can find $\theta \in \mathrm{dmn}(\Phi)$ so that $\Phi(\theta)$ divides each geodesic ball into two pieces with almost identical volumes. Hence, when p is sufficiently large, the isoperimetric inequality implies that $\Phi(\theta) \cap B_i$ has volume no smaller than $c(n)p^{-\frac{n}{n+1}}$ for all $i = 1, \dots, p$, where $c(n)$ is a universal constant. As a result $\Phi(\theta)$ has volume greater or equal than $c(n)p^{\frac{1}{n+1}}$.

The upper bound can be proven using a very nice bend-and-cancel argument introduced by Guth [21]. In the case when M is a $n+1$-dimensional sphere S^{n+1}, the upper bound has the following simple explanation. If we consider the set of all homogenous harmonic polynomials in S^{n+1} with degree less or equal than $d \in \mathbb{N}$, we obtain a vector space of dimension $p(d) + 1$, where $p(d)$ grows like d^{n+1}. Considering the zero set of all these polynomials we obtain a map Φ from a $p(d)$-dimensional projective plane into $\mathcal{Z}_n(S^{n+1}; \mathbb{Z}_2)$. Crofton formula implies that the zero-set of each of these polynomials has volume at most $\omega_n d$, where ω_n is the volume of an n-sphere. Thus, for every $\theta \in \mathbb{RP}^{p(d)}$, $\mathrm{vol}(\Phi(\theta))$ is at most a fixed multiple of $p(d)^{\frac{1}{n+1}}$.

7. Strategy to prove Theorem 1.3

The idea to find an infinite number of minimal surfaces consists in applying the Min-max Theorem to the family of p-sweepouts $\mathcal{P}_p$ for all $p \in \mathbb{N}$.

The first thing we show is that if $\omega_p(M) = \omega_{p+1}(M)$ for some $p \in \mathbb{N}$, then M admits an infinite number of minimal embedded hypersurfaces. We achieve this using Lusternick-Schnirelman and, roughly speaking, the idea is as follows (for details see [39]):

Suppose for simplicity that $\omega_p(M) = \omega_{p+1}(M) = \sup_{x \in X} \mathrm{vol}(\Phi(x))$ for some $p+1$-sweepout Φ. We argue by contradiction and assume that Ω, the set of all embedded minimal hypersurfaces (with possible multiplicities) and volume at most $\omega_{p+1}(M)$, is finite.

Let $K = \Psi^{-1}(\Omega)$ and $\lambda = \Phi^*(\bar{\lambda})$, where $\bar{\lambda}$ generates $H^1(\mathcal{Z}_n(M; \mathbb{Z}_2); \mathbb{Z}_2)$.

We must have λ vanishing on K because otherwise there would exist a curve γ in K so that $\lambda(\gamma) = \bar{\lambda}(\Phi \circ \gamma) \neq 0$, i.e. $\Phi \circ \gamma$ would be a nontrivial element of $\pi_1(\mathcal{Z}_n(M; \mathbb{Z}_2))$. But $\Phi \circ \gamma$ has image contained in the finite set Ω, which implies it is constant, and thus contractible.

Therefore λ^p cannot vanish on $X \setminus K$ because otherwise $\lambda^{p+1} = \lambda^p \smile \lambda$ would be zero on $(X \setminus K) \cup K = X$ and this is impossible because Φ is a $p+1$-sweepout. As a result $\Phi_{|X \setminus K}$ is a p-sweepout whose image contains no minimal hypersurfaces (with possible multiplicities), and so we pull-tight the family to obtain another p-sweepout Ψ so that

$$\omega_p(M) \leq \sup_{x \in X \setminus K} \mathrm{vol}(\Psi(x)) < \sup_{x \in X \setminus K} \mathrm{vol}(\Phi(x)) \leq \sup_{x \in X} \mathrm{vol}(\Phi(x)) = \omega_p(M).$$

This gives us the desired contradiction.

Hence we can assume that the sequence $\{\omega_p(M)\}_{p \in \mathbb{N}}$ is strictly increasing.

We then argue again by contradiction and assume that there exist only finitely many smooth, closed, embedded minimal hypersurfaces with multiplicity one, and we call this set

Λ. Using the Min-max Theorem we have that

$$\omega_p(M) = n_{p,1}\mathrm{vol}(\Sigma_{p,1}) + \ldots + n_{p,k}\mathrm{vol}(\Sigma_{p,k}), \quad n_{p,1}, \ldots, n_{p,k} \in \mathbb{N},$$

where $\{\Sigma_{p,1}, \ldots, \Sigma_{p,k}\}$ are multiplicity one minimal hypersurfaces with disjoint support. Because M has positive Ricci curvature, Frankel's Theorem [13] says that any two minimal embedded hypersurfaces intersect and so $\omega_p(M) = n_p\mathrm{vol}(\Sigma_p)$ for some $\Sigma_p \in \Lambda$ and $n_p \in \mathbb{N}$. The fact that $\omega_p(M)$ is strictly increasing and a counting argument shows that Λ being finite implies that $\omega_p(M)$ must grow linearly in p. This is in contradiction with the sublinear growth of $\omega_p(M)$ in p given by the Gromov and Guth's Theorem.

8. Open problems

Min-max Theory is an exciting technique which I think can be used not only to solve other open questions in Geometry but also to provide some new directions. Some of these questions are well-known and others arose from extensive discussions with Fernando Marques.

Min-max questions. The Almgren-Pitts Min-max Theory does not provide index estimates for the min-max minimal hypersurface. The importance of this issue was already clear to Almgren [3] who wrote

> *"The chief utility of the homology approach would lie in the attempt to assign a topological index to stationary integral varifolds in some analytically useful way."*

A folklore conjecture states that the if the homotopy class in the Min-max Theorem is defined with k-parameters, then the minimal hypersurface given by the Min-max Theorem has index at most k. It is implicit in the conjecture that one finds a meaningful way of assigning an index to a minimal embedded hypersurface with multiplicities. When $k = 1$, the conjecture was confirmed by Marques and myself if the ambient manifold is three dimensional and the metric has positive Ricci curvature [39]. Later this was extended to the case where the ambient manifold has dimension between three and seven and the metric has positive Ricci curvature [60].

Naively, one should also expect that for bumpy metrics the index is bounded from below by the number of parameters.

Many of the subtle issues in Min-max Theory are related with the fact that the min-max minimal hypersurface can have multiplicities. That said, one does not know an example where the width of some homotopy class is realized by an unstable minimal hypersurface with multiplicity. For instance, does the equator with multiplicity two (and so area 8π) realizes the width of some homotopy class in the round 3-sphere? It is highly conceivable that unstable minimal surfaces with higher multiplicity can be approximated (in the varifold norm) by a sequence of embedded minimal surfaces with smaller area and this is one of the reasons the question is interesting.

Old questions. We now mention four well known open problems which could be answered using Min-max Theory.

The first two are natural generalizations of the Willmore conjecture.

The Willmore conjecture in S^4 states that among all tori in S^4, the Clifford torus minimizes the Willmore energy. It is interesting that in this case there are minimal embedded projective planes (Veronese surface) which have area (6π) smaller than the Clifford torus and bigger than the equator.

For higher genus surfaces, Kusner [31] conjectured that the Lawson minimal surface $\xi_{1,g}$ minimizes the Willmore energy among all surfaces of genus g (numerical evidence was provided in [25]). It would be extremely interesting to find the index of $\xi_{1,2}$. Wishful thinking would suggest 9 but there is no real evidence.

The third problem consists of finding, among all non-totally geodesic minimal hypersurfaces in the unit n-sphere S^n, the one with least possible volume. The conjecture, due to Solomon, is that these minimal hypersurface are given by

$$S^{m-1}\left(\sqrt{\frac{m-1}{2m-1}}\right)\times S^m\left(\sqrt{\frac{m}{2m-1}}\right)\subset S^n$$

if $n=2m$, and by

$$S^{m-1}\left(\frac{1}{\sqrt{2}}\right)\times S^{m-1}\left(\frac{1}{\sqrt{2}}\right)\subset S^n$$

if $n=2m-1$. In S^3 this conjecture was confirmed by Marques and myself in [38] and in the general case there was some progress due to White and Ilmanen [26].

It would be desirable to have a sharp index characterization similar Urbano's Theorem for each of these three problems. In the third problem, Perdomo [45] achieved that assuming the hypersurfaces are preserved by the antipodal map.

The fourth and final problem is a beautiful conjecture of White [56] which says that any metric on a 3-sphere has five distinct minimal embedded tori and he proved this for small perturbations of the round metric [57]. An easier conjecture would be to say that any metric on a 3-sphere has nine distinct minimal surfaces of genus either zero or one.

Some new questions. For the purpose of applications in Geometry and Topology, it is important to estimate the topology of the minimal hypersurface given by the Min-max Theorem.

For ambient 3-manifolds, due to the combined work of Simon–Smith [49], De Lellis–Pellandini [10], and Ketover [29], it is now known that, roughly speaking, if the Min-max technique is applied to continuous one-parameter family of embedded surfaces of genus g, then the min-max minimal surface has at most genus g.

In higher dimensions it is not so clear how to control the topology of the min-max minimal hypersurface by the same methods.

An alternative approach would be to try to characterize the topology of the min-max minimal hypersurface via its index. Note that if the minimal hypersurfaces are produced via Min-max methods then one should expect some control on the index.

For ambient 3-manifolds, Ejiri–Micallef [12] showed that the index of a minimal orientable surface is bounded from above by a multiple of area plus genus and if the metric has positive Ricci curvature then it is known [59] that index one orientable minimal surfaces have genus 3 at most (a conjecture that I heard from Rick Schoen states that the genus should be two at most).

For higher dimensions, Rick Schoen conjectured that index one embedded orientable compact minimal hypersurfaces in ambient manifolds with positive Ricci curvature have

bounded first Betti number. We conjecture that if the ambient manifold has positive Ricci curvature then an index k embedded orientable compact minimal hypersurface has first Betti number bounded by fixed multiple of k. Savo [47] showed this holds on round spheres of any dimension.

Another direction of research would be to understand the p-widths $\omega_p(M)$ of (M^{n+1}, g) for $n \geq 2$. The sequence $\{\omega_p(M)\}_{p\in\mathbb{N}}$ can be thought of as a nonlinear spectrum for the manifold and we would expect it to be asymptotically related with the spectrum of the Laplacian. Taking this perspective, many interesting questions arise.

For instance, does the nonlinear spectrum satisfy a Weyl Law? More precisely, can we find a universal constant $a(n)$ so that

$$\lim_{p\to\infty} \omega_p(M) p^{-\frac{1}{n+1}} = a(n)(\mathrm{vol}(M,g))^{\frac{n}{n+1}}?$$

This question has been suggested by Gromov in [19, Section 8] and in [20, Section 5.2]. A classical result of Uhlenbeck [53] states that generic metrics have simple eigenvalues. Likewise, we expect that for generic metrics at least, $\omega_p(M)$ is achieved by a multiplicity one minimal hypersurface with index p. Can we say anything about how they look like? For instance, are they becoming equidistributed in space? The proof of Gromov-Guth's Theorem suggests that. Do they behave like nodal sets of eigenfunctions? Is their first betti number proportional to p?

Nodal sets of eigenfunctions provide a natural upper bound for $\omega_p(M)$. Making this more precise, denote by $\phi_0, \ldots, \phi_p$ the first $(p+1)$-eigenfunctions for the Laplace operator, where ϕ_0. Consider

$$\Phi_p : \mathbb{RP}^p \to \mathcal{Z}_n(M; \mathbb{Z}_2),$$
$$\Phi_p([a_0, \ldots, a_p]) = \partial\{x \in M : a_0\phi_0(x) + \ldots + a_p\phi_p(x) < 0\}.$$

and set

$$\bar{\omega}_p(M) = \sup_{\theta\in\mathbb{RP}^p} \mathrm{vol}(\Phi_p(\theta)) \geq \omega_p(M).$$

It seems a challenging question to determine how close to one $\frac{\bar{\omega}_p(M)}{\omega_p(M)}$ is getting as p tends to infinity. If the quotient is bounded, that would imply a conjecture of Yau regarding the asymptotic growth of the volume of nodal sets (which was proven in the analytic case by Donnelly and Fefferman [11] and for recent progress see [9, 50]). Can we determine that quotient on an n-sphere?

When symplectic topology meets Banach space geometry

Yaron Ostrover

Abstract. In this paper we survey some recent works that take the first steps toward establishing bilateral connections between symplectic geometry and several other fields, namely, asymptotic geometric analysis, classical convex geometry, and the theory of normed spaces.

Mathematics Subject Classification (2010). 53D35, 52A23, 52A40, 37D50, 57S05.

Keywords. Symplectic capacities, Viterbo's volume-capacity conjecture, Mahler's conjecture, Hamiltonian diffeomorphisms, Hofer's metric.

1. Introduction

In the last three decades, symplectic topology has had an astonishing amount of fruitful interactions with other fields of mathematics, including complex and algebraic geometry, dynamical systems, Hamiltonian PDEs, transformation groups, and low-dimensional topology; as well as with physics, where, for example, symplectic topology plays a key role in the rigorous formulation of mirror symmetry.

In this survey paper, we present some recent works that take first steps toward establishing novel interrelations between symplectic geometry and several fields of mathematics, namely, asymptotic geometric analysis, classical convex geometry, and the theory of normed spaces. In the first part of this paper (Sections 2 and 3) we concentrate on the theory of symplectic measurements, which arose from the foundational work of Gromov [34] on pseudoholomorphic curves; followed by the seminal works of Ekeland and Hofer [24] and Hofer and Zehnder [42] on variational theory in Hamiltonian systems, and Viterbo on generating functions [89]. This theory – also known as the theory of "symplectic capacities" – lies nowadays at the core of symplectic geometry and topology.

In Section 2, we focus on an open symplectic isoperimetric-type conjecture proposed by Viterbo in [88]. It states that among all convex domains with a given volume in the classical phase space $\mathbb{R}^{2n}$, the Euclidean ball has the maximal "symplectic size" (see Section 2 below for the precise statement). In a collaboration with S. Artstein-Avidan and V. D. Milman [6], we were able to prove an asymptotic version of Viterbo's conjecture, that is, we proved the conjecture up to a universal (dimension-independent) constant. This has been achieved by adapting techniques from asymptotic geometric analysis and adjusting them to a symplectic context, while working exclusively in the linear symplectic category.

Proceedings of the International Congress of Mathematicians, Seoul, 2014

The fact that one can get within a constant factor to the full conjecture using only linear embeddings is somewhat surprising from the symplectic-geometric point of view, as in symplectic geometry one typically needs highly nonlinear tools to estimate capacities. However, this fits perfectly into the philosophy of asymptotic geometric analysis. Finding dimension independent estimates is a frequent goal in this field, where surprising phenomena such as concentration of measure (see e.g. [67]) imply the existence of order and structures in high dimensions, despite the huge complexity it involves. It would be interesting to explore whether similar phenomena also exist in the framework of symplectic geometry. A natural important source for the study of the asymptotic behavior (in the dimension) of symplectic invariants is the field of statistical mechanics, where one considers systems with a large number of particles, and the dimension of the phase space is twice the number of degrees of freedom. It seems that symplectic measurements were overlooked in this context so far.

In Section 3 we go in the opposite direction: we show how symplectic geometry could potentially be used to tackle a 70-years-old fascinating open question in convex geometry, known as the Mahler conjecture. Roughly speaking, Mahler's conjecture states that the minimum of the product of the volume of a centrally symmetric convex body and the volume of its polar body is attained (not uniquely) for the hypercube. In a collaboration with S. Artstein–Avidan and R. Karasev [8], we combined tools from symplectic geometry, classical convex analysis, and the theory of mathematical billiards, and established a close relation between Mahler's conjecture and the above mentioned symplectic isoperimetric conjecture by Viterbo. More preciesly, we showed that Mahler's conjecture is equivalent to a special case of Viterbo's conjecture (see Section 3 for details).

In the second part of the paper (Section 4), we explain how methods from functional analysis can be used to address questions regarding the geometry of the group $\mathrm{Ham}(M,\omega)$ of Hamiltonian diffeomorphisms associated with a symplectic manifold (M,ω). One of the most striking facts regarding this group, discovered by Hofer in [40], is that it carries an intrinsic geometry given by a Finsler bi-invariant metric, nowadays known as Hofer's metric. This metric measures the time-averaged minimal oscillation of a Hamiltonian function that is needed to generate a Hamiltonian diffeomorphism starting from the identity. Hofer's metric has been intensively studied in the past twenty years, leading to many discoveries covering a wide range of subjects from Hamiltonian dynamics to symplectic topology (see e.g., [43, 59, 75] and the references therein). A long-standing question raised by Eliashberg and Polterovich in [26] is whether Hofer's metric is the only bi-invariant Finsler metric on the group $\mathrm{Ham}(M,\omega)$. Together with L. Buhovsky [17], and based on previous results by Ostrover and Wagner [72], we used methods from functional analysis and the theory of normed function spaces to affirmatively answer this question. We proved that any non-degenerate bi-invariant Finsler metric on $\mathrm{Ham}(M,\omega)$, which is generated by a norm that is continuous in the C^∞-topology, gives rise to the same topology on $\mathrm{Ham}(M,\omega)$ as the one induced by Hofer's metric.

As mentioned before, the outlined interdisciplinary connections described above are just the first few steps in what seems to be a promising new direction. We hope that further exploration of these connections will strengthen the dialogue between these fields and symplectic geometry, and expand the range of methodologies alongside research questions that can be tackled through these means.

We end this paper with several open questions and speculations regarding some of the mentioned topics (see Section 5).

2. A symplectic isoperimetric inequality

A classical result in symplectic geometry (Darboux's theorem) states that symplectic manifolds - in a sharp contrast to Riemannian manifolds - have no local invariants (except, of course, the dimension). The first examples of global symplectic invariants were introduced by Gromov in his seminal paper [34], where he developed and used pseudoholomorphic curve techniques to prove a striking symplectic rigidity result. Nowadays known as Gromov's "non-squeezing theorem", this result states that one cannot map a ball inside a thinner cylinder by a symplectic embedding. This theorem paved the way to the introduction of global symplectic invariants, called symplectic capacities which, roughly speaking, measure the symplectic size of a set.

We will focus here on the case of the classical phase space $\mathbb{R}^{2n} \simeq \mathbb{C}^n$ equipped with the standard symplectic structure $\omega = dq \wedge dp$. We denote by $B^{2n}(r)$ the Euclidean ball of radius r, and by $Z^{2n}(r)$ the cylinder $B^2(r) \times \mathbb{C}^{n-1}$. Gromov's non-squeezing theorem asserts that if $r < 1$ there is no symplectomorphism ψ of $\mathbb{R}^{2n}$ such that $\psi(B^{2n}(1)) \subset Z^{2n}(r)$. The following definition, which crystallizes the notion of "symplectic size", was given by Ekeland and Hofer in their influential paper [24].

Definition 2.1. A symplectic capacity on $(\mathbb{R}^{2n}, \omega)$ associates to each subset $U \subset \mathbb{R}^{2n}$ a number $c(U) \in [0, \infty]$ such that the following three properties hold:

(P1) $c(U) \leq c(V)$ for $U \subseteq V$ (monotonicity);

(P2) $c\big(\psi(U)\big) = |\alpha|\, c(U)$ for $\psi \in \mathrm{Diff}(\mathbb{R}^{2n})$ such that $\psi^*\omega = \alpha\omega$ (conformality);

(P3) $c\big(B^{2n}(r)\big) = c\big(Z^{2n}(r)\big) = \pi r^2$ (nontriviality and normalization).

Note that (P3) disqualifies any volume-related invariant, while (P1) and (P2) imply that for $U, V \subset \mathbb{R}^{2n}$, a necessary condition for the existence of a symplectomorphism ψ with $\psi(U) = V$, is $c(U) = c(V)$ for any symplectic capacity c.

It is a priori unclear that symplectic capacities exist. The above mentioned non-squeezing result naturally leads to the definition of two symplectic capacities: the Gromov radius, defined by $\underline{c}(U) = \sup\{\pi r^2 \,|\, B^{2n}(r) \overset{\mathrm{s}}{\hookrightarrow} U\}$; and the cylindrical capacity, defined by $\overline{c}(U) = \inf\{\pi r^2 \,|\, U \overset{\mathrm{s}}{\hookrightarrow} Z^{2n}(r)\}$, where $\overset{\mathrm{s}}{\hookrightarrow}$ stands for symplectic embedding. It is easy to verify that these two capacities are the smallest and largest possible symplectic capacities, respectively. Moreover, it is also known that the existence of a single capacity readily implies Gromov's non-squeezing theorem, as well as the Eliashberg-Gromov C^0-rigidity theorem, which states that for any closed symplectic manifold (M, ω), the symplectomorphism group $\mathrm{Symp}(M, \omega)$ is C^0-closed in the group of all diffeomorphisms of M (see e.g., Chapter 2 of [43]).

Shortly after Gromov's work, other symplectic capacities were constructed, such as the Hofer-Zehnder [43] and the Ekeland-Hofer [24] capacities, the displacement energy [40], the Floer-Hofer capacity [27, 28], spectral capacities [29, 70, 89], and, more recently, Hutchings's embedded contact homology capacities [44]. Nowadays, symplectic capacities are among the most fundamental objects in symplectic geometry, and are the subject of intensive research efforts (see e.g., [45, 47, 52, 55–57, 60, 63, 82], and [20] for a recent detailed survey and more references). However, in spite of the rapidly accumulating knowledge regarding symplectic capacities, they are notoriously difficult to compute, and there are no general methods even to effectively estimate them.

In [88], Viterbo investigated the relation between the symplectic way of measuring the size of sets using symplectic capacities, and the classical approach using volume. Among many other inspiring results, in that work he conjectured that in the class of convex bodies in $\mathbb{R}^{2n}$ with fixed volume, the Euclidean ball B^{2n} maximizes any given symplectic capacity. More precisely,

Conjecture 2.2 (Viterbo's volume-capacity inequality conjecture). *For any convex body K in $\mathbb{R}^{2n}$ and any symplectic capacity c,*

$$\frac{c(K)}{c(B)} \leq \left(\frac{\mathrm{Vol}(K)}{\mathrm{Vol}(B)}\right)^{1/n}, \text{ where } B = B^{2n}(1).$$

Here and henceforth a convex body of $\mathbb{R}^{2n}$ is a compact convex set with non-empty interior. The isoperimetric inequality above was proved in [88] up to a constant that depends linearly on the dimension using the classical John ellipsoid theorem. In a joint work with S. Artstein-Avidan and V. D. Milman (see [6]), we made further progress towards the proof of the conjecture. By customizing methods and techniques from asymptotic geometric analysis and adjusting them to the symplectic context, we were able to prove Viterbo's conjecture up to a universal (i.e., dimension-independent) constant. More precisely, we proved that

Theorem 2.3. *There is a universal constant A such that for any convex domain K in $\mathbb{R}^{2n}$, and any symplectic capacity c, one has*

$$\frac{c(K)}{c(B)} \leq A \left(\frac{\mathrm{Vol}(K)}{\mathrm{Vol}(B)}\right)^{1/n}, \text{ where } B = B^{2n}(1).$$

We emphasize that in the proof of Theorem 2.3 we work exclusively in the category of linear symplectic geometry. It turns out that even in this limited category of linear symplectic transformations, there are tools which are powerful enough to obtain a dimension-independent estimate as above. While this fits with the philosophy of asymptotic geometric analysis, it is less expected from a symplectic geometry point of view, where one expects that highly nonlinear methods, such as folding and wrapping techniques (see e.g., the book [82]), would be required to effectively estimate symplectic capacities.

The proof of Theorem 2.3 above is based on two ingredients. The first is the following simple geometric observation (see Lemma 3.3 in [6], cf. [1]).

Lemma 2.4. *If a convex body $K \subset \mathbb{C}^n$ satisfies $K = iK$, then $\overline{c}(K) \leq \frac{4}{\pi}\, \underline{c}(K)$.*

Sketch of Proof. Let rB^{2n} be the largest multiple of the unit ball contained in K, and let $x \in \partial K \cap rS^{2n-1}$ be a contact point between the boundary of K and the boundary of rB^{2n}. It follows from the convexity assumption that the body K lies between the hyperplanes $x + x^{\perp}$ and $-x + x^{\perp}$. Moreover, since $K = iK$, it lies also between $-ix + ix^{\perp}$ and $ix + ix^{\perp}$. Thus, the projection of K onto the plane spanned by x and ix is contained in a square of edge length $2r$. This square can be turned into a disc with area $4r^2$, after applying a non-linear symplectomorphism which is essentially two-dimensional. Therefore, K is contained in a symplectic image of the cylinder $Z^{2n}(\sqrt{4/\pi}\, r)$, and the lemma follows. □

Since by monotonicity, Conjecture 2.2 trivially holds for the Gromov radius $\underline{c}$, it follows from Lemma 2.4 that

Corollary 2.5. *Theorem 2.3 holds for convex bodies $K \subset \mathbb{C}^n$ such that $K = iK$.*

The second ingredient in the proof is a profound result in asymptotic geometric analysis discovered by V.D. Milman in the mid 1980's called the "reverse Brunn-Minkowski inequality" (see [65, 66]). Recall that the classical Brunn-Minkowski inequality states that if A and B are non-empty Borel subsets of $\mathbb{R}^n$, then

$$\mathrm{Vol}(A+B)^{1/n} \geq \mathrm{Vol}(A)^{1/n} + \mathrm{Vol}(B)^{1/n},$$

where $A + B = \{x + y \,|\, x \in A,\, y \in B\}$ is the Minkowski sum. Although at first glance it seems that one cannot expect any inequality in the reverse direction (consider, e.g., two very long and thin ellipsoids pointing in orthogonal directions in $\mathbb{R}^2$), it turns out that for convex bodies, if one allows for an extra choice of "position", i.e., a volume-preserving linear image of the bodies, then one can reverse the Brunn-Minkowski inequality up to a universal constant factor.

Theorem 2.6 (Milman's reverse Brunn-Minkowski inequality). *For any two convex bodies K_1, K_2 in $\mathbb{R}^n$, there exist linear volume preserving transformations T_{K_i} $(i = 1, 2)$, such that for $\widetilde{K}_i = T_{K_i}(K_i)$ one has*

$$\mathrm{Vol}(\widetilde{K}_1 + \widetilde{K}_2)^{1/n} \leq C\left(\mathrm{Vol}(\widetilde{K}_1)^{1/n} + \mathrm{Vol}(\widetilde{K}_2)^{1/n}\right),$$

for some absolute constant C.

We emphasize that the transformation $T_{K_i}(i = 1, 2)$ in Theorem 2.6 depends solely on the body K_i, and not on the joint configuration of the bodies K_1 and K_2. For more details on the reverse Brunn-Minkowski inequality see [66, 75].

We can now sketch the proof of Theorem 2.3 (for more details see [6]). Since every symplectic capacity is bounded above by the cylindrical capacity $\overline{c}$, it is enough to prove the theorem for $\overline{c}$. For the sake of simplicity, we assume in what follows that K is centrally symmetric, i.e., $K = -K$. This assumption is not too restrictive, since by a classical result of Rogers and Shephard [79] one has that $\mathrm{Vol}(K + (-K)) \leq 4^n \mathrm{Vol}(K)$. After adjusting Theorem 2.6 to the symplectic context, one has that for any convex body $K \subset \mathbb{R}^{2n}$, there exists a linear symplectomorphism $S \in \mathrm{Sp}(2n)$ such that SK and iSK satisfy the reverse Brunn-Minkowski inequality, that is, the volume $\mathrm{Vol}(SK + iSK)^{1/n}$ is less than some constant times $\mathrm{Vol}(K)^{1/n}$. Combining this with the properties of symplectic capacities and Corollary 2.5, we conclude that

$$\frac{\overline{c}(K)}{\overline{c}(B)} \leq \frac{\overline{c}(SK+iSK)}{\overline{c}(B)} \leq A\left(\frac{\mathrm{Vol}(SK+iSK)}{\mathrm{Vol}(B)}\right)^{\frac{1}{n}} \leq A'\left(\frac{\mathrm{Vol}(K)}{\mathrm{Vol}(B)}\right)^{\frac{1}{n}},$$

for some universal constant A', and thus Theorem 2.3 follows.

In the next section we will show a surprising connection between Viterbo's volume-capacity conjecture and a seemingly remote open conjecture from the field of convex geometric analysis: the Mahler conjecture on the volume product of centrally symmetric convex bodies.

3. A symplectic view on Mahler's conjecture

Let $(X, \|\cdot\|)$ be an n-dimensional normed space and let $(X^*, \|\cdot\|^*)$ be its dual space. Note that the product space $X \times X^*$ carries a canonical symplectic structure, given by the skew-symmetric bilinear form $\omega\big((x,\xi),(x',\xi')\big) = \xi(x') - \xi'(x)$, and a canonical volume form, the *Liouville* volume, given by $\omega^n/n!$. A fundamental question in the field of convex geometry, raised by Mahler in [58], is to find upper and lower bounds for the Liouville volume of $B \times B^\circ \subset X \times X^*$, where B and B° are the unit balls of X and X^*, respectively. In what follows we shall denote this volume by $\nu(X)$. The quantity $\nu(X)$ is an affine invariant of X, i.e. it is invariant under invertible linear transformations. We remark that in the context of convex geometry $\nu(X)$ is also known as the *Mahler volume* or the *volume product* of X.

The Blaschke-Santaló inequality asserts that the maximum of $\nu(X)$ is attained if and only if X is a Euclidean space. This was proved by Blaschke [14] for dimensions two and three, and generalized by Santaló [81] to higher dimensions. The following sharp lower bound for $\nu(X)$ was conjectured by Mahler [58] in 1939:

Conjecture 3.1 (Mahler's volume product conjecture). *For any n-dimensional normed space X one has $\nu(X) \geq 4^n/n!$.*

The conjecture has been verified by Mahler [58] in the two-dimensional case. In higher dimensions it is proved only in a few special cases (see e.g., [33, 49, 64, 69, 76–78, 80, 86]). A major breakthrough towards answering Mahler's conjecture is a result due to Bourgain and Milman [16], who used sophisticated tools from functional analysis to show that the conjecture holds asymptotically, i.e., up to a factor γ^n, where γ is a universal constant. This result has been re-proved later on, with entirely different methods, by Kuperberg [51], using differential geometry, and independently by Nazarov [68], using the theory of functions of several complex variables. A new proof using simpler asymptotic geometric analysis tools has been recently discovered by Giannopoulos, Paouris, and Vritsiou [32]. The best known constant today, $\gamma = \pi/4$, is due to Kuperberg [51].

Despite great efforts to deal with the general case, a proof of Mahler's conjecture has been insistently elusive so far, and is currently the subject of intensive research. A possible reason for this, as pointed out for example by Tao in [87], is that, in contrast with the above mentioned Blaschke-Santaló inequality, the equality case in Mahler's conjecture, which is obtained for example for the space l_∞^n of bounded sequences with the standard maximum norm, is not unique, and there are in fact many distinct extremizers for the (conjecturally) lower bound of $\nu(X)$ (see, e.g., the discussion in [87]). This practically renders impossible any proof based on currently known optimisation techniques, and a radically different approach seems to be needed.

We refer the reader to Section 5 below for further discussion on the characterization of the equality case of Mahler's conjecture, and its possible connection with symplectic geometry.

In a recent work with S. Artstein-Avidan and R. Karasev [8], we combined tools from symplectic geometry, convex analysis, and the theory of mathematical billiards, and established a close relationship between Mahler's conjecture and Viterbo's volume-capacity conjecture. More precisely, we proved in [8] that

Theorem 3.2. *Viterbo's volume-capacity conjecture implies Mahler's conjecture.*

In fact, it follows from our proof that Mahler's conjecture is equivalent to a special case of

Viterbo's conjecture, where the latter is restricted to the Ekeland-Hofer-Zehnder symplectic capacity, and to domains in the classical phase space of the form $\Sigma \times \Sigma^\circ \subset \mathbb{R}^{2n} = \mathbb{R}^n_q \times \mathbb{R}^n_p$ (for more details see [8], and in particular Remark 1.9 ibid.). Here, $\Sigma \subset \mathbb{R}^n_q$ is a centrally symmetric convex body, the space $\mathbb{R}^n_p$ is identified with the dual space $(\mathbb{R}^n_q)^*$, and

$$\Sigma^\circ = \{p \in \mathbb{R}^n_p \,|\, p(q) \leq 1 \text{ for every } q \in \Sigma\}$$

Theorem 3.2 is a direct consequence of the following result proven in [8].

Theorem 3.3. *There exists a symplectic capacity c such that $c(\Sigma \times \Sigma^\circ) = 4$ for every centrally symmetric convex body $\Sigma \subset \mathbb{R}^n_q$.*

With Theorem 3.3 at our disposal, it is not difficult to derive Theorem 3.2.

Proof of Theorem 3.2. Assume that Viterbo's volume-capacity conjecture holds. From Theorem 3.3 it follows that there exists a symplectic capacity c such that for every centrally symmetric convex body $\Sigma \subset \mathbb{R}^n_q$ one has

$$\frac{4^n}{\pi^n} = \frac{c^n(\Sigma \times \Sigma^\circ)}{\pi^n} \leq \frac{\mathrm{Vol}(\Sigma \times \Sigma^\circ)}{\mathrm{Vol}(B^{2n})} = \frac{n!\,\mathrm{Vol}(\Sigma \times \Sigma^\circ)}{\pi^n},$$

which is exactly the bound for $\mathrm{Vol}(\Sigma \times \Sigma^\circ)$ required by Mahler's conjecture. □

In the rest of this section we sketch the proof of Theorem 3.3 (see [8] for a detailed exposition). We remark that an alternative proof, based on an approach to billiard dynamics developed in [11], was recently given in [3]. We start with recalling the definition of the Ekeland-Hofer-Zehnder capacity, which is the symplectic capacity that appears in Theorem 3.3.

The restriction of the standard symplectic form $\omega = dq \wedge dp$ to a smooth closed connected hypersurface $\mathcal{S} \subset \mathbb{R}^{2n}$ defines a 1-dimensional subbundle $\ker(\omega|\mathcal{S})$, whose integral curves comprise the characteristic foliation of $\mathcal{S}$. In other words, a *closed characteristic* of $\mathcal{S}$ is an embedded circle in $\mathcal{S}$ tangent to the canonical line bundle

$$\mathfrak{S}_\mathcal{S} = \{(x, \xi) \in T\mathcal{S} \,|\, \omega(\xi, \eta) = 0 \text{ for all } \eta \in T_x\mathcal{S}\}.$$

Recall that the symplectic action of a closed curve γ is defined by $A(\gamma) = \int_\gamma \lambda$, where $\lambda = pdq$ is the Liouville 1-form. The action spectrum of $\mathcal{S}$ is

$$\mathcal{L}(\mathcal{S}) = \{\,|\,A(\gamma)\,|\,;\ \gamma \text{ closed characteristic on } \mathcal{S}\}\,.$$

The following theorem, which is a combination of results from [24] and [43], states that on the class of convex domains in $\mathbb{R}^{2n}$, the Ekeland-Hofer capacity c_{EH} and Hofer-Zehnder capacity c_{HZ} coincide, and are given by the minimal action over all closed characteristics on the boundary of the corresponding convex body.

Theorem 3.4. *Let $K \subseteq \mathbb{R}^{2n}$ be a convex bounded domain with smooth boundary. Then there exists at least one closed characteristic $\widetilde{\gamma} \subset \partial K$ satisfying*

$$c_{\mathrm{EH}}(K) = c_{\mathrm{HZ}}(K) = A(\widetilde{\gamma}) = \min \mathcal{L}(\partial K).$$

We remark that although the above definition of closed characteristics, as well as Theorem 3.4, were given only for the class of convex bodies with smooth boundary, they can naturally be generalized to the class of convex sets in $\mathbb{R}^{2n}$ with non-empty interior (see [7]). In what follows, we refer to the coinciding Ekeland-Hofer and Hofer-Zehnder capacities on this class as the Ekeland-Hofer-Zehnder capacity.

We turn now to show that for every centrally symmetric convex body $\Sigma \subset \mathbb{R}^n_q$, the Ekeland–Hofer–Zehnder capacity satisfies $c_{\rm EHZ}(\Sigma \times \Sigma^\circ) = 4$. For this purpose, we now switch gears and turn to mathematical billiards in Minkowski geometry.

It is folklore to people in the field that billiard flow can be treated, roughly speaking, as the limiting case of geodesic flow on a boundaryless manifold. Indeed, let Ω be a smooth plane billiard table, and consider its "thickening", i.e. an infinitely thin three dimensional body whose boundary Γ is obtained by pasting two copies of Ω along their boundaries and smoothing the edge. Thus, a billiard trajectory in Ω can be viewed as a geodesic line on the boundary of Γ, that goes from one copy of Ω to another each time the billiard ball bounces off the boundary. The main technical difficulties with this strategy is the rigorous treatment of the limiting process, and the analysis involved with the dynamics near the boundary. One approach to billiard dynamics and the existence question of periodic trajectories is an approximation scheme which uses a certain "penalization method" developed by Benci and Giannoni in [10] (cf. [5, 48]). In what follows we present an alternative approach, and use characteristic foliation on singular convex hypersurfaces in $\mathbb{R}^{2n}$ (see e.g., [21, 23, 50]) to describe Finsler type billiards for convex domains in the configuration space $\mathbb{R}^n_q$. The main advantage of this approach is that it allows one to use the natural one-to-one correspondence between the geodesic flow on a manifold and the characteristic foliation on its unit cotangent bundle, and thus provides a natural "symplectic setup" in which one can use tools such as Theorem 3.4 above in the context of billiard dynamics. In particular, we show that the Ekeland-Hofer-Zehnder capacity of certain Lagrangian product configurations $\mathcal{K} \times \mathcal{T}$ in the classical phase space $\mathbb{R}^{2n}$ is the length of the shortest periodic *$\mathcal{T}$-billiard trajectory in $\mathcal{K}$* (see e.g., [7, 88]), which we turn now to describe.

The general study of billiard dynamics in Finsler and Minkowski geometries was initiated by Gutkin and Tabachnikov in [36]. From the point of view of geometric optics, Minkowski billiard trajectories describe the propagation of light in a homogeneous anisotropic medium that contains perfectly reflecting mirrors. Below, we focus on the special case of Minkowski billiards in a smooth convex body $\mathcal{K} \subset \mathbb{R}^n_q$. We equip $\mathcal{K}$ with a metric given by a certain norm $\|\cdot\|$, and consider billiards in $\mathcal{K}$ with respect to the geometry induced by $\|\cdot\|$. More precisely, let $\mathcal{K} \subset \mathbb{R}^n_q$, and $\mathcal{T} \subset \mathbb{R}^n_p$ be two convex bodies with smooth boundary, and consider the unit cotangent bundle

$$U^*_{\mathcal{T}}\mathcal{K} := \mathcal{K} \times \mathcal{T} = \{(q,p) \,|\, q \in \mathcal{K}, \text{ and } g_{\mathcal{T}}(p) \leq 1\} \subset T^*\mathbb{R}^n_q = \mathbb{R}^n_q \times \mathbb{R}^n_p.$$

Here $g_{\mathcal{T}}$ is the gauge function $g_{\mathcal{T}}(x) = \inf\{r \,|\, x \in r\mathcal{T}\}$. When $\mathcal{T} = -\mathcal{T}$ is centrally symmetric one has $g_{\mathcal{T}}(x) = \|x\|_{\mathcal{T}}$. For $p \in \partial\mathcal{T}$, the gradient vector $\nabla g_{\mathcal{T}}(p)$ is the outer normal to $\partial\mathcal{T}$ at the point p, and is naturally considered to be in $\mathbb{R}^n_q = (\mathbb{R}^n_p)^*$.

Motivated by the classical correspondence between geodesics in a Riemannian manifold and characteristics of its unit cotangent bundle, we define $(\mathcal{K}, \mathcal{T})$-billiard trajectories to be characteristics in $U^*_{\mathcal{T}}\mathcal{K}$ such that their projections to $\mathbb{R}^n_q$ are closed billiard trajectories in $\mathcal{K}$ with a bouncing rule that is determined by the geometry induced from the body $\mathcal{T}$; and vice versa, the projections to $\mathbb{R}^n_p$ are closed billiard trajectories in $\mathcal{T}$ with a bouncing rule that is determined by $\mathcal{K}$. More precisely, when we follow the vector fields of the dynamics, we

move in $\mathcal{K} \times \partial\mathcal{T}$ from (q_0, p_0) to $(q_1, p_0) \in \partial\mathcal{K} \times \partial\mathcal{T}$ following the inner normal to $\partial\mathcal{T}$ at p_0. When we hit the boundary $\partial\mathcal{K}$ at the point q_1, the vector field changes, and we start to move in $\partial\mathcal{K} \times \mathcal{T}$ from (q_1, p_0) to $(q_1, p_1) \in \partial\mathcal{K} \times \partial\mathcal{T}$ following the outer normal to $\partial\mathcal{K}$ at the point q_1. Next, we move from (q_1, p_1) to (q_2, p_1) following the opposite of the normal to $\partial\mathcal{T}$ at p_1, and so on and so forth (see Figure 1). It is not hard to check that when one of the bodies, say $\mathcal{T}$, is a Euclidean ball, then when considering the projection to $\mathbb{R}^n_q$, the bouncing rule described above is the classical one (i.e., equal impact and reflection angles). Hence, the above reflection law is a natural variation of the classical one when the Euclidean structure on $\mathbb{R}^n_q$ is replaced by the metric induced by the norm $\|\cdot\|_{\mathcal{T}}$. We continue with a more precise definition.

Definition 3.5. Given two smooth convex bodies $\mathcal{K} \subset \mathbb{R}^n_q$ and $\mathcal{T} \subset \mathbb{R}^n_p$. A closed $(\mathcal{K}, \mathcal{T})$-billiard trajectory is the image of a piecewise smooth map $\gamma\colon S^1 \to \partial(\mathcal{K} \times \mathcal{T})$ such that for every $t \notin \mathcal{B}_\gamma := \{t \in S^1 \mid \gamma(t) \in \partial\mathcal{K} \times \partial\mathcal{T}\}$ one has

$$\dot{\gamma}(t) = d\,\mathfrak{X}(\gamma(t)),$$

for some positive constant d and the vector field $\mathfrak{X}$ given by

$$\mathfrak{X}(q,p) = \begin{cases} (-\nabla g_{\mathcal{T}}(p), 0), & (q,p) \in int(\mathcal{K}) \times \partial\mathcal{T}, \\ (0, \nabla g_{\mathcal{K}}(q)), & (q,p) \in \partial\mathcal{K} \times int(\mathcal{T}). \end{cases}$$

Moreover, for any $t \in \mathcal{B}_\gamma$, the left and right derivatives of $\gamma(t)$ exist, and

$$\dot{\gamma}^{\pm}(t) \in \{\alpha(-\nabla g_{\mathcal{T}}(p), 0) + \beta(0, \nabla g_{\mathcal{K}}(q)) \mid \alpha, \beta \geq 0,\ (\alpha, \beta) \neq (0,0)\}.$$

Although in Definition 3.5 there is a natural symmetry between the bodies $\mathcal{K}$ and $\mathcal{T}$, in what follows we shall assume that $\mathcal{K}$ plays the role of the billiard table, while $\mathcal{T}$ induces the geometry that governs the billiard dynamics in $\mathcal{K}$. We will use the following terminology: for a $(\mathcal{K}, \mathcal{T})$-billiard trajectory γ, the curve $\pi_q(\gamma)$, where $\pi_q\colon \mathbb{R}^{2n} \to \mathbb{R}^n_q$ is the projection of γ to the configuration space, shall be called a *$\mathcal{T}$-billiard trajectory in $\mathcal{K}$*. Moreover, similarly to the Euclidean case, one can check that $\mathcal{T}$-billiard trajectories in $\mathcal{K}$ correspond to critical points of a length functional defined on the j-fold cross product of the boundary $\partial\mathcal{K}$, where the distances between two consecutive points are measured with respect to the support function $h_{\mathcal{T}}$, where $h_{\mathcal{T}}(u) = \sup\{\langle x, u\rangle\,;\, x \in \mathcal{T}\}$.

Definition 3.6. A closed $(\mathcal{K}, \mathcal{T})$-billiard trajectory γ is said to be *proper* if the set $\mathcal{B}_\gamma$ is finite, i.e., γ is a broken bicharacteristic that enters and instantly exits the boundary $\partial\mathcal{K} \times \partial\mathcal{T}$ at the reflection points. In the case where $\mathcal{B}_\gamma = S^1$, i.e., γ is travelling solely along the boundary $\partial\mathcal{K} \times \partial\mathcal{T}$, we say that γ is a *gliding trajectory*.

The following theorem was proved in [7].

Theorem 3.7. *Let $\mathcal{K} \subset \mathbb{R}^n_q$, $\mathcal{T} \subset \mathbb{R}^n_p$ be two smooth convex bodies. Then, every $(\mathcal{K}, \mathcal{T})$-billiard trajectory is either a proper trajectory, or a gliding one. Moreover the Ekeland-Hofer-Zehnder capacity $c_{\mathrm{EHZ}}(\mathcal{K} \times \mathcal{T})$ of the Lagrangian product $\mathcal{K} \times \mathcal{T}$ is the length of the shortest periodic $\mathcal{T}$-billiard trajectory in $\mathcal{K}$ measured with respect to the support function $h_{\mathcal{T}}$.*

This theorem provides an effective way to estimate (and sometimes compute) the Ekeland-Hofer-Zehnder capacity of Lagrangian product configurations in the phase space. For example, in [8] (see Remark 4.2 therein) we used elementary tools from convex geometry to show

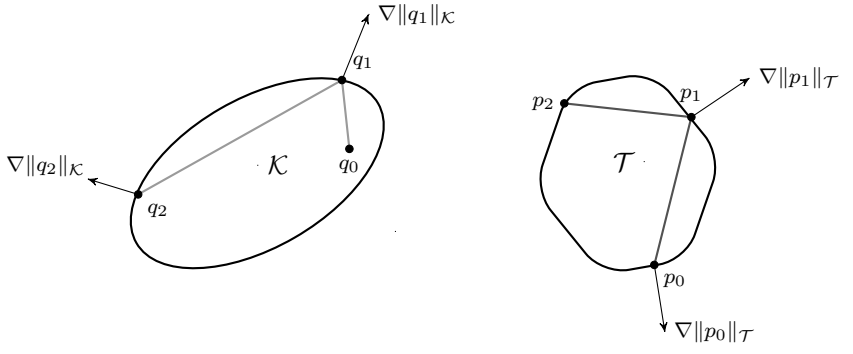

Figure 3.1. A proper $(\mathcal{K},\mathcal{T})$-Billiard trajectory.

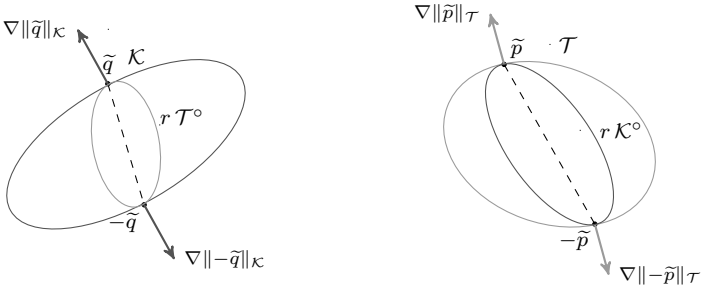

Figure 3.2. *$\mathcal{T}$-billiard trajectory in $\mathcal{K}$ of length* $4\,\mathrm{inrad}_{\mathcal{T}^\circ}(\mathcal{K})$.

that for centrally symmetric convex bodies, the shortest $\mathcal{T}$-billiard trajectory in $\mathcal{K}$ is a 2-periodic trajectory connecting a tangency point q_0 of $\mathcal{K}$ and a homotetic copy of $\mathcal{T}^\circ$ to $-q_0$ (see Figure 2). This result extends a previous result by Ghomi [31] for Euclidean billiards. In both cases, the main difficulty in the proof is to show that the above mentioned 2-periodic trajectory is indeed the shortest one. With this geometric observation at our disposal, we proved in [8] the following result: denote by $\mathrm{inrad}_{\mathcal{T}}(\mathcal{K}) = \max\{r \,|\, r\mathcal{T} \subset \mathcal{K}\}$.

Theorem 3.8. *If $\mathcal{K} \subset \mathbb{R}^n_q$, $\mathcal{T} \subset \mathbb{R}^n_p$ are centrally symmetric convex bodies, then*

$$c_{\mathrm{EHZ}}(\mathcal{K}\times\mathcal{T}) = \overline{c}(\mathcal{K}\times\mathcal{T}) = 4\,\mathrm{inrad}_{\mathcal{T}^\circ}(\mathcal{K})$$

Note that Theorem 3.8 immediately implies Theorem 3.3 above, which in turn implies Theorem 3.2. Thus, we have shown that Mahler's conjecture follows from a special case of Viterbo's conjecture. In fact, it follows immediately from the proof of Theorem 3.2 that Mahler's conjecture is equivalent to Viterbo's conjecture when the latter is restricted to the Ekeland-Hofer-Zehnder capacity, and to convex domains of the form $\Sigma\times\Sigma^\circ$, where $\Sigma \subset \mathbb{R}^n_q$ is a centrally symmetric convex body. We hope that further pursuing this line of research will lead to a breakthrough in understanding both conjectures.

3.1. Bounds on the length of the shortest billiard trajectory. Going somehow in the opposite direction, one can also use the theory of symplectic capacities to provide several bounds and inequalities for the length of the shortest periodic billiard trajectory in a smooth convex body in $\mathbb{R}^n$. In [7] we prove the following theorem, which for the sake of simplicity we state only for the case of Euclidean billiards (for several other related results see [3, 5, 11, 31, 47, 48, 88]).

Theorem 3.9. *Let $K \subset \mathbb{R}^n$ be a smooth convex body, and let $\xi(K)$ denote the length of the shortest periodic billiard trajectory in K. Then,*

(i) $\xi(K_1) \leq \xi(K_2)$*, for any convex domains $K_1 \subseteq K_2 \subseteq \mathbb{R}^n$ (monotonicity);*

(ii) $\xi(K) \leq C\sqrt{n}\,\mathrm{Vol}(K)^{\frac{1}{n}}$*, for some universal constant $C > 0$;*

(iii) $4\mathrm{inrad}(K) \leq \xi(K) \leq 2(n+1)\mathrm{inrad}(K)$*;*

(iv) $\xi(K_1 + K_2) \geq \xi(K_1) + \xi(K_2)$ *(Brunn-Minkowski type inequality).*

We remark that the inequality $4\mathrm{inrad}(K) \leq \xi(K)$ in (iii) above was proved already in [31], the monotonicity property was well known to experts in the field (although it has not been addressed in the literature to the best of our knowledge), and all the results in Theorem 3.9 were later recovered and generalized by different methods (see [3, 47, 48]). Moreover, in light of the "classical versus quantum" relation between the length spectrum in Riemannian geometry and the Laplace spectrum, via trace formulae and Poisson relations, Theorem 3.9 can be viewed as a classical counterpart of some well-known results for the first Laplace eigenvalue on convex domains. It is interesting to note that, to the best of the author's knowledge, the exact value of the constant C in part (ii) of Theorem 3.9 is unknown already in the two-dimensional case.

4. The Uniqueness of Hofer's Metric

One of the most striking facts regarding the group of Hamiltonian diffeomorphisms associated with a symplectic manifold is that it can be equipped with an intrinsic geometry given by a bi-invariant Finsler metric known as Hofer's metric [40]. In contrast to the case of finite-dimensional Lie groups, the existence of such a metric on an infinite-dimensional group of transformations is highly unusual due to the lack of local compactness. Hofer's metric is exceptionally important for at least two reasons: first, Hofer showed in [40] that this metric gives rise to an important symplectic capacity known as "displacement energy", which turns out to have many different applications in symplectic topology and Hamiltonian dynamics (see e.g., [18, 40, 43, 52, 53, 74, 75]). Second, it provides a certain geometric intuition for the understanding of the long-time behaviour of Hamiltonian dynamical systems.

In [26], Eliashberg and Polterovich initiated a discussion on the uniqueness of Hofer's metric (cf. [25, 75]). They asked whether for a closed symplectic manifold (M, ω), Hofer's metric is the only bi-invariant Finsler metric on the group of Hamiltonian diffeomorphisms. In this section we explain (following [17] and [72]) how tools from classical functional analysis and the theory of normed function spaces can be used to positively answer this question, and show that up to equivalence of metrics, Hofer's metric is unique. For this purpose, we now turn to more precise formulations.

Let (M,ω) be a closed $2n$-dimensional symplectic manifold, and denote by $C_0^\infty(M)$ the space of smooth functions that are zero-mean normalized with respect to the canonical volume form ω^n. With every smooth time-dependent Hamiltonian function $H : M\times[0,1] \to \mathbb{R}$, one associates a vector field X_{H_t} via the equation $i_{X_{H_t}}\omega = -dH_t$, where $H_t(x) = H(t,x)$. The flow of X_{H_t} is denoted by ϕ_H^t and is defined for all $t \in [0,1]$. The group of Hamiltonian diffeomorphisms consists of all the time-one maps of such Hamiltonian flows, i.e.,

$$\mathrm{Ham}(M,\omega) = \{\phi_H^1 \mid \phi_H^t \text{ is a Hamiltonian flow}\}.$$

When equipped with the standard C^∞-topology, the group $\mathrm{Ham}(M,\omega)$ is an infinite-dimensional Fréchet Lie group. Its Lie algebra, denoted here by $\mathcal{A}$, can be naturally identified with the space of normalized smooth functions $C_0^\infty(M)$. Moreover, the adjoint action of $\mathrm{Ham}(M,\omega)$ on $\mathcal{A}$ is the standard action of diffeomorphisms on functions, i.e., $\mathrm{Ad}_\phi f = f\circ\phi^{-1}$, for every $f \in \mathcal{A}$ and $\phi \in \mathrm{Ham}(M,\omega)$. For more details on the group of Hamiltonian diffeomorphisms see e.g., [43, 62, 75].

Next, we define a Finsler pseudo-distance on $\mathrm{Ham}(M,\omega)$. Given any pseudo-norm $\|\cdot\|$ on $\mathcal{A}$, we define the length of a path $\alpha : [0,1] \to \mathrm{Ham}(M,\omega)$ as

$$\mathrm{length}\{\alpha\} = \int_0^1 \|\dot\alpha\| dt = \int_0^1 \|H_t\| dt,$$

where $H_t(x) = H(t,x)$ is the unique normalized Hamiltonian function generating the path α. Here H is said to be normalized if $\int_M H_t\omega^n = 0$ for every $t \in [0,1]$. The distance between two Hamiltonian diffeomorphisms is given by

$$d(\psi,\varphi) := \inf \mathrm{length}\{\alpha\},$$

where the infimum is taken over all Hamiltonian paths α connecting ψ and φ. It is not hard to check that d is non-negative, symmetric, and satisfies the triangle inequality. Moreover, any pseudo-norm on the Lie algebra $\mathcal{A}$ that is invariant under the adjoint action yields a bi-invariant pseudo-distance function on $\mathrm{Ham}(M,\omega)$, i.e., $d(\psi,\phi) = d(\theta\,\psi,\theta\,\phi) = d(\psi\,\theta,\phi\,\theta)$, for every $\psi,\phi,\theta \in \mathrm{Ham}(M,\omega)$.

From here forth we deal solely with such pseudo-norms and we refer to d as the pseudo-distance generated by the pseudo-norm $\|\cdot\|$.

We remark in passing that a fruitful study of right-invariant Finsler metrics on $\mathrm{Ham}(M,\omega)$, motivated in part by applications to hydrodynamics, was initiated by Arnold [4]. In addition, non-Finslerian bi-invariant metrics on $\mathrm{Ham}(M,\omega)$ have been intensively studied in the realm of symplectic geometry, starting with the works of Viterbo [89], Schwarz [84], and Oh [70], and followed by many others.

Remark 4.1. When one studies geometric properties of the group of Hamiltonian diffeomorphisms, it is convenient to consider smooth paths $[0,1] \to \mathrm{Ham}(M,\omega)$, among which those that start at the identity correspond to smooth Hamiltonian flows. Moreover, for a given Finsler pseudo-metric on $\mathrm{Ham}(M,\omega)$, a natural geometric assumption is that every smooth path $[0,1] \to \mathrm{Ham}(M,\omega)$ has finite length. As it turns out, the latter assumption is equivalent to the continuity of the pseudo-norm on $\mathcal{A}$ corresponding to the pseudo-Finsler metric in the C^∞-topology (see [17]). Thus, in what follows we shall mainly consider such pseudo-norms.

It is highly non-trivial to check whether a distance function on the group of Hamiltonian diffeomorphisms generated by a pseudo-norm is non-degenerate, that is, $d(\mathrm{Id}, \phi) > 0$ for $\phi \neq \mathrm{Id}$. In fact, for closed symplectic manifolds, a bi-invariant pseudo-metric d on $\mathrm{Ham}(M, \omega)$ is either a genuine metric or identically zero. This is an immediate corollary of a well-known theorem by Banyaga [9], which states that $\mathrm{Ham}(M, \omega)$ is a simple group, combined with the fact that the null-set

$$\mathrm{null}(d) = \{\phi \in \mathrm{Ham}(M, \omega) \mid d(\mathrm{Id}, \phi) = 0\}$$

is a normal subgroup of $\mathrm{Ham}(M, \omega)$. A renowned result by Hofer [40] states that the L_∞-norm on $\mathcal{A}$ gives rise to a genuine distance function on $\mathrm{Ham}(M, \omega)$ known now as Hofer's metric. This was proved by Hofer for the case of $\mathbb{R}^{2n}$, then generalized by Polterovich [74], and finally proven in full generality by Lalonde and McDuff [53]. In a sharp contrast to the above, Eliashberg and Polterovich showed in [26] that for a closed symplectic manifold (M, ω) ons has

Theorem 4.2 (Eliashberg and Polterovich). *For $1 \leq p < \infty$, the pseudo-distances on $\mathrm{Ham}(M, \omega)$ corresponding to the L_p-norms on $\mathcal{A}$ vanish identically.*

The following question was asked in [26] (cf. [25, 75]):

Question 4.3. *What are the $\mathrm{Ham}(M, \omega)$-invariant norms on $\mathcal{A}$, and which of them give rise to genuine bi-invariant metrics on $\mathrm{Ham}(M, \omega)$?*

It was observed in [17] that any pseudo-norm $\|\cdot\|$ on the space $\mathcal{A}$ can be turned into a $\mathrm{Ham}(M, \omega)$-invariant pseudo-norm via a certain invariantization procedure $\|f\| \mapsto \|f\|_{\mathrm{inv}}$. The idea behind this procedure is based on the notion of infimal convolution (or epi-sum), from convex analysis. Recall that the infimal convolution of two functions f and g on $\mathbb{R}^n$ is defined by $(f \square g)(z) = \inf\{f(x) + g(y) \mid z = x + y\}$. This operator has a simple geometric interpretation: the epigraph (i.e., the set of points lying on or above the graph) of the infimal convolution of two functions is the Minkowski sum of the epigraphs of those functions. The invariantization $\|\cdot\|_{\mathrm{inv}}$ of $\|\cdot\|$ is obtained by taking the orbit of $\|\cdot\|$ under the group action, and consider the infimal convolution of the associated family of norms. More precisely, define

$$\|f\|_{\mathrm{inv}} = \inf\Big\{\sum \|\phi_i^* f_i\| \ ; \ f = \sum f_i, \text{ and } \phi_i \in \mathrm{Ham}(M, \omega)\Big\}.$$

We remark that in the above definition of $\|f\|_{\mathrm{inv}}$ the sum $\sum f_i$ is assumed to be finite. Note that $\|\cdot\|_{\mathrm{inv}} \leq \|\cdot\|$. Thus, if $\|\cdot\|$ is continuous in the C^∞-topology, then so is $\|\cdot\|_{\mathrm{inv}}$. Moreover, if $\|\cdot\|'$ is a $\mathrm{Ham}(M, \omega)$-invariant pseudo-norm, then:

$$\|\cdot\|' \leq \|\cdot\| \Longrightarrow \|\cdot\|' \leq \|\cdot\|_{\mathrm{inv}}.$$

In particular, the above invariantization procedure provides a plethora of $\mathrm{Ham}(M, \omega)$-invariant genuine norms on $\mathcal{A}$, e.g., by applying it to the $\|\cdot\|_{C^k}$-norms.

In [72] we made a first step toward answering Question 4.3 using tools from the theory of normed spaces and functional analysis. More precisely, regarding the first part of Question 4.3, we proved

Theorem 4.4 (Ostrover and Wagner). *Let $\|\cdot\|$ be a $\mathrm{Ham}(M, \omega)$-invariant norm on $\mathcal{A}$ such that $\|\cdot\| \leq C\|\cdot\|_\infty$ for some constant C. Then $\|\cdot\|$ is invariant under all measure preserving diffeomorphisms of M.*

In other words, any $\mathrm{Ham}(M,\omega)$-invariant norm on $\mathcal{A}$ that is bounded above by the L_∞-norm, must also be invariant under the much larger group of measure preserving diffeomorphisms. Theorem 4.4 plays an important role in the proof of the following result, which gives a partial answer to the second part of Question 4.3.

Theorem 4.5 (Ostrover and Wagner). *Let $\|\cdot\|$ be a $\mathrm{Ham}(M,\omega)$-invariant norm on $\mathcal{A}$ such that $\|\cdot\| \leq C\|\cdot\|_\infty$ for some constant C, but the two norms are not equivalent.*[1] *Then the associated pseudo-distance d on $\mathrm{Ham}(M,\omega)$ vanishes identically.*

Although Theorem 4.5 gives a partial answer to the second part of Question 4.3, prima facie, there might be $\mathrm{Ham}(M,\omega)$-invariant norms on $\mathcal{A}$ which are either strictly bigger than the L_∞-norm, or incomparable to it. In a joint work with L. Buhovsky [17] we showed that under the natural continuity assumption mentioned in Remark 4.1 above, this cannot happen. Hence, up to equivalence of metrics, Hofer's metric is unique. More precisely,

Theorem 4.6 (Buhovsky and Ostrover). *Let (M,ω) be a closed symplectic manifold. Any C^∞-continuous $\mathrm{Ham}(M,\omega)$-invariant pseudo-norm $\|\cdot\|$ on $\mathcal{A}$ is dominated from above by the L_∞-norm i.e., $\|\cdot\| \leq C\|\cdot\|_\infty$ for some constant C.*

Combining Theorem 4.6 and Theorem 4.5 above, we obtain:

Corollary 4.7. *For a closed symplectic manifold (M,ω), any bi-invariant Finsler pseudo-metric on $\mathrm{Ham}(M,\omega)$, obtained by a pseudo-norm $\|\cdot\|$ on $\mathcal{A}$ that is continuous in the C^∞-topology, is either identically zero, or equivalent to Hofer's metric. In particular, any non-degenerate bi-invariant Finsler metric on $\mathrm{Ham}(M,\omega)$ which is generated by a norm that is continuous in the C^∞-topology gives rise to the same topology on $\mathrm{Ham}(M,\omega)$ as the one induced by Hofer's metric.*

In the rest of this section we briefly describe the strategy of the proof of Theorem 4.6 in the two-dimensional case. For the proof of the general case see [17]. We start with two straightforward reduction steps. First, for technical reasons, we shall consider pseudo-norms on the space $C^\infty(M)$, instead of the space $\mathcal{A}$. The original claim will follow, since any $\mathrm{Ham}(M,\omega)$ invariant pseudo-norm $\|\cdot\|$ on $\mathcal{A}$ can be naturally extended to an invariant pseudo-norm $\|\cdot\|'$ on $C^\infty(M)$ by

$$\|f\|' := \|f - M_f\|, \text{ where } M_f = \tfrac{1}{\mathrm{Vol(M)}}\int_M f\omega^n.$$

Note that if $\|\cdot\|$ is continuous in the C^∞-topology, then so is $\|\cdot\|'$, and that the two norms coincide on the space $\mathcal{A}$. Second, by using a standard partition of unity argument, we can reduce the proof of Theorem 4.6 to a "local result", i.e., it is sufficient to prove the theorem for $\mathrm{Ham}_c(W,\omega)$-invariant pseudo-norms on the space of compactly supported smooth functions $C_c^\infty(W)$, where $W = (-L,L)^2$ is an open square in $\mathbb{R}^2$ (see [17] for the details).

The next step, which is one of the key ideas of the proof, is to define the "largest possible" $\mathrm{Ham}_c(W,\omega)$-invariant norm on the space of compactly supported smooth functions $C_c^\infty(W)$. To this end, we fix a (non-empty) finite collection of functions $\mathcal{F} \subset C_c^\infty(W)$, and define:

$$\mathcal{L}_{\mathcal{F}} := \Big\{\sum_{i,k} c_{i,k}\Phi_{i,k}^* f_i \,|\, c_{i,k} \in \mathbb{R}, \Phi_{i,k} \in \mathrm{Ham}_c(W,\omega), f_i \in \mathcal{F}, \text{ and } \#\{(i,k) \,|\, c_{i,k} \neq 0\} < \infty\Big\}.$$

[1] Two norms are said to be equivalent if $\frac{1}{C}\|\cdot\|_1 \leqslant \|\cdot\|_2 \leqslant C\|\cdot\|_1$ for some constant $C > 0$.

We equip the space $\mathcal{L}_{\mathcal{F}}$ with the norm

$$\|f\|_{\mathcal{L}_{\mathcal{F}}} = \inf \sum |c_{i,k}|,$$

where the infimum is taken over all the representations $f = \sum c_{i,k}\, \Phi_{i,k}^* f_i$ as above.

Definition 4.8. For any compactly supported function $f \in C_c^\infty(W)$, let

$$\|f\|_{\mathcal{F},\max} = \inf \big\{ \liminf_{i\to\infty} \|f_i\|_{\mathcal{L}_{\mathcal{F}}} \big\},$$

where the infimum is taken over all subsequences $\{f_i\}$ in $\mathcal{L}_{\mathcal{F}}$ which converge to f in the C^∞-topology. As usual, the infimum of the empty set is set to be $+\infty$.

The main feature of the norm $\|\cdot\|_{\mathcal{F},\max}$ is that it dominates from above any other $\mathrm{Ham}_c(W,\omega)$-invariant pseudo-norm that is continuous in the C^∞-topology.

Lemma 4.9. *Let $\mathcal{F} \subset C_c^\infty(W)$ be a non-empty finite collection of smooth compactly supported functions in W. Then any $\mathrm{Ham}_c(W,\omega)$-invariant pseudo-norm $\|\cdot\|$ on $C_c^\infty(W)$ that is continuous in the C^∞-topology satisfies*

$$\|\cdot\| \leqslant C\|\cdot\|_{\mathcal{F},\max},$$

for some absolute constant C.

Proof of Lemma 4.9. Since the collection $\mathcal{F}$ is finite, set $C = \max\{\|g\|;\, g \in \mathcal{F}\}$. For any $f = \sum c_{i,k}\, \Phi_{i,k}^* f_i \in \mathcal{L}_{\mathcal{F}}$, one has

$$\|f\| \leq \sum |c_{i,k}| \|\Phi_{i,k}^* f_i\| \leq C \sum |c_{i,k}|. \tag{4.1}$$

By the definition of $\|\cdot\|_{\mathcal{L}_{\mathcal{F}}}$, this immediately implies that $\|f\| \leq C\|f\|_{\mathcal{L}_{\mathcal{F}}}$. The lemma now follows by combining (4.1), the definition of $\|\cdot\|_{\mathcal{F},\max}$, and the fact that the pseudo-norm $\|\cdot\|$ is assumed to be continuous in the C^∞-topology. □

The next step, which is the main part of the proof, is to show that for a suitable collection of functions $\mathcal{F} \subset C_c^\infty(W)$, the norm $\|\cdot\|_{\mathcal{F},\max}$ is in turn bounded from above by the L_∞-norm. In light of the above, this would complete the proof of Theorem 4.6 in the two-dimensional case.

There are two independent components in the proof of this claim. First, we show that one can decompose any $f \in C_c^\infty(W^2)$ with $\|f\|_\infty \leqslant 1$ into a finite combination $f = \sum_{i=1}^{N_0} \epsilon_j \Psi_j^* g_j$. Here, $\epsilon_j \in \{-1, 1\}$, $\Psi_j \in \mathrm{Ham}_c(W^2,\omega)$, and g_j are smooth rotation-invariant functions whose L_∞-norm is bounded by an absolute constant, and which satisfy certain other technical conditions (see Proposition 3.5 in [17] for the precise statement). In what follows we call such functions "simple functions". We emphasize that N_0 is a constant independent of f. Thus, we can restrict ourselves to the case where f is a "simple function". In the second part of the proof, we construct an explicit collection $\mathcal{F} = \{\mathfrak{f}_0, \mathfrak{f}_1, \mathfrak{f}_2\}$, where $\mathfrak{f}_i \in C_c^\infty(W^2)$, and $i = 0, 1, 2$. Using an averaging procedure (see the proof of Theorem 3.4 in [17]), one can show that every "simple function" $f \in C_c^\infty(W^2)$ can be approximated arbitrarily well in the C^∞-topology by a sum of the form

$$\sum_{i,k} \alpha_{i,k} \widetilde{\Psi}_{i,k}^* \mathfrak{f}_k, \text{ where } \widetilde{\Psi}_{i,k} \in \mathrm{Ham}_c(W^2,\omega),\ k \in \{0,1,2\},$$

and such that $\sum |\alpha_{i,k}| \leq C\|f\|_\infty$ for some absolute constant C. Combining this with the above definition of $\|\cdot\|_{\mathcal{F},\max}$, we conclude that $\|f\|_{\mathcal{F},\max} \leq C\|f\|_\infty$ for every $f \in C_c^\infty(W^2)$. Together with Lemma 4.9, this completes the proof of Theorem 4.6 in the 2-dimensional case.

5. Some open questions and speculations

Do symplectic capacities coincide on the class of convex domains? As mentioned above, since the time of Gromov's original work, a variety of symplectic capacities have been constructed and the relations between them often lead to the discovery of surprising connections between symplectic geometry and Hamiltonian dynamics. In the two-dimensional case, Siburg [85] showed that any symplectic capacity of a compact connected domain with smooth boundary $\Omega \subset \mathbb{R}^2$ equals its Lebesgue measure. In higher dimensions symplectic capacities do not coincide in general. A theorem by Hermann [37] states that for any $n \geq 2$ there is a bounded star-shaped domain $S \subset \mathbb{R}^{2n}$ with cylindrical capacity $\overline{c}(S) \geq 1$, and arbitrarily small Gromov radius $\underline{c}(S)$. Still, for large classes of sets in $\mathbb{R}^{2n}$, including ellipsoids, polydiscs and convex Reinhardt domains, all symplectic capacities coincide [37]. In [88] Viterbo showed that for any bounded convex subset Σ of $\mathbb{R}^{2n}$ one has $\overline{c}(\Sigma) \leq 4n^2\underline{c}(\Sigma)$. Moreover, one has (see [37, 41, 88]) the following:

Conjecture 5.1. *For any convex domain Σ in $\mathbb{R}^{2n}$ one has $\underline{c}(\Sigma) = \overline{c}(\Sigma)$.*

This conjecture is particularly challenging due to the scarcity of examples of convex domains in which capacities have been computed. Moreover, note that Conjecture 5.1 is stronger than Viterbo's conjecture (Conjecture 2.2 above), as the latter holds trivially for the Gromov radius.

A somewhat more modest question in this direction is whether Conjecture 5.1 holds asymptotically, i.e., whether there is an absolute constant A such that for any convex domain $K \subset \mathbb{R}^{2n}$ one has $\overline{c}(K) \leq A\,\underline{c}(K)$. It would be interesting to explore whether methods from asymptotic geometric analysis can be used to answer this question.

Are Hanner polytopes in fact symplectic balls in disguise? Recall that Mahler's conjecture states that the minimum possible Mahler volume is attained by a hypercube. It is interesting to note that the corresponding product configuration, when looked at through symplectic glasses, is in fact a Euclidean ball in disguise. More precisely, it was proved in §7.9 of [82] (cf. Corollary 4.2 in [56]) that the interior of the product of a hypercube $Q \subset \mathbb{R}^n_q$ and its dual body, the cross-polytope $Q^\circ \subset \mathbb{R}^n_p$, is symplectomorphic to the interior of a Euclidean ball $B^{2n}(r) \subset \mathbb{R}^n_q \times \mathbb{R}^n_p$ with the same volume. On the other hand, as mentioned in Section 3 above, if Mahler's conjecture holds, then there are other minimizers for the Mahler volume aside of the hypercube. For example, consider the class of Hanner polytopes. A d-dimensional centrally symmetric polytope P is a Hanner polytope if either P is one-dimensional (i.e., a symmetric interval), or P is the free sum or direct product of two (lower dimensional) Hanner polytopes P_1 and P_2. Recall that the free sum of two polytopes, $P_1 \subset \mathbb{R}^n$, $P_2 \subset \mathbb{R}^m$ is a $n+m$ polytope defined by $P_1 \oplus P_2 = \mathrm{Conv}(\{P_1 \times \{0\}\} \cup \{\{0\} \times P_2\}) \subset \mathbb{R}^{n+m}$. It is not hard to check (see e.g. [80]) that the volume product of the cube is the same as that of Hanner polytopes. Thus every Hanner polytope is also a candidate for a minimizer of the volume product among symmet-

ric convex bodies. In light of the above mentioned result from [82], a natural question is the following:

Question 5.2. *Is every Hanner polytope a symplectic image of a Euclidean ball?*

More precisely, is the interior of every Hanner polytope symplectomorphic to the interior of a Euclidean ball with the same volume? A negative answer to this question would give a counterexample to Conjecture 5.1 above, since it would show that the Gromov radius must be different from the Ekeland-Hofer-Zehnder capacity.

Symplectic embeddings of Lagrangian products. Since Gromov's work [34], questions about symplectic embeddings have lain at the heart of symplectic geometry (see e.g., [12, 13, 35, 45, 56, 60, 61, 63, 82, 83]). These questions are usually notoriously difficult, and up to date most results concern only the embeddings of balls, ellipsoids and polydiscs. Note that even for this simple class of examples, only recently has it become possible to specify exactly when a four-dimensional ellipsoid is embeddable in a ball (McDuff and Schlenk [63]), or in another four-dimensional ellipsoid (McDuff [60]). For some other related works we refer the reader to [15, 19, 22, 30, 38, 39, 71].

Since symplectic capacities can naturally be used to detect symplectic embedding obstructions, and in light of the results mentioned in Section 3 (in particular, Theorem 3.8), it is only natural to try to extend the above list of currently-known examples, and study symplectic embeddings of convex "Lagrangian products" in the classical phase space. The main advantage of this class of bodies is that the action spectrum can be computed via billiard dynamics. This property would presumably make it easier to compute or estimate the Ekeland-Hofer capacities [24], or Hutchings' embedded contact homology capacities [44, 45], in this setting. A natural first step in this direction would be to consider the embedding of the Lagrangian product of two balls into a Euclidean ball. More precisely, to study the function $\sigma : \mathbb{N} \to \mathbb{R}$ defined by

$$\sigma(n) = \inf\big\{a \,|B_q^n(1) \times B_p^n(1) \overset{\text{symp}}{\hookrightarrow} B^{2n}(a)\big\}.$$

To the best of the author's knowledge, the value of $\sigma(n)$ is unknown already for the case $n = 2$.

Acknowledgements. I am deeply indebted to Leonid Polterovich for generously sharing his insights and perspective on topics related to this paper, as well as for many inspiring conversations throughout the years. I have also benefited significantly from an ongoing collaboration with Shiri Artstein-Avidan, I am grateful to her for many stimulating and enjoyable hours working together. I would also like to thank Felix Schlenk and Leonid Polterovich for their valuable comments on an earlier draft of this paper.

On the future stability of cosmological solutions to Einstein's equations with accelerated expansion

Hans Ringström

Abstract. The solutions of Einstein's equations used by physicists to model the universe have a high degree of symmetry. In order to verify that they are reasonable models, it is therefore necessary to demonstrate that they are future stable under small perturbations of the corresponding initial data. The purpose of this contribution is to describe mathematical results that have been obtained on this topic. A question which turns out to be related concerns the topology of the universe: what limitations do the observations impose? Using methods similar to ones arising in the proof of future stability, it is possible to construct solutions with arbitrary closed spatial topology. The existence of these solutions indicate that the observations might not impose any limitations at all.

Mathematics Subject Classification (2010). Primary 83C05; Secondary 35Q76.

Keywords. General relativity, stability of solutions, Einstein-Vlasov system.

1. Introduction

In 1915, the interpretation of gravitational forces was fundamentally altered by the introduction of Einstein's general theory of relativity. The underlying mathematical structures of the theory were not well understood at the time, and as a consequence, some of the fundamental questions have only recently been phrased in the form of mathematical problems. Since Einstein's equations are not as commonly studied in mathematics as many other equations that appear in physics, we here wish to give a brief description of their origin and of how different perspectives on them have developed since the inception of general relativity. However, the main purpose of this contribution is more specific. Recent observational data indicate that the universe is expanding at an accelerated rate. As a consequence, physicists nowadays use solutions to Einstein's equations with accelerated expansion to model the universe. Since the model solutions are highly symmetric (they are spatially homogeneous and isotropic), a natural question to ask is: are they stable? In order to phrase this question in a more precise way, it is necessary to formulate Einstein's equations (coupled to various matter equations) as an initial value problem. It turns out that there is a natural and geometric notion of initial data, and that, given initial data, there is a uniquely associated maximal Cauchy development. A more precise formulation of the question of stability is then: given initial data corresponding to one of the standard models, do small perturbations thereof yield maximal Cauchy developments that are globally similar? The currently preferred models have a big bang type singularity and an expanding direction. Proving stability in the direction of the

Proceedings of the International Congress of Mathematicians, Seoul, 2014

singularity is quite difficult (there are some results in the case of special matter fields), but there are several results on stability in the expanding direction. For that reason we shall focus on the expanding direction here, and we shall think of it as corresponding to the future.

The outline of this contribution is as follows. We begin, in Section 2, by giving a brief description of the origin of the general theory of relativity. Moreover, we explain how the present contribution fits into the general context of mathematical studies of Einstein's equations. In Sections 3 and 4, we then discuss the formulation of the initial value problem, which is needed in order for us to be able to state a stability result. In Section 5, we then discuss the topic of stability in general. We give a rough description of some of the results that have been obtained in the past, as well as of some of the methods. However, we shall only formulate a theorem in the case of the Einstein-Vlasov system. In order to be able to do so, we devote Section 6 to a discussion of this system. In Sections 7 and 8, we then describe the background solutions we are interested in proving stability of, and state the relevant results. Finally, in Section 9, we discuss a construction which indicates that the observations do not impose any restrictions on the topology of the universe.

2. General relativity

In order to discuss the general theory of relativity, it is natural to begin with Einstein's paper on special relativity [6]. The starting point of the paper is the contemporary interpretation of electrodynamics. Noting that this interpretation involves asymmetries, and postulating that the speed of light is independent of inertial observer, Einstein was led to the Poincaré group of transformations, relating the observations of inertial observers. Due to the added insight of Poincaré and Minkowski, it was realized that this group is the group of isometries of Minkowski space; recall that Minkowski space is $\mathbb{R}^4$ with the inner product $\langle x, y\rangle = x^t \eta y$, where $\eta = \mathrm{diag}(-1, 1, 1, 1)$. This interpretation indicates the importance of geometry. As a next step, it is clear that Newtonian gravity has to be modified. Two important principles that guided Einstein in his search for a modified theory were the *equivalence principle* (the equality between inert and gravitational mass; this is roughly speaking the idea that it is not possible to distinguish between a coordinate system at rest in a uniform gravitational field and a uniformly accelerated coordinate system far away from all matter, for example) and the *principle of general covariance*, the idea that the equations should be independent of the choice of coordinate system. By a simple thought experiment involving rotating coordinate systems, it can be argued (heuristically) that acceleration distorts the geometry; cf. [7, pp. 58–59]. Combining this observation with the equivalence principle indicates that gravitation should affect the geometry. In fact, it is not unnatural to equate gravitation with distorsion of the geometry. Since the geometry at a point should be described by the Minkowski metric (with respect to a suitable choice of coordinates), the natural underlying object in general relativity is a Lorentz manifold; in other words, a manifold M on which a smooth symmetric covariant two-tensor field g is defined, where g is such that it, at each point of M, equals the Minkowski metric with respect to suitable coordinates. The standard notions and constructions in Riemannian geometry (Levi-Civita connection, curvature tensor, Ricci tensor, scalar curvature, geodesics etc.) can be defined in the same way in Lorentz geometry, and we shall use them below without further comment. The one question that remains is: what equation should (M, g) satisfy? In some way, the geometry should be related to the matter sources. On the level of special relativity, it was already clear that the matter should

be combined into the so-called stress-energy tensor; a symmetric covariant two-tensor field, the exact form of which depends on the specific matter model. Let us denote this object by T. It should be the source term in Einstein's equations (it can be thought of as a generalization of the matter density in Poisson's equation in Newtonian gravity). As a consequence, what remains is to determine what the left hand side of the equation should be. To begin with, it should clearly be symmetric. Due to the equations for the matter, the stress-energy tensor should be divergence free. As a consequence, the left hand side should be as well. Moreover, it should be such that the resulting equations are independent of the choice of coordinates. Finally, it is natural (for the sake of simplicity, and in analogy with the Poisson equation) to require that the left hand side should contain at most second order derivatives of the gravitational field (i.e., the metric). However, the only equations fulfilling these requirements are the ones of the form

$$G + \Lambda g = \alpha T, \tag{2.1}$$

where Λ and α are constants and

$$G = \mathrm{Ric} - \frac{1}{2} S g$$

is the *Einstein tensor*, defined in terms of the Ricci tensor, Ric, and the scalar curvature, S, of the metric g (the reader interested in a justification of this statement is referred to the corollary of [15, Theorem 1, p. 500]). In (2.1), we shall, for simplicity, assume $\alpha = 1$. Moreover, we shall refer to Λ as the *cosmological constant*. The resulting equations are

$$G + \Lambda g = T, \tag{2.2}$$

and we shall refer to them as *Einstein's equations*.

2.1. Historical development. It is of interest to say a few words concerning how different perspectives on these equations have developed over time. In the intial phase, physicists tried to find explicit solutions to the equations. In order to do so, they imposed symmetry assumptions adapted to the physical situation of interest. When considering physical objects such as a star, a galaxy, a globular cluster etc. (i.e., an *isolated system*), a natural first symmetry assumption to make is that of spherical symmetry. This assumption led to the class of Schwarzschild spacetimes, which can be used to model the gravitational field outside a non-rotating star or black hole. Much later, the Kerr family of solutions was found, describing the rotating case. When modelling the universe as a whole, another type of symmetry assumption is required. Guided by the Copernican principle, a natural starting point in this case is the assumption of spatial homogeneity and isotropy; this is the assumption that at 'one moment in time', it is not possible to distinguish between two points in space, nor is it possible to distinguish between two directions. Symmetry assumptions of this type (corresponding to the so-called *cosmological setting*) led to the Friedman-Lemaître-Robertson-Walker metrics, which are still used to this very day when modelling the universe (though the preferred matter models have changed over time). Even though mathematicians nowadays consider significantly less symmetric solutions, the problems considered can still be divided into ones concerning isolated systems and ones concerning the cosmological setting.

In the initial stages of the development of general relativity, when the emphasis was on finding explicit solutions, the geometry remained somewhat obscure. As a consequence, some of the features of, e.g., the Schwarzschild solutions were misunderstood for several

decades. In the 50's and 60', the geometry received more attention, and the so-called *singularity theorems* were proven. In order to give an idea of the statements of these results, it is necessary to introduce the notion of causal geodesics. To begin with, a vector v in Minkowski space is said to be *timelike* if $\langle v, v\rangle < 0$; *lightlike* or *null* if $\langle v, v\rangle = 0$ and $v \neq 0$; and *spacelike* if $\langle v, v\rangle > 0$ or $v = 0$. A vector which is either timelike or null is said to be *causal*. These notions can be generalized to Lorentz manifolds. Moreover, it makes sense to speak of timelike curves etc. as well as spacelike hypersurfaces. In particular, the character of a geodesic (timelike, null, spacelike) is preserved, so that it is meaningful to speak of timelike geodesics etc. In the interpretation of general relativity, a causal curve corresponds to an observer that travels at a speed less than or equal to that of light. Moreover, a timelike geodesic corresponds to a freely falling test particle, and a null geodesics corresponds to a light ray. Thus causal geodesics are of particular importance in general relativity. A notion which is also of importance is that of a time orientation. At a given spacetime point, the set of causal vectors based at that point has two components. A continuous choice of component corresponds to a *time orientation* (and we shall, from now on, assume all Lorentz manifolds to be time oriented). Vectors belonging to the chosen component will be referred to as *future oriented*.

The singularity theorems of Hawking and Penrose give general conditions that ensure the existence of incomplete causal geodesics. Since the existence of such a geodesic means that there is a freely falling test particle (or a light ray) which exits the spacetime in finite parameter time, Hawking and Penrose equated causal geodesic incompleteness with the existence of a singularity (examples illustrate that this is not always reasonable). Due to the results, it is to be expected that singularities, in the sense of causal geodesic incompleteness, occur generically in solutions to Einstein's equations. These results changed the perspective concerning the occurrences of singularities. Moreover, due to the methods used to prove them, the importance of the subject of Lorentz geometry became apparent.

In the early 50's, Yvonne Choquet-Bruhat formulated Einstein's equations as an initial value problem [8]. It took a significant amount of time before this perspective became a natural starting point in the subject. Since the initial data cannot be specified freely (they have to satisfy an underdetermined, non-linear system of elliptic PDE's, referred to as the *constraint equations*), and since, given initial data, the evolution problem typically involves proving global existence of solutions to a non-linear system of hyperbolic PDE's, this is perhaps not so surprising. In particular, the relevant PDE tools were not so well developed in the early 50's. Nevertheless, this perspective has become more and more important in the subject. This is, in particular, due to the fact that central questions such as that of stability are most naturally formulated using it.

With the above description in mind, the present contribution can be said to be concerned with the initial value formulation of Einstein's equations in the cosmological setting. Moreover, the precise notion of stability we shall use is highly dependent on a Lorentz geometric interpretation of the outcome of the PDE analysis.

3. On the character of Einstein's equations

In order to justify that it is meaningful to formulate Einstein's equations as an initial value problem, let us begin by focusing on the vacuum equations with a vanishing cosmological constant. Since these equations can be written $\mathrm{Ric} = 0$, it is of interest to know if Ric,

considered as a differential operator acting on the components of the metric, has a particular character (elliptic, hyperbolic etc.). Due to the diffeomorphism invariance of the equations, this is not to be expected. On the other hand, it is possible to break the diffeomorphism invariance by making a special choice of coordinates. In fact, choosing coordinates such that the contracted Christoffel symbols vanish, the Ricci tensor (schematically) takes the form

$$\mathrm{Ric}_{\alpha\beta} = -\frac{1}{2} g^{\mu\nu} \partial_\mu \partial_\nu g_{\alpha\beta} + F_{\alpha\beta}(g, \partial g), \tag{3.1}$$

where F is a quadratic expression in the first derivatives of the metric components. In this equation, we assume Greek indices to range from 0 to n, where $n+1$ is the dimension of the Lorentz manifold, and we tacitly assume that repeated indices are summed over (the Einstein summation convention). With respect to these coordinates, Einstein's vacuum equations can thus be thought of as a system of non-linear wave equations for the metric components. As a consequence, it seems natural to formulate a corresponding inital value problem.

It is of interest to note that the above issues arise not only in general relativity, but also in Riemannian geometry and in Ricci flow. In Riemannian geometry, it is sometimes convenient to think of the Ricci tensor as an elliptic differential operator acting on the components of the metric; this yields good control of the metric components, given information concerning the Ricci tensor. It is therefore of interest to consider the so-called *harmonic coordinates*, defined by the condition that the contracted Christoffel symbols vanish. The reason for referring to these coordinates as harmonic is that their defining requirement is equivalent to

$$\Delta_g x^\mu = 0,$$

where Δ_g is the scalar covariant Laplacian associated with the metric g and x^μ are the components of the coordinate system. The analogous coordinates in the Lorentzian setting are sometimes, by analogy, referred to as harmonic coordinates (and sometimes as wave coordinates). In Ricci flow, the relevant equation is $\partial_t g = -2\mathrm{Ric}[g]$, and when dealing with this equation analytically, it would be convenient if Ric were an elliptic operator. Hamilton's original idea concerning how to prove local existence was to appeal to the Nash-Moser inverse function theorem. However, later proofs instead relied on breaking the diffeomorphism invariance in order to obtain a strictly parabolic equation.

4. The initial value problem

With the above observations in mind, it seems natural to formulate an initial value problem. However, it is not so clear what the initial data should be, nor where they should be specified. It turns out that there are several ways of proceeding, but we shall here focus on the perspective that arises in analogy with the standard Cauchy problem for the ordinary wave equation. In that setting, the initial data are specified on a $t = \mathrm{const}$ hypersurface in Minkowski space. These hypersurfaces are special in several ways. First of all, they are *spacelike*, meaning that the induced metric is Riemannian (in this particular case, they are in fact the ordinary Euclidean metric). Moreover, they are intersected exactly once by every inextendible causal curve; cf. the above terminology. Hypersurfaces in Lorentz manifolds which are intersected exactly once by every inextendible casual curve are referred to as *Cauchy hypersurfaces*. They are natural surfaces on which to specify initial data, since given initial data on a Cauchy hypersurface (for the linear wave equation on the Lorentz

manifold), there is a unique corresponding solution. A Lorentz manifold which admits a Cauchy hypersurface is called *globally hyperbolic*.

Turning to the choice of the intial data, it would seem natural to specify the metric components and their normal derivative at the initial hypersurface (keeping (3.1) in mind). However, since Einstein's equations are geometric in nature, the initial data should be geometric as well. On the other hand, the induced metric and second fundamental form are geometric in nature and correspond to a part of the desired information; with respect to local coordinates, they yield some of the metric components and the normal derivative of some metric components. The induced metric and second fundamental form would thus seem to constitute minimal information needed in order to construct a solution. On the other hand, it unfortunately turns out that these initial data cannot be specified freely. In order to be more specific, let Σ be a spacelike hypersurface in a Lorentz manifold on which Einstein's equations (2.2) are satisfied. Contracting the equations twice with respect to the future directed unit normal, say N, yields

$$\frac{1}{2}[\bar{S} - \bar{k}_{ij}\bar{k}^{ij} + (\mathrm{tr}_{\bar{g}}\bar{k})^2] = \rho + \Lambda, \tag{4.1}$$

where $\bar{g}$ and $\bar{k}$ are the induced metric and second fundamental form on the hypersuface Σ respectively; cf. [18, Proposition 13.3, p. 149]. Moreover, $\bar{S}$ is the scalar curvature of the metric $\bar{g}$, indices are raised and lowered with $\bar{g}$ and $\rho = T(N, N)$. In particular, all the ingredients in (4.1) are intrinsic to the hypersurface. Contracting (2.2) once with respect to the future directed unit normal and once with respect to a tangential vector yields the equation

$$\overline{\nabla}^j \bar{k}_{ji} - \overline{\nabla}_i \mathrm{tr}_{\bar{g}}\bar{k} = -J_i, \tag{4.2}$$

where $\overline{\nabla}$ is the Levi-Civita connection associated with the metric $\bar{g}$ and J is the one-form field defined by $J = -T(N, \cdot)$; cf. [18, Proposition 13.3, p. 149]. Again, the ingredients of (4.2) are intrinsic to the hypersurface Σ. Clearly, the initial data have to satisfy (4.1) and (4.2), which are referred to as the *Hamiltonian* and *momentum constraints* respectively; collectively, we shall refer to them as the *constraint equations*. It is natural to ask whether the constraint equations are sufficient in order to guarantee the existence of a corresponding development. In the vacuum setting, this question was settled in the seminal result of Yvonne Choquet-Bruhat [8], which we now formulate.

Theorem 4.1. *Let $(\Sigma, \bar{g}, \bar{k})$ be initial data for Einstein's vacuum equations; i.e., Σ is an n-dimensional manifold, $\bar{g}$ is a Riemannian metric and $\bar{k}$ is a symmetric covariant 2-tensor field satisfying the vacuum constraint equations; i.e., (4.1) and (4.2) with $\Lambda = 0$, $\rho = 0$ and $J = 0$. Then there is a globally hyperbolic development of the initial data. In other words, a Lorentz manifold (M, g) satisfying Einstein's vacuum equations and an embedding $i : \Sigma \to M$ such that $i^* g = \bar{g}$ and $i^* \kappa = \bar{k}$, where κ is the second fundamental form of $i(\Sigma)$ in (M, g). Moreover, $i(\Sigma)$ is a Cauchy hypersurface in (M, g).*

This result has been generalized to include many different types of matter models. We shall not list them, but for all the matter models discussed in this contribution, there is a result analogous to Theorem 4.1.

Even though Theorem 4.1 is important, it does have one deficiency; there is no uniqueness statement. Given initial data, there are infinitely many inequivalent globally hyperbolic developments associated with it. In order to obtain uniqueness, it is necessary to require

some sort of maximality. In fact, the fundamental result, due to Yvonne Choquet-Bruhat and Robert Geroch [4], is the following.

Theorem 4.2. *Let $(\Sigma, \bar{g}, \bar{k})$ be initial data for Einstein's vacuum equations. Then there is a unique maximal globally hyperbolic development.*

Due to this theorem, it is clear that the notion of initial data introduced in the statement of Theorem 4.1 is meaningful. Unfortunately, there are examples of maximal globally hyperbolic developments that are extendible in the class of all (not necessarily globally hyperbolic) developments. In fact, there might even be inequivalent maximal developments, indicating that the general theory of relativity is not deterministic. Since the examples are very special, one is led to the strong cosmic censorship conjecture. However, that is not the main topic of this contribution. In fact, we shall here be content with the maximal globally hyperbolic development as *the* development of the intial data.

5. Stability

Since Einstein's equations can be formulated as an initial value problem, it is possible to phrase the stability question: Given initial data corresponding to a specific solution, do small perturbations thereof yield maximal globally hyperbolic developments which are globally similar? The question is still somewhat vague, since we have not specified what is meant by globally similar, nor what is meant by small perturbations. However, the precise meaning in practice depends on the particular solution under consideration, and even for a given solution it is sometimes possible to take different perspectives.

Turning to the stability results that have been obtained in the past, the first one is due to Helmut Friedrich; cf. [9], which contains a proof of stability of de Sitter space. In the same paper, he also proved future stability of Minkowski space, starting with hyperboloidal initial data. Later on, Demetrios Christodoulou and Sergiu Klainerman proved stability of Minkowski space [5]. That stability holds when using harmonic coordinates was only demonstrated much later by Hans Lindblad and Igor Rodnianski [13]. Another perspective on the stability of Minkowski space is given by the work of Lydia Bieri; cf. [3]. Even though all of the references [3, 5, 9, 13] pertain to the problem of stability of Minkowski space, they are very different in nature; the assumptions and conclusions are different in all of these references, and the results correspond to different notions of 'smallness' and 'global similarity'.

Minkowski space is a natural solution to start with when one is interested in isolated systems. However, the topic of the present contribution is cosmology. Of the references mentioned above, the one which is of interest in that setting is [9], in which Friedrich proves stability of de Sitter space. For an appropriate value of the cosmological constant, Λ, the metric of de Sitter space is given by

$$g_{\mathrm{dS}} = -dt \otimes dt + \cosh^2(t)\bar{g}_{\mathbb{S}^3}$$

on $\mathbb{R} \times \mathbb{S}^3$, where $\bar{g}_{\mathbb{S}^3}$ is the standard metric on $\mathbb{S}^3$. The de Sitter space is a solution to Einstein's vacuum equations with a positive cosmological constant; i.e.,

$$G + \Lambda g = 0.$$

The result of Friedrich is peculiar to $3+1$-dimensions, but Michael Anderson later generalized it to $n+1$-dimensions, with n odd; cf. [1]. Friedrich also generalized [9] to include matter of Maxwell and Yang-Mills type; cf. [10]. All of these references yield stability of cosmological solutions with accelerated expansion. They thus belong to the class of results we wish to discuss here. It is of interest to note that the proofs given in [1, 9, 10] are based on conformal reformulations of the equations. The idea is to first rescale the background spacetime by a conformal factor, so that what corresponds to past and future infinity in the physical spacetime is at a finite distance away with respect to the rescaled metric. The second step is then to derive a suitable system of equations for the rescaled metric and conformal factor (in reality, the variables might be quite different). This step can be expected to be very difficult, and the only cases in which it is known to be possible is when the matter sources have suitable conformal invariance properties. However, when it is possible, the problem of global existence and stability becomes an issue of continuous dependence on initial data. Assuming the conformally rescaled equations admit a well posed initial value problem (with respect to an appropriately chosen gauge; i.e., an appropriate choice of how to break the diffeomorphism invariance), this is, however, immediate, so that the desired result follows. It is of interest to note that, even though [1] yields stability in the case of higher dimensions, it can be used to prove stability in $3+1$-dimensions for spacetimes with a special type of matter source; cf. [12]. The results mentioned above are appealing due the the geometric nature of the arguments involved. However, the methods used seem to suffer from a lack of robustness. This leads us to the different perspective developed in [17].

In [17], we considered the case of Einstein's equations coupled to a non-linear scalar field. The relevant stress-energy tensor in that case is

$$T = d\phi \otimes d\phi - \left[\frac{1}{2} g(\mathrm{grad}\phi, \mathrm{grad}\phi) + V(\phi)\right] g, \tag{5.1}$$

where ϕ is a scalar valued function on the manifold (the so-called *scalar field*) and V is a smooth function on $\mathbb{R}$ referred to as the *potential*. The relevant matter field equations are

$$\Box_g \phi - V' \circ \phi = 0, \tag{5.2}$$

where $\Box_g$ is the scalar wave operator associated with g (defined in the same way as the scalar Laplacian in the case of Riemannian geometry). Note that (5.1) is divergence free if (5.2) holds. In [17], it is assumed that $V(0) > 0$, $V'(0) = 0$ and $V''(0) > 0$; in other words, that 0 is a positive non-degenerate local minimum of the potential. Moreover, the scalar field is assumed to be small initially.

The motivation for studying non-linear scalar fields is partly due to their interest in physics. Once it became clear that the observational data indicate that the universe is expanding at an accelerated rate, it was natural to try to find matter models that induce accelerated expansion. One possibility is to include a positive cosmological constant. Another is to add matter of non-linear scalar field type. The types of potentials considered above specialize to the case of a positive cosmological constant when demanding that $\phi = 0$ (a case which can already be handled using conformal methods). However, they are more general, and only in the case of special relations between $V(0)$ and $V''(0)$ do the conformal methods seem to work; cf. [11].

Following the appearance of [17], there were several results obtained using similar methods; cf. [19] (treating the case of an exponential potential and generalizing the results of

[12]), [16, 23] (in which an electromagnetic field was added), [21, 22] (in which the Euler-Einstein system was considered). However, the situation we focus on in what follows is the Einstein-Vlasov setting, discussed in [20].

6. The Einstein-Vlasov system

The physical situation matter of Vlasov type is supposed to represent is that of a gas. The fundamental assumption is that collisions are sufficiently rare that they can be negelected (including binary collisions would, e.g., lead to the Boltzmann equation, which we do not consider here). In the case of general relativity, each particle in the gas can thus be expected to behave as a freely falling test particle. A test particle with a non-zero rest mass (also referred to as a *massive* particle) can thus be expected to travel along a timelike geodesic. In the case of a zero rest mass (i.e., a *massless*) particle, the relevant curves are the null geodesics. On the other hand, the particles collectively generate a gravitational field which, in its turn, affects the geometry (and thereby the geodesics). In order to describe the gas, it is convenient to use a distribution function. The natural space on which this function is defined is the space of states of particles. Assuming all the particles to have rest mass 1, the space of states is given by the set of future directed unit timelike vectors. We shall denote this set by P, and we shall refer to it as the *mass shell*. The *distribution function*, say f, is then a function from P to the non-negative real numbers.

In order to couple Vlasov matter to Einstein's equations, it is necessary to explain how to construct a stress-energy tensor, given a distribution function. Moreover, it is necessary to formulate an evolution equation for the distribution function. The relevant stress-energy tensor is defined by

$$T|_{T_\xi M \times T_\xi M} = \int_{P_\xi} f(p) p^\flat \otimes p^\flat \mu_{P_\xi}(p). \tag{6.1}$$

In this equation, ξ is a spacetime point (i.e., an element of the spacetime manifold M); P_ξ is the mass shell above ξ (i.e., the elements of P based at ξ); p is an element of P_ξ; $p^\flat$ is the one-form metrically associated with p (i.e., $p^\flat(X) = g(p, X)$ for $X \in T_\xi M$); and μ_{P_ξ} is a volume form defined on P_ξ in the following way: the metric g induces a Lorentz metric g_ξ on $T_\xi M$, the Lorentz metric g_ξ induces a Riemannian metric on P_ξ, and this Riemannian metric induces a volume form on P_ξ (which we denote by μ_{P_ξ}). It is important to note that it is necessary to impose fall-off conditions on the distribution function in order for (6.1) to make sense. Often the requirement of compact support in the momentum directions is imposed, but we here prefer to demand that the distribution function belong to Sobolev spaces with appropriate weights in the momentum directions.

Turning to the equation for the distribution function, it is given by

$$\mathcal{L} f = 0, \tag{6.2}$$

and it is referred to as the *Vlasov equation*. Here $\mathcal{L}$ is a vector field on P defined as follows. Given an element of P, say v, there is a unique geodesic γ such that $\dot\gamma(0) = v$. Moreover, $\dot\gamma(s)$ is a curve in P, and its tangent vector at 0 (considered as a curve in P) is $\mathcal{L}_v$, the vector field $\mathcal{L}$ at the point v. Note that the Vlasov equation is equivalent to the requirement that $f(\dot\gamma)$ be constant for each geodesic γ with initial values on P. Moreover, this requirement corresponds to the assumption that collisions can be neglected, so that the particles travel

along timelike geodesics. It is of interest to note that (6.2) implies that the stress energy tensor defined by (6.1) is divergence free (regardless of whether Einstein's equations are satisfied or not).

Summing up the above discussion, the *Einstein-Vlasov* system with a positive cosmological constant is given by the equations

$$\begin{aligned} G + \Lambda g =& T, \\ \mathcal{L} f =& 0, \end{aligned}$$

where T is defined by (6.1). It is also possible to couple this system to a non-linear scalar field, but we shall focus on the above equations in what follows. There are results corresponding to Theorems 4.1 and 4.2 in this setting. We shall not write them down in detail, but it is of some interest to clarify what the initial data are.

Initial data for the Einstein-Vlasov system. For the geometry, the relevant initial data are the induced metric and second fundamental form, just as before. Since the Vlasov equation is a first order equation, we only need one initial datum for the distribution function. In order to explain how it is related to the spacetime picture, let us assume that we have a solution (M, g, f) and a spacelike hypersurface Σ in (M, g). Then there is a diffeomorphism from P_Σ (the mass shell above Σ) to $T\Sigma$ obtained by projecting orthogonally to the normal of Σ. Let us denote it by proj_Σ. The initial datum for the distribution function is given by $\bar{f} = f \circ \mathrm{proj}_\Sigma^{-1}$, and it is defined on $T\Sigma$. In the case of the Einstein-Vlasov system, the relevant initial data are $(\Sigma, \bar{g}, \bar{k}, \bar{f})$, where Σ is an n-dimensional manifold, $\bar{g}$ is a Riemannian metric on Σ, $\bar{k}$ is a symmetric covariant 2-tensor field on Σ and $\bar{f}$ is a smooth, non-negative function on $T\Sigma$. Moreover, these data should satisfy the constraint equations (4.1) and (4.2) (where the matter quantities should be expressed in terms of $\bar{g}$ and $\bar{f}$, something which can be done; cf. [20, (7.20) and (7.21), p. 92]). In order to phrase a stability result, we also need a notion of distance between initial data sets.

Distance between initial data sets. Let us assume Σ to be a closed manifold. Then we can use ordinary Sobolev norms on manifolds to measure the distance between two metrics and between two symmetric covariant 2-tensor fields. Since the tangent space of Σ is non-compact, we do, however, need a different norm to measure the difference between initial data for the distribution function. We shall use

$$\|\bar{f}\|_{H^l_{\mathrm{V}1,\mu}} = \left(\sum_{i=1}^{j} \sum_{|\alpha|+|\beta|\leq l} \int_{\bar{\mathsf{x}}_i(U_i)\times\mathbb{R}^n} \langle \bar{\varrho} \rangle^{2\mu+2|\beta|} \bar{\chi}_i(\bar{\xi}) (\partial_{\bar{\xi}}^{\alpha} \partial_{\bar{\varrho}}^{\beta} \bar{\mathsf{f}}_{\bar{\mathsf{x}}_i})^2 (\bar{\xi}, \bar{\varrho}) d\bar{\xi} d\bar{\varrho} \right)^{1/2}. \quad (6.3)$$

In this expression, $(U_i, \bar{\mathsf{x}}_i)$, $i = 1, \ldots, j$, is a covering of Σ by coordinate neighbourhoods, and $\{\bar{\chi}_i\}$ is a partition of unity subordinate to the covering $\{U_i\}$. The expression $\bar{\mathsf{f}}_{\bar{\mathsf{x}}_i}$ is the distribution function expressed with respect to the local coordinates on $T\Sigma$ induced by $(U_i, \bar{\mathsf{x}}_i)$; in particular, it is a function on $\bar{\mathsf{x}}_i(U_i) \times \mathbb{R}^n$, where the $\mathbb{R}^n$-factor corresponds to the tangential directions. Finally, we use the notation

$$\langle \bar{\varrho} \rangle = (1 + |\bar{\varrho}|^2)^{1/2}.$$

Considering the norm (6.3), there are two contributions to the power of the weight $\langle \bar{\varrho} \rangle$; 2μ and $2|\beta|$. The reason for including μ is that it yields an overall decay (assuming it to be positive). In fact, for $\mu > n/2 + 1$, the relevant matter quantities are well defined, assuming the

right hand side of (6.3) to be bounded (for a high enough l). The reason for including $2|\beta|$ is that it ensures that the notion of smallness obtained using (6.3) is geometrically meaningful; the exact value of the right hand side of (6.3) depends on the coordinates and the partition of unity, but different choices lead to equivalent norms, assuming we include $2|\beta|$ in the power of the weight. We shall refer to the space of functions $\bar{f}$ such that (6.3) is bounded for all l by $\bar{\mathfrak{D}}^{\infty}_{\mu}(T\Sigma)$ (this space can also be defined in case Σ is not compact; we then only require the integrals appearing in the definition of the norm to be bounded on compact subsets of Σ). The reader interested in a more detailed discussion of norms such as (6.3) is referred to [20]. In this reference, there is also a description of the relevant function spaces for the corresponding distribution functions on the maximal globally hyperbolic development associated with the initial data. The final ingredient we need before phrasing a stability result is a description of the relevant background solutions. We turn to this topic next.

7. Background solutions

Let us begin by describing the class of solutions to Einstein's equations which is currently preferred by physicists when modelling the universe. The geometry is taken to be spatially homogeneous and isotropic, as well as spatially flat. In other words, the relevant metrics take the form

$$g_{\mathrm{model}} = -dt \otimes dt + a^2(t)\bar{g}_{\mathrm{E}}$$

on $I \times \mathbb{R}^3$ (or $I \times \mathbb{T}^3$), where I is an open interval, $\bar{g}_{\mathrm{E}}$ is the standard Euclidean metric on $\mathbb{R}^3$, and a is a positive smooth function on I. Concerning the matter sources, they are usually taken to be a combination of so-called *perfect fluids*. In the case of a perfect fluid (and the above type of symmetry conditions), the stress energy tensor is of the form

$$T = (\rho + p)dt \otimes dt + p g_{\mathrm{model}}.$$

Here the functions ρ and p are referred to as the *energy density* and the *pressure* respectively. In order to obtain evolution equations for p and ρ, it is common to introduce an *equation of state*, giving p in terms of ρ. The condition that T be divergence free then yields an evolution equation for ρ. Two equations of state that are often used by physicists are *dust* (in which case $p = 0$) and *radiation* (in which case $p = \rho/3$). In fact, the early universe is expected to have been radiation dominated, and at late times, the matter is expected to behave as dust. Physicists often study one of these situations at at time, and then they include only dust or only radiation. However, it is possible to include both at the same time, and we shall take the matter content of the standard model to consist of a radiation fluid and dust. The corresponding stress energy tensors are required to be divergence free individually, and this yields evolution equations for the corresponding energy densities. Finally, a mechanism is required in order to produce the observed accelerated expansion. One possibility is to include a non-linear scalar field, but we shall here simply add a positive cosmological constant Λ to the above description. The relevant equations are then

$$\begin{aligned} G + \Lambda g_{\mathrm{model}} =& T_{\mathrm{rad}} + T_{\mathrm{dust}}, \\ T_{\mathrm{rad}} =& (\rho_{\mathrm{rad}} + p_{\mathrm{rad}})dt \otimes dt + p_{\mathrm{rad}} g_{\mathrm{model}}, \\ T_{\mathrm{dust}} =& \rho_{\mathrm{dust}} dt \otimes dt, \end{aligned}$$

$$\dot{\rho}_{\mathrm{rad}} = -4\frac{\dot{a}}{a}\rho_{\mathrm{rad}},$$
$$\dot{\rho}_{\mathrm{dust}} = -3\frac{\dot{a}}{a}\rho_{\mathrm{dust}},$$

where $p_{\mathrm{rad}} = \rho_{\mathrm{rad}}/3$ and G is the Einstein tensor of g_{model}. It should be pointed out that solutions of the above type are only relevant models after decoupling (i.e., the time at which matter and radiation decoupled). In particular, inflationary phases etc. are not included. The above matter models are not of Vlasov type. However, it turns out to be possible to approximate the above solutions arbitrarily well with solutions to the Einstein-Vlasov system with a positive cosmological constant and the above type of symmetry; cf. [20, Chapter 28]. Moreover, Vlasov matter is such that it naturally behaves as a radiation fluid close to the singularity and as dust in the expanding direction. In other words, it is not necessary to put in a dust and a radiation fluid by hand; Vlasov matter is such that this emerges naturally. Finally, Vlasov matter is conceptually natural in the later part of the evolution of the universe. As a consequnce, we shall prefer it here.

Spatial homogeneity. It is of interest to put the above example into a slightly bigger context, namely that of spatially homogeneous solutions. In [24], Robert Wald presented general ideas for how to analyze the future asymptotics of spatially homogeneous solutions to Einstein's equations with a positive cosmological constant (assuming the matter sources satisfy certain energy conditions). He did not address the issue of future global existence; this was taken for granted. However, he did obtain quite general results. The most fundamental ingredient of the argument is the Hamiltonian constraint (4.1). This equation can be written

$$(\mathrm{tr}_{\bar{g}}\bar{k})^2 = -\frac{3}{2}\bar{S} + \frac{3}{2}\bar{\sigma}_{ij}\bar{\sigma}^{ij} + 3\rho + 3\Lambda, \tag{7.1}$$

where $\bar{\sigma}_{ij}$ are the components of the trace free part of the second fundamental form. Assuming the matter to satisfy the *dominant energy condition* (i.e., the requirement that $T(u,v) \geq 0$ for future directed timelike vectors), the energy density ρ is non-negative. Considering (7.1), it is thus clear that the only term on the right hand side which might be negative is the first one. However, the sign of the scalar curvature of the metric induced on the hypersurfaces of spatial homogeneity is intimately connected with the symmetry type. Before describing this connection in detail, let us give a formal definition of a spatially homogeneous spacetime: it is the maximal globally hyperbolic development of homogeneous initial data (we assume the relevant matter model to be such that the initial value problem is well posed). Initial data, given by a manifold Σ, a metric $\bar{g}$, a symmetric covariant 2-tensor field, as well as matter fields, are said to be homogeneous if there is a smooth transitive Lie group action on Σ which leaves the initial data invariant. In the 3-dimensional case, there are two possibilities. Focusing on the simply connected setting for simplicity, Σ is either a Lie group or $\mathbb{S}^2 \times \mathbb{R}$. The latter case is referred to as Kantowski-Sachs in the physics community, and we shall ignore it in what follows, since the corresponding metrics have positive scalar curvature; cf. (7.1). That is not to say that it is not possible to obtain results in the Kantowski-Sachs setting, but rather that the statements of the corresponding results would be more involved. Turning to the Lie group setting, $\mathrm{SU}(2)$ constitutes a particular case; it is the only simply connected 3-dimensional Lie group which admits a left invariant metric with positive scalar curvature. Again, there are results in the $\mathrm{SU}(2)$ setting, but the statements of the results are more involved. Ignoring Kantowski-Sachs and $\mathrm{SU}(2)$ for the moment, the remaining symmetry

types are such that the corresponding invariant metrics have non-positive scalar curvature. Returning to (7.1), we conclude that the right hand side has a positive lower bound. On the other hand, since the left hand side is zero when the volume is at a local maximum (or minimum), this indicates that there is no local maximum or minimum. Naively, one would then expect that there is a big bang in one time direction and infinite expansion in the other. In fact, the corresponding solutions all have an expanding direction (which we shall refer to as the future). Moreover, it is possible to say something concerning the future asymptotics: the solution isotropizes and the matter content becomes irrelevant.

Spatially homogeneous solutions to the Einstein-Vlasov system. As mentioned above, the results in [24] were based on the assumption that the solution exists globally to the future. When studying a particular case, it thus has to be verified that this holds. In the case of the Einstein-Vlasov equations with a positive cosmological constant, this was done in [14] (the result was later extended to the case of non-compact support in the momentum directions in [20]). Moreover, asymoptotic information concerning the solution was obtained. In what follows, we wish to describe a stability result for these solutions.

8. Stability in the Einstein-Vlasov setting

Before stating the main stability result, let us define the relevant background initial data; the definition below is a specialization of [20, Definition 7.21, p. 107] to the case of the Einstein-Vlasov system with a positive cosmological constant.

Definition 8.1. Let G be a 3–dimensional Lie group and $5/2 < \mu \in \mathbb{R}$. Let $\bar{g}$ and $\bar{k}$ be a left invariant Riemannian metric and a left invariant symmetric covariant 2–tensor field on G respectively. Furthermore, let $\bar{f} \in \bar{\mathfrak{D}}^{\infty}_{\mu}(TG)$ be left invariant; in other words, if $h \in G$, then $\bar{f} \circ L_{h*} = \bar{f}$. Then $(G, \bar{g}, \bar{k}, \bar{f})$ are referred to as *Bianchi initial data* for the Einstein–Vlasov system with a positive cosmological constant, assuming they constitute initial data in the ordinary sense.

As discussed in the previous section, the corresponding solutions have an expanding direction (if the universal covering group of the Lie group is not isomorphic to $\mathrm{SU}(2)$), and it is of interest to prove global non-linear stability in that direction. It is also important to keep in mind that by letting $G = \mathbb{R}^3$ (or $G = \mathbb{T}^3$); taking $\bar{g}$ and $\bar{k}$ to be suitable multiples of the standard Euclidean metric; and by making an appropriate choice of $\bar{f}$, one obtains initial data corresponding to a solution which is consistent with observations. Future stability of solutions consistent with observations is thus a corollary of the result below. The following theorem is a specialization of [20, Theorem 7.22, p. 108] to the case of the Einstein-Vlasov system with a positive cosmological constant.

Theorem 8.2. *Let $5/2 < \mu \in \mathbb{R}$ and $(G, \bar{g}_{\mathrm{bg}}, \bar{k}_{\mathrm{bg}}, \bar{f}_{\mathrm{bg}})$ be Bianchi initial data for the Einstein–Vlasov system with a positive cosmological constant, where*

- *the universal covering group of G is not isomorphic to $\mathrm{SU}(2)$,*
- $\mathrm{tr}\bar{k}_{\mathrm{bg}} = \bar{g}^{ij}_{\mathrm{bg}} \bar{k}_{\mathrm{bg},ij} > 0$.

Assume that there is a cocompact subgroup Γ of the isometry group of the initial data. Let Σ be the compact quotient. Then the initial data induce initial data on Σ which, by abuse

of notation, will be denoted by the same symbols. Make a choice of Sobolev norms $\| \cdot \|_{H^l}$ *on tensor fields on* Σ *and a choice of norms* $\| \cdot \|_{H^l_{\mathrm{Vl},\mu}}$. *Then there is an* $\epsilon > 0$ *such that if* $(\Sigma, \bar{g}, \bar{k}, \bar{f})$ *are initial data for the Einstein–Vlasov system with a positive cosmological constant with the property that*

$$\|\bar{g} - \bar{g}_{\mathrm{bg}}\|_{H^5} + \|\bar{k} - \bar{k}_{\mathrm{bg}}\|_{H^4} + \|\bar{f} - \bar{f}_{\mathrm{bg}}\|_{H^4_{\mathrm{Vl},\mu}} \leq \epsilon,$$

then the maximal globally hyperbolic development of $(\Sigma, \bar{g}, \bar{k}, \bar{f})$ *is future causally geodesically complete.*

It is perhaps worth commenting on the requirement that there be a cocompact subgroup of the isometry group of the initial data. We expect this requirement to be unnecessary (though we have not proven this statment). However, it would then be necessary to introduce a more complicated notion of distance between initial data sets in the formulation of stability. The reason for focusing on future causal geodesic completeness in the conclusions is the physical interpretation that freely falling test particles (light) follow timelike (null) geodesics. Future causal geodesic completeness thus implies that freely falling test particles do not exit the spacetime in finite proper time to the future. In this geometric sense, the solution is thus future global. It is of course also of interest to write down estimates characterizing the asymptotic behaviour. This has been done in [20, Theorem 7.16, p. 104–106]; cf. [20, Theorem 7.22, p. 108]. We shall not repeat the technical details here.

In the presence of a positive cosmological constant, solutions are expected to homogenize and isotropize at late times. In fact, they are expected to appear de Sitter like, and this rough expectation goes under the name of the *cosmic no-hair conjecture*. A more precise formulation of this expectation is given in [2, Definition 8, p. 7]. We shall not write down the formal definition here, as it requires a somewhat technical discussion of the causal structure of solutions (the main point is to focus on the parts of the spacetime that can actually be seen by observers). However, the solutions that arise as a result of Theorem 8.2 become de Sitter like asymptotically to the future, in the sense of [2, Definition 8, p. 7].

Even though we have excluded Lie groups whose universal covers are isomorphic to $\mathrm{SU}(2)$, there are results in that setting. However, it is then necessary to impose additional conditions. An example of a result which holds when perturbing isotropic solutions is given in [20, Theorem 7.28, p. 109].

The $\mathbb{T}^3$-Gowdy symmetric setting. Beyond the above stability results concerning spatially homogeneous solutions, there are results in the $\mathbb{T}^3$-Gowdy symmetric setting. The main assumption that characterizes this symmetry class is the requirement that the initial data be invariant under a 2-torus action. In practice, the effective number of spacetime dimensions is thus 2. On the other hand, the symmetry class admits both inhomogeneities and anisotropies. Nevertheless, it turns out that solutions to the Einstein-Vlasov system in the $\mathbb{T}^3$-Gowdy symmetric setting homogeneize and isotropize. In fact, they are future asymptotically de Sitter like. Moreover, perturbing the initial data corresponding to a $\mathbb{T}^3$-Gowdy symmetric solution in the class of all solutions yields maximal globally hyperbolic developments with the same properties. The reader interested in a more detailed description is referred to [2].

9. On the topology of the universe

In Section 7, we described the solutions that physicists normally use to model the universe. Note that the justification for using them is based not only on observations, but also on the philosophical idea that all observers should see something which is roughly similar (an assumption which cannot be tested). In practice, the assumption that leads to the standard models is that every observer sees exactly the same spatially homogeneous and isotropic solution. Clearly, this is asking too much, since what we see is not exactly spatially homogeneous and isotropic. An assumption which would be slightly more reasonable would be to fix a standard model and to say that every observer should see something which is very close to that standard model. It is of interest to ask what limitations on the topology such an assumption imposes; note that the standard perspective, which implies a locally homogeneous and isotropic spatial geometry, is only consistent with a topology which is the 3-sphere, hyperbolic space or Euclidean space, or a quotient thereof. However, using methods similar to ones on which the future global non-linear stability result is based, it turns out to be possible to prove that, given

- a closed 3-manifold, say Σ,
- a standard solution (with flat spatial geometry and $\mathbb{R}^3$ spatial topology),
- a time t_0 in the existence interval of the standard solution (note that the matter models discussed here are only valid after decoupling, and we shall think of t_0 as representing decoupling),
- a choice of norm (say C^k-norm) and $\epsilon > 0$,

there is a solution to the Einstein-Vlasov system with a positive cosmological constant, such that

- it is the maximal globally hyperbolic development of initial data,
- it is future causally geodesically complete,
- it has spatial topology Σ (globally hyperbolic Lorentz manifolds have topology $\mathbb{R} \times \Sigma$, where Σ is a Cauchy hypersurface; Σ is referred to as the *spatial topology*),
- every observer considers the solution to be at distance ϵ away from the chosen standard solution to the future of t_0 and with respect to the chosen C^k-norm,
- the solution is stable with all these properties (in other words, if we perturb the corresponding initial data, we obtain a maximal globally hyperbolic development with the same properties).

Under the given assumptions, it is thus not possible to draw any conclusions concerning the topology of the universe.

The statement is still somewhat imprecise; it is not so clear how to measure the distance (as percieved by an observer) between the solution and the background solution. This is a somewhat technical issue, and we refer the interested reader to [20, Section 7.9] for a discussion.

The above description is somewhat brief, and we refer the reader interested in more details to [20, Section 7.9] for a mathematical statement of the result, and to [20, Chapter 34] for a proof.

Solitons in geometric evolution equations

Natasa Sesum

Abstract. We will discuss geometric properties and classification of special solutions to geometric evolution equations called solitons. Our focus will be on the Ricci flow and the Yamabe flow solitons. These are very special solutions to considered geometric evolution equations that move by diffeomorphisms and homotheties. Solitons are very important solutions to our equations because very often they arise as singularity models. Therefore classifying the solitons helps us understand and classify encountered singularities in geometric flows.

Mathematics Subject Classification (2010). 53C44.

Keywords. Ricci flow, Yamabe flow, solitons.

1. Introduction

We will focus on two geometric evolution equations. The first one is the Ricci flow equation, that is,

$$\begin{aligned} \frac{\partial}{\partial t} g_{ij} &= -2R_{ij}, \\ g(\cdot, 0) &= g_0(\cdot), \end{aligned} \tag{1.1}$$

where (M, g_0) is an arbitrary Riemannian manifold. The second one is the Yamabe flow equation, that is,

$$\begin{aligned} \frac{\partial}{\partial t} g_{ij} &= -R g_{ij}, \\ g_0(\cdot, 0) &= g_0(\cdot). \end{aligned} \tag{1.2}$$

In both geometric equations a singularity is most likely to occur in finite time. The singularity in both flows is characterized by the norm of the curvature operator blowing up at a singular time. In order to understand any of those singularities one defines a sequence of parabolic dilations in a space-time neighborhood of a considered singularity. The limit of that sequence is called a *singularity model* and turns out to be either an *ancient* solution, which means a solution that lives from $(-\infty, T)$ where $T < \infty$, or an *eternal* solution, which is a solution that lives for all times, from $(-\infty, \infty)$. Hence, understanding the ancient and eternal solutions help us understand the singularities in geometric flows, which is crucial if we want to use the flow in order to better understand topological and geometric properties of our manifold M.

Proceedings of the International Congress of Mathematicians, Seoul, 2014

Special examples of ancient and eternal solutions are given by *solitons*. These are the solutions to the considered flow equations that move just by diffeomorphisms and homotheties. In this article we focus on solitons, their classification if possible and also their geometric and topological properties.

2. Ricci solitons

There has been a lot of interest in Ricci solitons recently. They are natural generalizations of Einstein metrics and play important role in the singularity analysis of the Ricci flow. The concept of Ricci solitons was introduced by Hamilton in mid 80's.

Definition 2.1. A complete Riemannian metric g on a smooth Riemannian manifold M is called a *Ricci soliton* if there exists a smooth vector field V such that

$$R_{ij} + (\mathcal{L}_V g)_{ij} = \lambda g_{ij},$$

for some constant λ and $(\mathcal{L}_V g)_{ij} = \frac{1}{2}(\nabla_i V_j + \nabla_j V_i)$. If $V = \nabla f$ for some smooth function f then

$$R_{ij} + \nabla_i \nabla_j f = \lambda g_{ij}, \tag{2.1}$$

and we say we have a *gradient Ricci soliton*. We call it *expanding*, *steady* or *shrinking*, depending on whether $\lambda < 0$, $\lambda = 0$ or $\lambda > 0$, respectively.

By a suitable rescaling of metric g, we can normalize $\lambda = -\frac{1}{2}, 0$ or $\frac{1}{2}$. Below we focus on gradient Ricci solitons and we will be denoting them as a triple (M, g, f) and refer to a function f as to the *potential* function.

2.1. Examples of Ricci solitons. There are not so many examples of Ricci solitons so far. Below we describe a few well known examples.

1. **(Gaussian solitons)** (R^n, g) with the flat Euclidean metric can be equipped with both, the shrinking and the expanding Ricci soliton. More precisely $(\mathrm{R}^n, g, \frac{|x|^2}{4})$ is a gradient Ricci shrinker and $(\mathrm{R}^n, g, -\frac{|x|^2}{4})$ is a gradient Ricci expander.
2. The generalized round cylinders $S^k \times \mathrm{R}^{n-k}$ are gradient Ricci shrinkers.
3. **(The cigar soliton)** In dimension two, Hamilton [32] discovered the first example of complete, noncompact steady soliton on R^2, called the *cigar soliton*, where

$$ds^2 = \frac{dx^2 + dy^2}{1 + x^2 + y^2}, \qquad \text{with} \quad f = -\log(1 + x^2 + y^2).$$

4. **(The Bryant soliton)** Higher dimensional ($n \geq 3$) noncompact gradient steady solitons on R^n were discovered by Bryant. They are rotationally symmetric, have positive sectional curvature and the geodesic sphere S^{n-1} of radius s has the diameter of order $\sqrt{s}$. Recently Brendle ([5]) showed they are the only steady κ-noncollapsed solitons with positive sectional curvature (noncollapsing here is in the sense of Perelman [44]).

2.2. Ricci solitons as singularity models. In order to study the Ricci flow and its singularity models Perelman ([44]) introduced the $\mathcal{W}$-functional

$$\mathcal{W}(g,f,\tau)=\int_M [\tau(R+|\nabla f|^2)+f-n](4\pi\tau)^{-\frac{n}{2}}e^{-f}\,dV_g,$$

where g is a Riemannian metric, f is a smooth function on M^n and τ a positive scale parameter. It is easy to see that the functional $\mathcal{W}$ is invariant under scaling and diffeomorphisms, that is, $\mathcal{W}(\alpha\phi^*g,\phi^*f,\alpha\tau)=\mathcal{W}(g,f,\tau)$, for any positive number α and any diffeomorphism ϕ. Perelman showed the Ricci flow is up to diffeomorphisms the gradient flow of functional $\mathcal{W}$, which is also monotone along the flow. More precisely, he finds that

$$\frac{d}{dt}\mathcal{W}=2\tau\int_M |R_{ij}+\nabla_i\nabla_j f-\frac{g_{ij}}{2\tau}|^2(4\pi\tau)^{-\frac{n}{2}}e^{-f}\,dV,$$

under the flow

$$\frac{\partial}{\partial t}g_{ij}=-2R_{ij},\qquad \frac{\partial f}{\partial t}=-\Delta f+|\nabla f|^2-R+\frac{n}{2\tau},\qquad \dot\tau=-1.$$

It is now even more apparent that Ricci solitons whose equation appears in the evolution of the monotone quantity $\mathcal{W}$ play an important role in the study of the Ricci flow. The solitons are related to the Li-Yau-Hamilton inequality, also called differential Harnack estimate. More precisely, the Li-Yau-Hamilton quantity vanishes on expanding solitons. More importantly, Ricci solitons often appear as blow-up limits around the singularities in the Ricci flow.

A complete solution $g(t)$ to (1.1) is called *ancient* if it is defined for $-\infty<t<T$. It turns out that Type I and Type II singularity models are ancient (those singularity models are defined to be the limits of dilations of solutions to the Ricci flow around their Type I and Type II space-time singularities, respectively, which are to be defined below). Steady and shrinking Ricci solitons are special examples of ancient solutions. Using Perelman's monotonicity formula for $\mathcal{W}$ in [48] we showed that if a singularity model is compact, it has to be a gradient shrinking Ricci soliton. In [42], Naber removed our assumption that a singularity model is compact but did not show the singularity model is always non-flat. Nonflatness of the singularity model has been obtained in [29] and [13] independently.

Consider a solution $(M,g(\cdot,t))$ to (1.1) for $t\in[0,T)$ and $T\le\infty$, where either M is compact or at each time the metric is complete and has bounded curvature. Hamilton [34] showed that if T is a *maximal* singularity time then either $T=\infty$ or the curvature tensor $|Rm|$ is unbounded as $t\to T$. More precisely we have showed that

Theorem 2.2 ([47]). *Let $(M,g(\cdot,t))$ be a compact solution to* (1.1) *for $t\in[0,T)$ and $T\le\infty$. Then if T is a maximal singularity time we have either $T=\infty$ or the Ricci curvature tensor $|Ric|$ is unbounded as $t\to T$.*

Intuitively it is clear that if we take a dumbbell metric in S^3 with a neck like $S^2\times B^1$, we expect the neck will shrink because the positive curvature in the S^2 direction will dominate the slightly negative curvature in the B^1 direction. These intuitive picture of a neck pinching off in some finite time and having the sequence of dilations around the singularity converging to a round infinite cylinder $S^2\times\mathrm{R}$ was justified in [1] (they actually showed the same phenomenon occurs in higher dimensions as well). They considered an open set of initial

metrics of *rotationally symmetric* metrics evolving on S^{n+1}. These are **Type I** singularities, meaning that

$$\limsup_{t\to T}\sup_{M}(T-t)\,|Rm(\cdot,t)|<\infty.$$

If the above quantity is equal to infinity we say we have a **Type II** singularity. In [37] we have recently considered the generalized Berger warped product metrics on $S^1\times S^3$ and we have constructed open sets of initial metrics (not necessarily rotationally symmetric) of the form

$$g=ds^2+f(s)^2w^1\otimes w^1+g(s)^2\,(w^2\otimes w^2+w^3\otimes w^3),$$

where s is the arc length from an arbitrary, but a fixed point s_0 on S^1 and where w^1,w^2,w^3 is a coframe, algebraically dual to a fixed Milnor frame on $S^3=SU(2)$. The behavior of the Ricci flow around the singularities is the same as the one in the intuitive picture of a Ricci flow behavior on a dumbbell. More precisely we have the following result.

Theorem 2.3 ([37]). *The eccentricity of every warped Berger solution of Ricci flow is uniformly bounded: there exists C_0 depending only on the initial data such that the estimate*

$$|f-g|\le C_0\min\{f,g\} \tag{2.2}$$

holds pointwise for as long as the solution exists, without additional assumptions.

(i) *There exist open sets of warped Berger metrics satisfying certain assumptions such that all solutions originating in these sets develop local neckpinch singularities at some $T<\infty$. Each such solution has the properties that*

(a) *the ordering $f\le g$ is preserved;*

(b) *the singularity is Type-I, with $|Rc|\le C\big(\min f(\cdot,t)\big)^{-2}$, and*

$$\frac{1}{C}\sqrt{T-t}\le\min f(\cdot,t)\le C\sqrt{T-t};$$

(c) *the diameter is bounded as $t\nearrow T$.*

(ii) *There exist open sets of warped Berger metrics satisfying certain assumptions such that as solutions originating in these sets become singular, they become asymptotically round at rates that break scale invariance. Specifically, in addition to the properties above, they satisfy the following C^0, C^1, and C^2 bounds at the neck:*

$$(T-t)^{-1/2}|f-g|\le C\sqrt{T-t}, \tag{2.3}$$

$$(T-t)|\kappa_{12}-\kappa_{23}|\le C\sqrt{T-t}, \tag{2.4}$$

$$(T-t)|\kappa_{01}-\kappa_{02}|\le C\sqrt{T-t}. \tag{2.5}$$

In a neighborhood of each smallest neck, where $\kappa_{01}<0$, there is the further bound

$$(T-t)\,\big(|\kappa_{01}|+|\kappa_{02}|\big)\le\frac{C}{|\log(T-t)|}, \tag{2.6}$$

where $\kappa_{12},\kappa_{31},\kappa_{23}$ are the curvatures of the corresponding vertical planes in the total space and $\kappa_{01},\kappa_{02},\kappa_{03}$ are the curvatures of mixed vertical-horizontal planes in the total space. As a corollary of the cylindrical estimate (2.6) *we have that Type-I blowups $\tilde G=(T-t)^{-1}G$ of the solution converge near each neck to the shrinking cylinder soliton.*

We say the examples constructed in [1] and [37] develop *non-degenerate neckpinch* singularities and the round cylinder, which is an example of a Ricci shrinking soliton, is their *singularity model*. In [34] Hamilton also described the intuitive picture of a degenerate neckpinch singularity. Imagine the dumbbell is not symmetric and that one side is much bigger than the other. If we choose the sizes of the spheres on both sides appropriately, we expect a *degenerate* singularity, which means pinching off the little sphere and there is nothing left on one side. In [31] it was verified that such a degenerate neck-pinching Type II singularity can be formed on S^n with suitable rotationally symmetric metric for all $n \geq 3$. The precise singularity formation of those Type II singularities was discussed in [2]. One of the conclusions is that the sequence of dilations around this Type II singularity converges to the Bryant soliton.

2.3. Classification results for Ricci solitons. As we have discussed above, gradient shrinking Ricci solitons arise as singularity models of Type I singularities of the Ricci flow and that is why understanding of those is important in studying the singularities of the Ricci flow. Classification of gradient shrinking Ricci solitons has been a subject of interest for many people.

Hamilton [32] showed that the only closed gradient shrinking Ricci solitons in two dimensions are Einstein. In the case of three dimensions, Ivey proved that all compact, gradient shrinking Ricci solitons must have constant positive curvature. The recent work of Böhm and Wilking [4] implies the compact gradient shrinking Ricci solitons with positive curvature operator in any dimension have to be of constant curvature, generalizing Ivey's result. Koiso ([38]), H.-D.Cao [8], Feldman, Ilmanen and Knopf [30] constructed examples of both, compact and complete non-compact gradient shrinking Ricci solitons that are not Einstein. Some properties of compact shrinking Ricci solitons have been proved in [28].

The classification of complete, noncompact gradient shrinking Ricci solitons has been recently studied by many people. The Hamilton-Ivey estimate shows that those three dimensional solitons have nonnegative sectional curvatures. Combining this with the results of Perelman yields that the three dimensional gradient shrinking solitons with bounded sectional curvatures are S^3, $\mathbb{R}^3$, $S^2 \times \mathbb{R}$ and the quotients of those. Recently Ni and Wallach ([43]) studied the classification of complete gradient shrinking Ricci solitons with vanishing Weyl curvature tensor, in any dimension, under the assumptions of nonnegative Ricci curvature and at most exponential growth of the norm of curvature operator. They showed under their assumptions we can only have S^n, $\mathbb{R}^n$, $S^{n-1} \times \mathbb{R}$ and the quotient of those. In [14] the assumption on nonnegative Ricci curvature has been relaxed to having the Ricci curvature bounded from below. In [45] Petersen and Wylie obtained the same classification under a different assumption. Besides the vanishing of the Weyl tensor they assumed a certain integral bound involving the potential function f,

$$\int_M |Ric|^2 e^{-f}\, dV < \infty. \tag{2.7}$$

The question whether certain integral curvature estimates including (2.7) for complete gradient shrinking Ricci solitons are true has been raised in [45] and [14]. The motivation, as pointed out also in [9], is to prove a classification result for complete gradient shrinkers which are locally conformally flat, thus extending a theorem of Perelman. In [50] Zhang proved that gradient shrinking Ricci solitons with vanishing Weyl tensor must have nonnegative curvature operator, which proved the classification of such solitons as finite quotients

of $\mathbb{R}^n$, $\mathbb{S}^{n-1}\times\mathbb{R}$ or $\mathbb{S}^n$.

Besides being interesting on their own, proving that certain curvature integral quantities (including (2.7)) are finite would have as a consequence an alternate, simpler proof for this classification. In [39] we prove the following.

Theorem 2.4. *Let M^n be a complete gradient shrinking Ricci soliton normalized such that*

$$Ric + Hess_f = \frac{1}{2}g$$

Then we have

$$\int_M |Ric|^2 e^{-f} < \infty.$$

Moreover, for any $\lambda > 0$ we have

$$\int_M |Ric|^2 e^{-\lambda f} < \infty.$$

As a consequence of Theorem 2.4 we have the following classification result for complete gradient shrinking Ricci solitons.

Theorem 2.5. *Any $n-$dimensional complete shrinking gradient Ricci soliton with harmonic Weyl tensor (meaning $div\, W = 0$) is a finite quotient of $\mathbb{R}^n$, $\mathbb{S}^{n-1}\times\mathbb{R}$ or $\mathbb{S}^n$.*

In [39] we show that the volume of a gradient steady soliton is infinite. More precisely, we show there are uniform constants $c, r_0 > 0$ so that for any $r > r_0$,

$$Vol(B_p(r)) \geq cr.$$

In [13] it was proved that a complete non-compact gradient shrinking Ricci soliton has at most Euclidean volume growth. In [40] was obtained that the volume of a non-compact shrinking Ricci soliton must be of at least linear growth and this is the best we can expect due to the examples of shrinking cylinders on which the volume of geodesic balls grow exactly linearly. This linear lower bound on volume was obtained as an application of the spectral analysis of weighted laplacian to the study of the geometry and topology of gradient Ricci solitons.

Under a restrictive assumption on scalar curvature we also show that a gradient shrinking Kähler-Ricci soliton is connected at infinity, that is, it has one end. In a recent work [41], Munteanu and Wang show that any shrinking Kähler-Ricci soliton must be connected at infinity.

Recall that a gradient shrinking Ricci soliton (M, g, f) satisfies the equation (after rescaling)

$$R_{ij} + \nabla_i\nabla_j f = \frac{1}{2}g_{ij}.$$

An important ingredient we used in [39] and that has been used in some of above mentioned results is the asymptotic behavior of the potential function f. It has been showed in [13] that the potential function f satisfies the estimate

$$\frac{1}{4}(r(x) - c_1)^2 \leq f(x) \leq \frac{1}{4}(r(x) + c_2)^2,$$

where $r(x) = dist(x_0, x)$ is the distance from some fixed point $x_0 \in M$, c_1 and c_2 are positive constants depending only on n and the geometry of g_{ij} on a unit ball $B_{x_0}(1)$.

2.4. Eternal solutions in two dimensions. In [22] we have considered *eternal* solutions (the ones that live for all $t \in \mathrm{R}$) of the logarithmic fast diffusion equation

$$\frac{\partial u}{\partial t} = \Delta \log u \qquad \text{on } \mathrm{R}^2 \times \mathrm{R}. \tag{2.8}$$

This equation represents the evolution of the conformally flat metric $g_{ij} = u\, I_{ij}$ under the *Ricci Flow*

$$\frac{\partial g_{ij}}{\partial t} = -2\, R_{ij}.$$

The equivalence follows from the observation that the metric $g_{ij} = u\, I_{ij}$ has scalar curvature $R = -(\Delta \log u)/u$ and in two dimensions $R_{ij} = \frac{1}{2}\, R\, g_{ij}$.

In [21] we introduced the width w of the metric $g = u\, I_{ij}$. Let $F : \mathrm{R}^2 \to [0, \infty)$ denote a proper function F, such that $F^{-1}(a)$ is compact for every $a \in [0, \infty)$. The width of F is defined to be the supremum of the lengths of the level curves of F, namely $w(F) = \sup_c L\{F = c\}$. The width w of the metric g is defined to be the infimum

$$w(g) = \inf_F w(F).$$

Theorem 2.6. *Assume that u is a positive smooth eternal solution of equation* (2.8) *which defines a complete metric and satisfies conditions*

$$w(g(t)) < \infty, \qquad \forall t \in \mathrm{R}, \tag{2.9}$$

$$\|R(\cdot, t)\|_{L^\infty(\mathrm{R}^2)} < \infty, \qquad \forall t \in \mathrm{R}. \tag{2.10}$$

Then, u is a gradient soliton of the form

$$U(x,t) = \frac{2}{\beta\,(|x - x_0|^2 + \delta\, e^{2\beta t})} \tag{2.11}$$

for some $x_0 \in \mathrm{R}^2$ and some constants $\beta > 0$ and $\delta > 0$. It is known as the cigar soliton on R^2.

It is shown in [21] that maximal solutions u of the initial value problem $u_t = \Delta \log u$ on $\mathrm{R}^2 \times [0, T)$, $u(x, 0) = f(x)$ which vanish at time $T < \infty$ satisfy the width bound $c\,(T - t) \le w(g(t)) \le C\,(T - t)$ and the maximum curvature bound $c\,(T - t)^{-2} \le R_{\max}(t) \le C\,(T - t)^{-2}$ for some constants $c > 0$ and $C < \infty$, independent of t. Hence, one may rescale u near $t \to T$ and pass to the limit to obtain an eternal solution of equation (2.8) which satisfies the bounds (2.9) and (2.10). Theorem 2.6 provides then a classification of the limiting solutions.

The bounded width assumption (2.9) is necessary for the conclusion of the Theorem. If this condition is not satisfied, then (2.8) admits for example the flat (constant) solutions. This has been discussed in [18]. He shows that all eternal solutions with bounded curvature at each time slice are either the plane or the cigar soliton.

In [25] we consider ancient compact solutions to the Ricci flow in dimension two. We show the following result.

Theorem 2.7. *Let $g(\cdot, t)$ be an ancient compact two dimensional solution to the Ricci flow. Then, it is either one of the contracting spheres or one of the King-Rosenau solutions.*

3. Yamabe solitons

We start with the definition of a *Yamabe soliton*.

Definition 3.1. A Riemannian manifold (M^n, g_{ij}) is called a Yamabe gradient soliton if there exists a smooth scalar (potential) function $f : M^n \to \mathrm{R}$ and a constant $\rho \in \mathbb{R}$ such that

$$(R - \rho)\, g_{ij} = \nabla_i \nabla_j f. \tag{3.1}$$

If $\rho > 0$, $\rho < 0$ or $\rho = 0$, then g is called a Yamabe shrinker, Yamabe expander or Yamabe steady soliton respectively. By scaling the metric, we may assume with no loss of generality that $\rho = 1, -1, 0$ respectively.

When f is a constant function in (3.1) we say that the corresponding Yamabe soliton is a trivial Yamabe soliton. It has been known (see [17], [27], [36]) that every compact Yamabe soliton is of constant scalar curvature, hence trivial, since in this case the potential function f turns out to be constant.

Yamabe solitons are special solutions to the Yamabe flow

$$\frac{\partial}{\partial t} g_{ij} = -R\, g_{ij}. \tag{3.2}$$

This flow was introduced by R. Hamilton [35] as an approach to solve the *Yamabe problem* on manifolds of positive conformal Yamabe invariant. It is the negative L^2-gradient flow of the total scalar curvature, restricted to a given conformal class. Hamilton [35] showed the existence of the normalized Yamabe flow (which is the re-parametrization of (3.2) to keep the volume fixed) for all time; moreover, in the case when the scalar curvature of the initial metric is negative, he showed the exponential convergence of the flow to a metric of constant scalar curvature.

Since then, a number of works have been established on the convergence of the Yamabe flow on a compact manifold to a metric of constant scalar curvature. Chow [16] showed the convergence of the flow under the conditions that the initial metric is locally conformally flat and of positive Ricci curvature. The convergence of the flow for any locally conformally flat initial metric was shown by Ye [49]. Inspired by this result, Del Pino and Saez [26] proved the convergence to the sphere of a conformally flat metric on $\mathbb{R}^n$ evolving by the Yamabe flow and satisfying a decay condition at infinity.

More recently, Schwetlick and Struwe [46] obtained the convergence of the Yamabe flow on a general compact manifold under a suitable Kazdan-Warner type of condition that rules out the formation of bubbles and that is verified (via the positive mass Theorem) in dimensions $3 \leq n \leq 5$. The convergence result for any general compact manifold was established by Brendle [6] and [7] (up to a technical assumption, in dimensions $n \geq 6$, on the rate of vanishing of Weyl tensor at the points at which it vanishes): starting with any smooth metric on a compact manifold, the normalized Yamabe flow converges to a metric of constant scalar curvature.

Even though the analogue of Perelman's monotonicity formula is still lacking for the Yamabe flow, one expects that Yamabe soliton solutions model finite time singularities. One of results in [23] indicates that in certain cases of Type II singularities one may expect the steady Yamabe solitons to be the singularity models.

Although the Yamabe flow on compact manifolds is well understood, the complete non-compact case is unsettled. In [24] the authors showed that in the conformally flat case and

under certain conditions on the initial data, which in particular imply that the initial metric admits the asymptotic behavior of the cylindrical metric at infinity, complete non-compact solutions to the Yamabe flow develop a finite time singularity and after re-scaling the metric converges to the Barenblatt solution (a certain type of a shrinker, corresponding to the Type I singularity). The general case even when the solution is conformally equivalent to R^n is not well understood. In fact in [24] we show there exist infinitely many shrinking solitons which behave as cylinders at infinity and they are all different than the Barenblatt solution (which unlike other Yamabe shrinkers is given in the explicit form).

All such solutions are prototypes of Type I singularities of the complete non-compact Yamabe flow.

3.1. Classification of Yamabe solitons. One of our results in [24] establishes the rotational symmetry of locally conformally flat Yamabe solitons.

Theorem 3.2 (Rotational symmetry of Yamabe solitons). *All locally conformally flat complete Yamabe gradient solitons with positive sectional curvature have to be rotationally symmetric.*

Our proof of Theorem 3.2 is inspired by the proof of the analogous theorem for complete gradient steady Ricci solitons in [10]. Some time after posting our paper [24], a related work by Cao, Sun and Zhang [11] was posted. Inspired by our work, it was shown in [11] that every complete nontrivial gradient Yamabe soliton admits a special global warped product structure with an one-dimensional base. Consequently, locally conformally flat complete gradient Yamabe solitons with nonnegative Ricci curvature are rotationally symmetric. There is also a related work by Catino, Mantegazza and Mazzieri [15].

One of the goals in [24] was to classify rotationally symmetric Yamabe solitons on R^n. In order to state the theorem which deals with that question lets first state the following proposition.

Proposition 3.3 (PDE formulation of Yamabe solitons). *Let $g_{ij} = u^{\frac{4}{n+2}}\, dx^2$ be a conformally flat rotationally symmetric Yamabe gradient soliton. Then, u is a smooth solution to the elliptic equation*

$$\frac{n-1}{m}\,\Delta u^m + \beta\, x\cdot\nabla u + \gamma\, u = 0, \qquad \text{on } \mathrm{R}^n \tag{3.3}$$

where $\beta \geq 0$ and

$$\gamma = \frac{2\beta+\rho}{1-m}, \qquad m = \frac{n-2}{n+2}.$$

In the case of expanders $\beta > 0$. In addition, any smooth solution to the elliptic equation (3.3) *with β and γ as above defines a gradient Yamabe soliton.*

To simplify the notation, we will assume from now on that $\rho = 1$ in (3.1) in the case of the Yamabe shrinkers, and that $\rho = -1$ in the case of the Yamabe expanders. This can be easily achieved by scaling our metric g. The following result provides the classification of radially symmetric and smooth solutions of the elliptic equation (3.3).

Theorem 3.4 (Classification of radially symmetric Yamabe solitons). *Let $m = (n-2)/(n+2)$. The elliptic equation* (3.3) *admits non-trivial radially symmetric smooth solutions if and only if $\beta \geq 0$ and $\gamma := (2\beta+\rho)/(1-m) > 0$. More precisely, we have:*

(1) **Yamabe shrinkers** $\rho = 1$**:** *For any* $\beta > 0$ *and* $\gamma = (2\beta+1)/(1-m)$*, there exists an one parameter family* u_λ*,* $\lambda > 0$*, of smooth radially symmetric solutions to equation* (3.3) *on* R^n *of slow-decay rate at infinity, namely* $u_\lambda(x) = O(|x|^{-2/(1-m)})$ *as* $|x| \to \infty$*. This asymptotic behavior of* u_λ *gives the asymptotic cylindrical behavior of the corresponding metric* $g_\lambda = u_\lambda^{\frac{4}{n+2}}\, dx^2$*. We will refer to those solutions as to cigar solutions. In the case* $\gamma = \beta n$ *the solutions are given in the closed form*

$$u_\lambda(x) = \left(\frac{C_n}{\lambda^2 + |x|^2}\right)^{\frac{1}{1-m}}, \qquad C_n = (n-2)(n-1) \tag{3.4}$$

and will refer to them as to the Barenblatt solutions. When $\beta = 0$ *and* $\gamma = 1/(1-m)$ *equation* (3.3) *admits the explicit solutions of fast-decay rate*

$$u_\lambda(x) = \left(\frac{C_n\,\lambda}{\lambda^2 + |x|^2}\right)^{\frac{2}{1-m}}, \qquad C_n = (4n(n-1))^{\frac{1}{2}}. \tag{3.5}$$

We will refer to them as to the spheres.

(2) **Yamabe expanders** $\rho = -1$**:** *For any* $\beta > 0$ *and* $\gamma = (2\beta-1)/(1-m) > -1/(1-m)$ *there exists an one parameter family* u_λ*,* $\lambda > 0$*, of smooth radially symmetric solutions to equation* (3.3) *on* R^n*.*

(3) **Yamabe steady solitons** $\rho = 0$**:** *For any* $\beta > 0$ *and* $\gamma = 2\beta/(1-m) > 0$ *there exists an one parameter family* u_λ*,* $\lambda > 0$*, of smooth solutions to equation* (3.3) *on* R^n *which satisfy the asymptotic behavior* $u_\lambda(x) = O((\log|x|/|x|^2)^{1/(1-m)})$*, as* $|x| \to \infty$*. We will refer to them as to logarithmic cigars. For* $\beta = \gamma = 0$*, the solution* u_λ *is a constant, defining the euclidean metric on* $\mathbb{R}^n$*.*

In all of the above cases the solution u_λ *is uniquely determined by its value at the origin.*

Most of the Yamabe solitons we find in Theorem 3.4 have nonnegative sectional curvature.

3.2. Yamabe solitons as singularity models. We consider a complete non-compact metric $g = u^{4/(N+2)}\, dx^2$ which is conformally equivalent to the standard euclidean metric of R^N and evolves by the *Yamabe flow*

$$\frac{\partial g}{\partial t} = -R\, g \tag{3.6}$$

where R denotes the scalar curvature with respect to metric g. Our goal is to study the *singularity formation* of metric g at a singular time T, under the assumption that the initial metric g_0 has *cylindrical behavior* at infinity.

By observing that the conformal metric $g = u^{4/(N+2)}\, dx^2$ has scalar curvature

$$R = -\frac{4(N-1)}{N-2}\, u^{-1}\, \Delta u^{\frac{N-2}{N+2}}$$

it follows that the function u evolves by the fast diffusion equation $u_t = \frac{N-1}{m}\, \Delta u^m$, with exponent $m = (N-2)/(N+2)$. Therefore studying the Yamabe flow equation (3.6) in the conformally flat case is equivalent to studying the fast diffusion equation on R^N.

We would like to relate the singularity profile of conformally flat solutions to the Yamabe flow whose conformal factors have *cylindrical behavior at infinity* with a class of self-similar

shrinking Yamabe solitons that have matched asymptotic behavior at infinity. One special result in this direction was previously shown for example in [24] where the L^1 stability around the explicit Barenblatt profile was established (Barenblatt solution is a complete Yamabe shrinker given by an explicit formula as in Proposition 3.4).

We will assume that the initial metric $g_0 = u_0^{4/(N+2)}\, dx_i dx_j$ is complete, non-compact and has *cylindrical behavior* at infinity, namely

$$u_0(x) = \left(\frac{C^* T}{|x|^2}\right)^{1/n} \big(1 + o(1)\big), \qquad \text{as } |x| \to \infty \tag{3.7}$$

with C^* given by

$$C^* := \frac{2\,\big(((1-m)N - 2\big)}{n}, \qquad n = 1 - m, \quad m = \frac{N-2}{N+2} \tag{3.8}$$

and $T > 0$ any positive constant. In [19] we show that if the initial data $u_0(x)$ satisfies (3.7) then for the solution u we have

$$u(x,t) = \left(\frac{C^*(T-t)}{|x|^2}\right)^{1/n} (1 + o(1)), \qquad \text{as } |x| \to \infty. \tag{3.9}$$

We have seen in [19] that the solution u starting at u_0 that satisfies (3.7) *may or may not become extinct at time* T, depending on the *second order asymptotic behavior*, as $|x| \to \infty$, of the cylindrical tail of the initial data. In either case the metric $g(t) = u^{4/(N+2)}(\cdot, t)\, dx^2$ will develop a singularity at time T. Our goal is to study these singularities. We showed that rescaled limits of solutions u with initial condition satisfying (3.7) behave near a singularity at time T as self-similar shrinking solutions (Yamabe shrinkers). These can be viewed as special solutions of the fast-diffusion equation

$$u_t = \Delta u^{\frac{N-2}{N+2}} \tag{3.10}$$

of the form

$$U(x,t) = (T-t)^{\alpha}\, f(y), \quad y = x\,(T-t)^{\beta}, \qquad \alpha = \frac{1+2\beta}{n}, \;\; \beta > 0, \tag{3.11}$$

where the function f satisfies the elliptic equation

$$\Delta f^{\frac{N-2}{N+2}} + \beta\, y \cdot \nabla f + \alpha\, f = 0. \qquad \text{on } \mathrm{R}^N \tag{3.12}$$

In order to study the singularities of a metric $g = u^{4/(N+2)} dx^2$ evolving by (2.8) and with initial data satisfying (3.7) we need to understand the second order asymptotic behavior at infinity of the self-similar profiles f_λ. We will achieve this by linearizing equation (3.12) around the cylindrical solution.

Let $\gamma_{1,2}$ be the solutions to the characteristic equation of the corresponding linearized equation. They satisfy

$$\gamma^2 + \beta(N-2)\gamma + (N-2) = 0, \tag{3.13}$$

which gives

$$\gamma_{1,2} = \frac{\beta(N-2) \mp \sqrt{\beta^2(N-2)^2 - 4(N-2)}}{2}. \tag{3.14}$$

We see that we need to have $\beta \geq 2/\sqrt{N-2}$ in order for $\gamma_{1,2}$ to be real and the corresponding solution to have non-oscillatory behavior.

One of our results in [19] concerns the second order asymptotics of smooth profiles f on R^N which appear to model the singular behavior of some evolving metrics $g = u^{4/(N+2)}dx^2$ that become extinct at a singular time T. We already know the first order asymptotics is given by a cylindrical behavior at infinity.

Theorem 3.5. *Let $m = (N-2)/(N+2)$, $n = 1-m$, $N \geq 3$, $C^* = 2\left((1-m)N-2\right)/n$, $\beta_0 := 2/\sqrt{N-2}$ and $\beta_1 := 1/(2m)$ (this particular parameter corresponds to having the Barenblatt solution given by* (3.4)*. The following hold:*

- *Let $N \geq 6$ and $\beta > \beta_0$ or $3 \leq N < 6$ and $\beta > \beta_1$: For any $B > 0$ there exists a unique radially symmetric smooth solution $f_{\beta,B}$ of* (3.12) *that satisfies*

$$f_{\beta,B}(y) = \left(\frac{C^*}{|y|^2}\right)^{1/n} \left(1 - B\,|y|^{-\gamma} + o_B(|y|^{-\gamma})\right) \tag{3.15}$$

  with $\gamma = \gamma_1$ given by (3.14)*.*
- *Let $3 \leq N < 6$ and $\beta_0 < \beta < \beta_1$: For any $B < 0$ there exists a unique radially symmetric smooth solution $f_{\beta,B}$ of* (3.12) *that satisfies* (3.15) *with $\gamma = \gamma_1$ given by* (3.14)*.*
- *Let $3 \leq N < 6$ and $\beta = \beta_1$: For any $B < 0$ there exists a unique radially symmetric smooth solution $f_{\beta,B}$ of* (3.12) *that satisfies* (3.15) *with $\gamma = \gamma_2 = 2$ and which is given in closed form by* (3.4)*.*

In all of the above cases we will denote by $U_{\beta,B}$ the self-similar solution of equation (3.10)*. It is given in terms of $f_{\beta,B}$ by* (3.11) *where $f_{\beta,B}$ solves* (3.12)*.*

In describing the asymptotic profile of the solution slightly before time T we will consider the rescaling from the left defined by

$$\bar{u}(y,\tau) := (T-t)^{-\alpha} u(y\,(T-t)^{-\beta}, t)|_{t=T(1-e^{-\tau})}, \qquad (y,\tau) \in \mathbb{R}^N \times (0,\infty). \tag{3.16}$$

Here we discuss only the case when the solution with the cylindrical behavior at infinity becomes extinct at the time T which is the vanishing time of its cylindrical tail as well (in [19] other cases have been considered as well). We will assume in this case that either

- $N \geq 3$ and $\beta \geq \beta_1$ (or equivalently $N\beta \geq \alpha$), or
- $N \geq 6$ and $\beta_0 < \beta < \beta_1$.

The condition $\beta \geq \beta_0 := 2/\sqrt{N-2}$ is imposed so that the self similar solution $U_{\beta,B}$ has non-oscillating behavior as $|x| \to +\infty$. The common feature in both considered cases is that the difference of two self-similar solutions

$$|U_{\beta,B_1} - U_{\beta,B_2}| \notin L^1(\mathbb{R}^N), \qquad \text{if } B_1 \neq B_2.$$

The next theorem generalizes the result proved in [22] in the special case when $\beta = \beta_1$ (see also in [3] for an improvement of the result in [22] shown independently). Our first result is concerned with the case $\beta \geq \beta_1$ in all dimensions $N \geq 3$.

Theorem 3.6. *Let $\beta \geq \beta_1$ and let $u : \mathbb{R}^N \times [0,T) \to \mathbb{R}$ be a solution to* (2.8) *with the initial data u_0 satisfying $0 \leq u_0 \leq U_{\beta,B_1}(\cdot,0)$, for some $B_1 > 0$. Assume in addition that*

$$u_0 - U_{\beta,B} \in L^1(\mathbb{R}^N) \tag{3.17}$$

for some $B > 0$. Then, the rescaled solution $\bar{u}$ given by (3.16) *converges as $\tau \to \infty$ uniformly on compact subsets of R^N to the self-similar solution $U_{\beta,B}$. Moreover, we also have convergence in the $L^1(\mathbb{R}^N)$ norm. If $\beta > \beta_1$ the convergence is exponential.*

In [19] we also consider the case when $\beta < \beta_1$.

Extremal Kähler metrics

Gábor Székelyhidi

Abstract. This paper is a survey of some recent progress on the study of Calabi's extremal Kähler metrics. We first discuss the Yau-Tian-Donaldson conjecture relating the existence of extremal metrics to an algebro-geometric stability notion and we give some example settings where this conjecture has been established. We then turn to the question of what one expects when no extremal metric exists.

Mathematics Subject Classification (2010). Primary 58E11; Secondary 32Q20.

Keywords. Extremal metrics, Kähler-Einstein metrics, K-stability.

1. Introduction

A basic problem in differential geometry is to find "best" or "canonical" metrics on smooth manifolds. The most famous example is the classical uniformization theorem, which says that every closed 2-dimensional manifold admits a metric with constant curvature, and moreover this metric is essentially unique in its conformal class. Calabi's introduction of extremal Kähler metrics [10] is an attempt at finding a higher dimensional generalization of this result, in the setting of Kähler geometry.

There are of course other ways in which one could attempt to generalize the uniformization theorem to higher dimensional manifolds. One possibility is the Yamabe problem in the context of conformal geometry. This says [31] that on a closed manifold of arbitrary dimension, every conformal class admits a metric of constant scalar curvature. Moreover this metric is often, but not always, unique up to scaling. A different generalization to 3-dimensional manifolds is given by Thurston's geometrization conjecture, established by Perelman [41]. In this case the goal is to find metrics of constant curvature on a 3-manifold, but this is too ambitious. Instead it turns out that every 3-manifold can be decomposed into pieces each of which admits one of 8 model geometries.

The search for extremal Kähler metrics can be thought of as a complex analogue of the Yamabe problem, where we try to find canonical representatives of a given Kähler class, rather than a conformal class. In both cases the effect of restricting the space of metrics that we allow results in the problems reducing to scalar equations involving the conformal factor, and the Kähler potential, respectively. We will see, however, that in contrast with the Yamabe problem extremal metrics do not always exist, and in these cases one can hope to find a canonical "decomposition" of the manifold into pieces somewhat reminiscent of the geometrization of 3-manifolds.

In order to define extremal metrics, let M be a compact complex manifold of dimension n, equipped with a Kähler class $\Omega \in H^2(M, \mathbf{R})$. Denote by $\mathcal{K}_\Omega$ the set of Kähler metrics in

Proceedings of the International Congress of Mathematicians, Seoul, 2014

the class Ω.

Definition 1.1. An extremal metric is a critical point of the Calabi functional

$$\begin{aligned} \mathrm{Cal} : \mathcal{K}_\Omega &\to \mathbf{R} \\ \omega &\mapsto \int_M (S(\omega) - \underline{S})^2 \, \omega^n, \end{aligned} \tag{1.1}$$

where $S(\omega)$ is the scalar curvature of ω, and $\underline{S}$ is the average of $S(\omega)$ with respect to the volume form ω^n. Note that $\underline{S}$ is independent of the choice of $\omega \in \mathcal{K}_\Omega$.

Calabi [10] has shown that ω is an extremal metric if and only if the gradient $\nabla S(\omega)$ is a holomorphic vector field. Since most complex manifolds do not admit any non-trivial holomorphic vector fields, most extremal metrics are constant scalar curvature Kähler (cscK) metrics. A particularly important special case is when the first Chern class $c_1(M)$ is proportional to the Kähler class Ω. If $c_1(M) = \lambda\Omega$, and $\omega \in \mathcal{K}_\Omega$ is a cscK metric, then it follows that

$$\mathrm{Ric}(\omega) = \lambda\omega, \tag{1.2}$$

and so ω is a Kähler-Einstein metric.

It is known that any two extremal metrics in a fixed Kähler class are isometric (see Chen-Tian [16]), which makes extremal metrics good candidates for being canonical metrics on Kähler manifolds. On the other hand, not every Kähler class admits an extremal metric, the first examples going back to Levine [32] of manifolds which do not admit extremal metrics in any Kähler class. The basic problems are therefore to understand which Kähler classes admit extremal metrics, and what we can say when no extremal metric exists.

The most interesting case of the existence question is when $\Omega = c_1(L)$ is the first Chern class of a line bundle, and consequently M is a projective manifold. In this case the Yau-Tian-Donaldson conjecture predicts that the existence of an extremal metric is related to the stability of the pair (M, L) in the sense of geometric invariant theory. In Section 2 we will discuss two such notions of stability: K-stability, and a slight refinement of it which we call $\widehat{K}$-stability.

As a consequence of work of Tian [54], Donaldson [18, 20], Mabuchi [34], Stoppa [44], Stoppa-Székelyhidi [45], Paul [39], Berman [7], and others, there are now many satisfactory results that show that the existence of an extremal metric implies various notions of stability. The converse direction, however, is largely open. In Section 3 we will discuss two results in this direction. One is the recent breakthrough of Chen-Donaldson-Sun [12] on Kähler-Einstein metrics with positive curvature, and the other is work of the author on extremal metrics on blowups.

Finally in Section 4 we turn to what is to be expected when no extremal metric exists, i.e. when a pair (M, L) is unstable. It is still a natural problem to try minimizing the Calabi functional in a Kähler class, and we will discuss a conjecture due to Donaldson relating this to finding the optimal way to destabilize (M, L). We will give an example where this can be interpreted as the canonical decomposition of the manifold alluded to above.

2. The Yau-Tian-Donaldson conjecture

It is a conjecture going back to Yau (see e.g. [60]) that if M is a Fano manifold, i.e. the anticanonical line bundle K_M^{-1} is ample, then M admits a Kähler-Einstein metric if and

only if M is stable in the sense of geometric invariant theory. Tian [54] introduced the notion of K-stability as a precise candidate of such a stability condition and showed that it is necessary for the existence of a Kähler-Einstein metric. Donaldson [17, 19] generalized the conjecture to pairs (M, L) where $L \to M$ is an ample line bundle, not necessarily equal to the anticanonical bundle. More precisely, Donaldson formulated a more algebraic version of K-stability, and conjectured that K-stability of the pair (M, L) is equivalent to the existence of a cscK metric in the class $c_1(L)$. We start by giving a definition of Donaldson's version of K-stability.

Definition 2.1. A *test-configuration* for (M, L) of exponent r is a $\mathbf{C}^*$-equivariant, flat, polarized family $(\mathcal{M}, \mathcal{L})$ over $\mathbf{C}$, with generic fiber isomorphic to (M, L^r).

The central fiber (M_0, L_0) of a test-configuration has an induced $\mathbf{C}^*$-action, and we write A_k for the infinitesimal generator of this action on $H^0(M_0, L_0^k)$. In other words, the eigenvalues of A_k are the weights of the action. There are expansions

$$\begin{aligned} \dim H^0(M_0, L_0^k) &= a_0 k^n + a_1 k^{n-1} + O(k^{n-2}) \\ \mathrm{Tr}(A_k) &= b_0 k^{n+1} + b_1 k^n + O(k^{n-1}) \\ \mathrm{Tr}(A_k^2) &= c_0 k^{n+2} + O(k^{n+1}). \end{aligned} \tag{2.1}$$

Definition 2.2. Given a test-configuration χ of exponent r for (M, L) as above, its Futaki invariant is defined to be

$$\mathrm{Fut}(\chi) = \frac{a_1 b_0 - a_0 b_1}{a_0^2}. \tag{2.2}$$

The norm of χ is defined by

$$\|\chi\|^2 = r^{-n-2} \left(c_0 - \frac{b_0^2}{a_0} \right), \tag{2.3}$$

where the factor involving r is used to make the norm unchanged if we replace L by a power.

With these preliminaries, we can give a definition of K-stability.

Definition 2.3. The pair (M, L) is K-stable if $\mathrm{Fut}(\chi) > 0$ for all test-configurations χ with $\|\chi\| > 0$.

The condition $\|\chi\| > 0$ is required to rule out certain "trivial" test-configurations. An alternative definition by Li-Xu [33] requires $\mathcal{M}$ to be a normal variety distinct from the product $M \times \mathbf{C}$, but the condition using the norm $\|\chi\|$ will be more natural below, when discussing filtrations.

The central conjecture in the field is the following.

Conjecture 2.4 (Yau-Tian-Donaldson). *Suppose that M has no non-zero holomorphic vector fields. Then M admits a cscK metric in $c_1(L)$ if and only of (M, L) is K-stable.*

When M admits holomorphic vector fields which can be lifted to L, then it is never K-stable according to the previous definition, since in that case one can find test-configurations with total space $\mathcal{M} = M \times \mathbf{C}$, with a non-trivial $\mathbf{C}^*$-action whose Futaki invariant is non-positive. In this case a variant of K-stability, called K-polystability, is used, which rules out such "product test-configurations" and is conjecturally equivalent to the existence of a

cscK metric, even when M admits holomorphic vector fields. A further variant of K-stability, called relative K-stability, was defined by the author [49], and it is conjecturally related to the existence of extremal metrics. In relative K-stability one only considers test-configurations which are orthogonal to a maximal torus of automorphisms of M in a suitable sense.

Example 2.5. Let $(M, L) = (\mathbf{P}^1, \mathcal{O}(1))$. The family of conics $xz = ty^2$ for $t \in \mathbf{C}$ gives a test-configuration χ for (M, L) of exponent 2, degenerating a smooth conic into the union of two lines (see Figure 2.1). A small computation gives $\mathrm{Fut}(\chi) = 1/8$. It is not surprising that this is positive, since the Fubini-Study metric on $\mathbf{P}^1$ has constant scalar curvature.

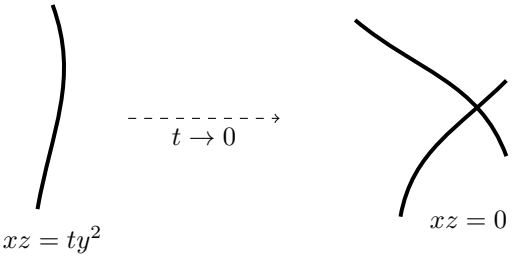

Figure 2.1. A test-configuration degenerating a conic into two lines.

Calculations in Apostolov-Calderbank-Gauduchon-Tønnesen-Friedman [1] suggest that K-stability might not be sufficient to ensure the existence of a cscK metric in general. Indeed they construct examples where the existence of an extremal metric is equivalent to the positivity of a certain function F on an interval (a, b), while relative K-stability only ensures that F is positive at rational points $(a, b) \cap \mathbf{Q}$. It is thus natural to try to work with a completion of the space of test-configurations in a suitable sense in order to detect when this function F vanishes at an irrational point. This motivates the the author's work [47] on filtrations.

Definition 2.6. Let $R = \bigoplus_{k \geqslant 0} H^0(M, L^k)$ denote the homogeneous coordinate ring of (M, L). A filtration of R is a family of subspaces

$$\mathbf{C} = F_0 R \subset F_1 R \subset \ldots \subset R, \tag{2.4}$$

satisfying

1. $(F_i R)(F_j R) \subset F_{i+j} R$,
2. If $s \in F_i R$, and s has degree k piece $s_k \in H^0(M, L^k)$, then $s_k \in F_i R$.
3. $R = \bigcup_{i \geqslant 0} F_i R$.

Witt Nyström [58] showed that every test-configuration for (M, L) gives rise to a filtration. In fact the Rees algebra of the filtration is the coordinate ring of the total space of the test-configuration. On the other hand given any filtration χ of the homogeneous coordinate ring of (M, L), we obtain a flag of subspaces

$$\{0\} = F_0 R_r \subset F_1 R_r \subset \ldots \subset R_r \tag{2.5}$$

of the degree r piece $R_r = H^0(M, L^r)$ for all $r > 0$. In turn, such a flag gives rise to a test-configuration of exponent r for (M, L) – by embedding M into projective space using

a basis of $H^0(M, L^r)$, and acting by a $\mathbf{C}^*$-action whose weight filtration is given by our flag. Therefore any filtration χ induces a sequence of test-configurations $\chi^{(r)}$, where $\chi^{(r)}$ has exponent r. It is natural to think of χ as the limit of the $\chi^{(r)}$, and thus to define

$$\begin{aligned} \mathrm{Fut}(\chi) &= \liminf_{r\to\infty} \mathrm{Fut}(\chi^{(r)}) \\ \|\chi\| &= \lim_{r\to\infty} \|\chi^{(r)}\|, \end{aligned} \tag{2.6}$$

where the limit can be shown to exist. The main difference between filtrations arising from test-configurations, and general filtrations, is that the Rees algebras of the latter need not be finitely generated.

In terms of filtrations we define the following stability notion, which is stronger than K-stability.

Definition 2.7. The pair (M, L) is $\widehat{K}$-stable, if $\mathrm{Fut}(\chi) > 0$ for all filtrations of the homogeneous coordinate ring of (M, L) satisfying $\|\chi\| > 0$.

In view of the examples of Apostolov-et. al. that we mentioned above, it may be that in the Yau-Tian-Donaldson conjecture one should assume $\widehat{K}$-stability instead of K-stability. One direction of this modified conjecture has been established by Boucksom and the author [47].

Theorem 2.8. *Suppose that M has no non-zero holomorphic vector fields. If M admits a cscK metric in $c_1(L)$, then (M, L) is $\widehat{K}$-stable.*

The analogous result for K-stability was shown in Stoppa [44], building on work of Donaldson [20] which we will see in Theorem 4.1, and Arezzo-Pacard [2] which we will discuss in Section 3. In the proof of Theorem 2.8 the main additional ingredient is the use of the Okounkov body [8, 29, 37, 58]. Note that when $L = K_M^{-1}$, then related results were shown by Tian [54] and Paul-Tian [40]. It is likely that a result analogous to Theorem 2.8 can be shown for extremal metrics along the lines of [45].

3. Some existence results

In this section we discuss two special cases, where the Yau-Tian-Donaldson conjecture has been verified.

Kähler-Einstein metrics. We first focus on Kähler-Einstein metrics, i.e. when $c_1(M)$ is proportional to $c_1(L)$. When $c_1(M) = 0$, or $c_1(M) < 0$, then the celebrated work of Yau [59] implies that M admits a Kähler-Einstein metric, and a stability condition does not need to be assumed (see also Aubin [6] for the case when $c_1(M) < 0$).

In the remaining case, when $c_1(M) > 0$, i.e. M is Fano, it was known from early on (see e.g. Matsushima [35]) that a Kähler-Einstein metric does not always exist, and Yau conjectured that the existence is related to stability of M in the sense of geometric invariant theory. Tian [53] found all two-dimensional M which admit a Kähler-Einstein metric, and in [54] he formulated the notion of K-stability, which he conjectured to be equivalent to the existence of a Kähler-Einstein metric. The main difference between Tian's notion of K-stability and the one in Definition 2.3 is that Tian's version of K-stability only requires

$\mathrm{Fut}(\chi) > 0$ for very special types of test-configurations with only mild singularities. In particular their Futaki invariants can be computed differential geometrically using the formula Futaki [24] originally used to define his invariant. By the work of Li-Xu [33] it turns out that in the Fano case Tian's notion of K-stability is equivalent to the a priori stronger condition of Definition 2.3.

Recently, Chen-Donaldson-Sun [12–15] have proved Conjecture 2.4 for Fano manifolds:

Theorem 3.1. *Suppose that M is a Fano manifolds and (M, K_M^{-1}) is K-polystable. Then M admits a Kähler-Einstein metric.*

To construct a Kähler-Einstein metric, the continuity method is used, with a family of equations of the form

$$\mathrm{Ric}(\omega_t) = t\omega_t + \frac{1-t}{m}[D], \tag{3.1}$$

where D is a smooth divisor in the linear system $|mK_M^{-1}|$, and $[D]$ denotes the current of integration. More precisely, a metric ω_t is a solution of (3.1) if $\mathrm{Ric}(\omega_t) = t\omega_t$ on $M \setminus D$, while ω_t has conical singularities along D with cone angle $\frac{2\pi}{m}(1-t)$. One then shows that Equation 3.1 can be solved for $t \in [t_0, T)$ for some $t_0, T > 0$ (see Donaldson [22] for the openness statement), and the question is what happens when $t \to T$.

One of the main results of the work of Chen-Donaldson-Sun is, roughly speaking, that along a subsequence the manifolds (M, ω_{t_i}) have a Gromov-Hausdorff limit W which is a $\mathbf{Q}$-Fano variety, such that the divisor $D \subset M$ converges to a Weil divisor Δ, and W admits a weak Kähler-Einstein metric with conical singularities along Δ (defined in an appropriate sense). Moreover, there are embeddings $\phi_i : M \to \mathbf{P}^N$ and $\phi : W \to \mathbf{P}^N$ into a sufficiently large projective space, such that the pairs $(\phi_i(M), \phi_i(D))$ converge to $(\phi(W), \phi(\Delta))$ in an algebro-geometric sense. In this case either $(\phi(W), \phi(\Delta))$ is in the $SL(N+1, \mathbf{C})$-orbit of the $(\phi_i(M), \phi_i(D))$ in which case we can solve Equation (3.1) for $t = T$, or otherwise we can find a test-configuration for (M, D) with central fiber (W, Δ) to show that (M, K_M^{-1}) is not K-stable. Note that here one needs to extend the theory described in Section 2 to pairs (M, D) resulting in the notion of log K-stability [22].

The fact that a sequence of solutions to Equation (3.1) has a Gromov-Hausdorff limit which is a $\mathbf{Q}$-Fano variety originates in work of Tian [53] on the 2-dimensional case, and it is essentially equivalent to what Tian calls the "partial C^0-estimate" being satisfied by such a sequence of solutions. This partial C^0-estimate was first shown in dimensions greater than 2 by Donaldson-Sun [23] for sequences of Kähler-Einstein metrics, and their method has since been generalized to many other settings: Chen-Donaldson-Sun [14, 15] to solutions of (3.1); Phong-Song-Sturm [42] for sequences of Kähler-Ricci solitons; Tian-Zhang [55] along the Kähler-Ricci flow in dimensions at most 3; the author [48] along Aubin's continuity method; Jiang [28] using only a lower bound for the Ricci curvature, in dimensions at most 3. Note that Tian's original conjecture on the partial C^0-estimate is still open in dimensions greater than 3 – namely we do not yet understand Gromov-Hausdorff limits of Fano manifolds under the assumption of only a positive lower bound on the Ricci curvature.

To close this subsection we mention a possible further result along the lines of Chen-Donaldson-Sun's work. As we described above, if M does not admit a Kähler-Einstein metric, then a sequence of solutions to Equation (3.1) will converge to a weak conical Kähler-Einstein metric on a pair (W, Δ) as $t \to T$. Suppose $T < 1$. We can think of this metric as a suitable weak solution to the equation

$$\mathrm{Ric}(\omega_t) = t\omega_t + \frac{(1-t)}{m}[\Delta] \tag{3.2}$$

for $t = T$ on the space W. Since the pair (W, Δ) necessarily has a non-trivial automorphism group, we cannot expect to solve this equation for $t > T$, however it is reasonable to expect that we can still find weak conical Kähler-Ricci solitons, i.e. we can solve

$$\mathrm{Ric}(\omega_t) + L_{X_t}\omega_t = t\omega_t + \frac{(1-t)}{m}[\Delta], \tag{3.3}$$

for some range of values $t > T$, with suitable vector fields X_t fixing Δ. An extension of Chen-Donaldson-Sun's work to Kähler-Ricci solitons, generalizing Phong-Song-Sturm [42], could then be used to extract a limit (W_1, Δ_1) as $t \to T_1$, with yet another (weak) conical Kähler-Ricci soliton, and so on. Based on this heuristic argument we make the following conjecture.

Conjecture 3.2. *We can solve Equation* (3.3) *up to* $t = 1$ *by passing through finitely many singular times, changing the pair* (W, Δ) *each time. At* $t = 1$ *we obtain a* $\mathbf{Q}$*-Fano variety* W_k *admitting a weak Kähler-Ricci soliton. Moreover, there is a test-configuration for* (M, K_M^{-1}) *with central fiber* W_k.

A further natural expectation would be that the Kähler-Ricci soliton obtained in this way is related to the limiting behavior of the Kähler-Ricci flow on M. Indeed, according to the Hamilton-Tian conjecture (see Tian [54]), the Kähler-Ricci flow is expected to converge to a Kähler-Ricci soliton with mild singularities.

Blow-ups. Beyond the Kähler-Einstein case there are very few general existence results for cscK or extremal metrics. One example is the case of toric surfaces, where Conjecture 2.4 has been established by Donaldson [21], with an extension to extremal metrics by Chen-Li-Sheng [11]. In this section we will discuss a perturbative existence result for cscK metrics on blow-ups.

Suppose that ω is a cscK metric on a compact Kähler manifold M, and choose a point $p \in M$. For all sufficiently small $\epsilon > 0$ the class

$$\Omega_\epsilon = \pi^*[\omega] - \epsilon^2[E] \tag{3.4}$$

is a Kähler class on the blowup $\mathrm{Bl}_p M$, where $\pi : \mathrm{Bl}_p M \to M$ is the blowdown map, and $[E]$ denotes the Poincaré dual of the exceptional divisor. A basic question, going back to work of LeBrun-Singer [30], is whether $\mathrm{Bl}_p M$ admits a cscK (or extremal) metric in the class Ω_ϵ for sufficiently small ϵ. This problem was studied extensively by Arezzo-Pacard [2, 3], and Arezzo-Pacard-Singer [4]. See also Pacard [38] for a survey. The following is the most basic result in this direction.

Theorem 3.3 (Arezzo-Pacard [2]). *Suppose that* M *admits a cscK metric* ω*, and it admits no non-zero holomorphic vector fields. Then there is an* $\epsilon_0 > 0$ *such that* $\mathrm{Bl}_p M$ *admits a cscK metric in the class* Ω_ϵ *for all* $\epsilon \in (0, \epsilon_0)$.

This result not only provides many new examples of cscK metrics, but it is also a key ingredient in the proofs of results such as Theorem 2.8. The construction of cscK metrics on blowups is a typical example of a gluing theorem in geometric analysis. First, one obtains a metric $\omega_\epsilon \in \Omega_\epsilon$ on the blowup, by gluing the metric ω to a scaled down version $\epsilon^2\eta$ of the scalar flat Burns-Simanca [43] metric η on $\mathrm{Bl}_0\mathbf{C}^n$. This is shown in Figure 3.1. In a suitable weighted Hölder space the metric ω_ϵ is sufficiently close to having constant scalar

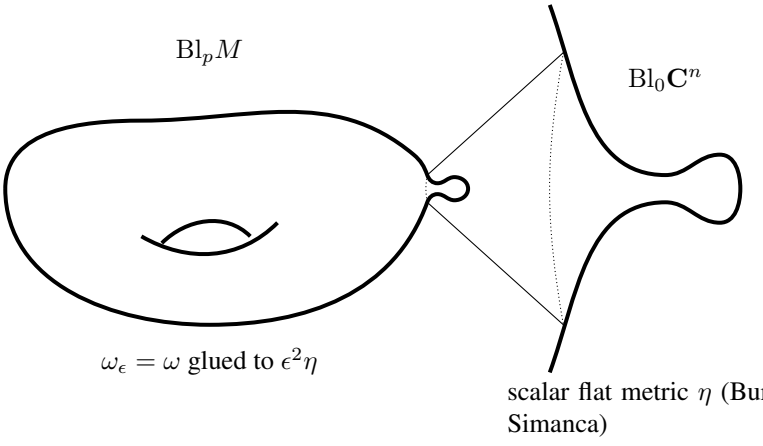

Figure 3.1. The construction of the approximate metric ω_ϵ.

curvature, that one can perturb it to a cscK metric using a contraction mapping argument, for sufficiently small ϵ.

When M admits non-zero holomorphic vector fields, then the problem becomes more subtle, since then $\mathrm{Bl}_p M$ may not admit a cscK (or even extremal) metric for every point p. The problem was addressed by Arezzo-Pacard [3] and Arezzo-Pacard-Singer [4] in the case of extremal metrics, as well as the author [46, 51]. For the case of cscK metrics the sharpest result from [46] is as follows, showing that the Yau-Tian-Donaldson conjecture holds for the pair $(\mathrm{Bl}_p M, \Omega_\epsilon)$ for sufficiently small ϵ.

Theorem 3.4. *Suppose that $\dim M > 2$, M admits a cscK metric ω, and $p \in M$. Then for sufficiently small $\epsilon > 0$, the blowup $\mathrm{Bl}_p M$ admits a cscK metric in the class Ω_ϵ if and only if $(\mathrm{Bl}_p M, \Omega_\epsilon)$ is K-polystable.*

For K-polystability to be defined algebraically, the class Ω_ϵ should be rational, but in fact a very weak version of K-polystability, which can be defined for Kähler manifolds, is sufficient in this theorem. Indeed what we can prove is that if $\mathrm{Bl}_p M$ does not admit a cscK metric in the class Ω_ϵ for sufficiently small ϵ, then there is a $\mathbf{C}^*$-action λ on M such that if we let

$$q = \lim_{t \to 0} \lambda(t) \cdot p, \tag{3.5}$$

then the $\mathbf{C}^*$-action on $\mathrm{Bl}_q M$ induced by λ has non-positive Futaki invariant. In other words when ϵ is sufficiently small, then it is enough to consider test-configurations for $\mathrm{Bl}_p M$ which arise from one-parameter subgroups in the automorphism group of M. While there are also existence results for cscK metrics when $\dim M = 2$, and also for general extremal metrics, in these cases the precise relation with (relative) K-stability has not been established yet.

In the remainder of this section we will give a rough idea of the proof of these existence results. The basic ingredient is the existence of a scalar flat, asymptotically flat metric η on $\mathrm{Bl}_0 \mathbf{C}^n$ due to Burns-Simanca [43], of the form

$$\eta = \sqrt{-1} \partial \overline{\partial} \Big[|w|^2 + \psi(w) \Big] \tag{3.6}$$

on $\mathbf{C}^n \setminus \{0\}$, where

$$\psi(w) = -|w|^{4-2n} + O(|w|^{2-2n}), \quad \text{as } |w| \to \infty \tag{3.7}$$

for $n > 2$. Under the change of variables $w = \epsilon^{-1} z$, we have

$$\epsilon^2 \eta = \sqrt{-1}\partial\overline{\partial}\Big[|z|^2 + \epsilon^2 \psi(\epsilon^{-1} z)\Big]. \tag{3.8}$$

At the same time there are local coordinates near $p \in M$ for which the metric ω is of the form

$$\omega = \sqrt{-1}\partial\overline{\partial}\Big[|z|^2 + \phi(z)\Big], \tag{3.9}$$

where $\phi(z) = O(|z|^4)$. One can then use cutoff functions to glue the metrics ω and $\epsilon^2\eta$ on the level of Kähler potentials on the annular region $r_\epsilon < |z| < 2r_\epsilon$ for some small radius r_ϵ. The result is a metric $\omega_\epsilon \in \Omega_\epsilon$ on $\mathrm{Bl}_p M$, which in a suitable weighted Hölder space is very close to having constant scalar curvature if ϵ is small. It is important here that η is scalar flat, since if it were not, then $\epsilon^2\eta$ would have very large scalar curvature once ϵ is small.

When M has no holomorphic vector fields, then one can show that for sufficiently small ϵ this metric ω_ϵ can be perturbed to a cscK metric in its Kähler class, and this proves Theorem 3.3. Analytically the main ingredient in this proof is to show that the linearization of the scalar curvature operator is invertible, and to control the norm of its inverse in suitable Banach spaces as $\epsilon \to 0$.

The difficulty when M has holomorphic vector fields, or more precisely when when the Hamiltonian isometry group G of (M, ω) is non-trivial, is that the linearized operator will no longer be surjective, since its cokernel can be identified with the Lie algebra $\mathfrak{g}$ of G. One way to overcome this issue is to try to solve a more general equation of the form

$$F(u, \xi) = 0, \tag{3.10}$$

where $\omega_\epsilon + \sqrt{-1}\partial\overline{\partial} u$ is a Kähler metric and $\xi \in \mathfrak{g}$. The operator F is constructed so that if $F(u, \xi) = 0$ and $\xi \in \mathfrak{g}_p$ is in the stabilizer of p, then $\omega_\epsilon + \sqrt{-1}\partial\overline{\partial} u$ is an extremal metric, which has constant scalar curvature if $\xi = 0$. At the same time the linearization of F is surjective. One can then show that for sufficiently small ϵ, for every point $p \in M$ we can find a solution $(u_{\epsilon,p}, \xi_{\epsilon,p})$ of the corresponding equation. The search for cscK metrics is then reduced to the finite dimensional problem of finding zeros of the map

$$\begin{aligned} \mu_\epsilon : M &\to \mathfrak{g} \\ p &\mapsto \xi_{\epsilon,p}, \end{aligned} \tag{3.11}$$

since if $\mu_\epsilon(p) = 0$, then we have found a cscK metric on $\mathrm{Bl}_p M$ in the class Ω_ϵ. More generally to find extremal metrics we need to find p such that $\mu_\epsilon(p) \in \mathfrak{g}_p$.

At this point it becomes important to understand better what the map μ_ϵ is, and for this one needs to construct better approximate solutions than our crude attempt ω_ϵ above. In turn this requires more precise expansions of the metrics $\epsilon^2\eta$ and ω than what we had in Equations (3.8) and (3.9). For the Burns-Simanca metric, according to Gauduchon [25] we have

$$\epsilon^2 \eta = \sqrt{-1}\partial\overline{\partial}\Big[|z|^2 - d_0 \epsilon^{2m-2}|z|^{4-2m} + d_1 \epsilon^{2m}|z|^{2-2m} + O(\epsilon^{4m-4}|z|^{6-4m})\Big], \tag{3.12}$$

where $d_0, d_1 > 0$, while for the metric ω we have

$$\omega = \sqrt{-1}\partial\overline{\partial}\Big[|z|^2 + A_4(z) + A_5(z) + O(|z|^6)\Big], \tag{3.13}$$

where A_4 and A_5 are quartic and quintic expressions. Essentially A_4 is the curvature of ω at p, while A_5 is its covariant derivative at p. The way to obtain better approximate solutions than ω_ϵ is to preserve more terms in these expansions rather than multiplying them all with cutoff functions. In practice this involves modifying the metric ω on the punctured manifold $M \setminus \{p\}$ and $\epsilon^2\eta$ on $\mathrm{Bl}_0\mathbf{C}^n$ to incorporate new terms in their Kähler potentials that are asymptotic to $-d_0\epsilon^{2m-2}|z|^{4-2m} + d_1\epsilon^{2m}|z|^{2-2m}$ and $A_4(z) + A_5(z)$ respectively.

The upshot is that we can obtain an expansion for μ_ϵ which is roughly of the form

$$\mu_\epsilon(p) = \mu(p) + \epsilon^2\Delta\mu(p) + O(\epsilon^\kappa) \tag{3.14}$$

for some $\kappa > 2$, where $\mu : M \to \mathfrak{g}$ is the moment map for the action of G on M, and $\Delta\mu$ is its Laplacian. At this point one can exploit the special structure of moment maps to show that if $\mu(p) + \epsilon^2\Delta\mu(p)$ is in the stabilizer $\mathfrak{g}_p$, and ϵ is sufficiently small, then there is a point $q \in G^c \cdot p$ in the orbit of p under the complexified group such that $\mu_\epsilon(q) \in \mathfrak{g}_q$. Since Bl_pM is biholomorphic to Bl_qM in this case, we end up with an extremal metric on Bl_pM. Under the K-polystability assumption this extremal metric is easily seen to have constant scalar curvature.

Finally, if $\mu(q) + \epsilon^2\Delta\mu(q) \notin \mathfrak{g}_q$ for any $q \in G^c \cdot p$ and sufficiently small ϵ, then the Kempf-Ness principle [36] relating moment maps to GIT stability can be exploited to find a $\mathbf{C}^*$-action on M which induces a destabilizing test-configuration for Bl_pM.

There are several interesting problems which we hope to address in future work.

1. One should extend Theorem 3.4 to the case when $\dim M = 2$ and to general extremal metric. In principle both of these extensions should follow from a more refined expansion of the function μ_ϵ than what we have in Equation (3.14), but it may be more practical to find a different, more direct approach.
2. Can one obtain similar existence results for blow-ups along higher dimensional submanifolds?
3. If M is an arbitrary compact Kähler manifold, is it possible to construct a cscK metric on the blowup of M in a sufficiently large number of points? This would be analogous to Taubes's result [52] on the existence of anti-self-dual metrics on the blowup of a 4-manifold in sufficiently many points. See Tipler [56] for a related result for toric surfaces, where iterated blowups are also allowed.

4. What if no extremal metric exists?

Even if M does not admit an extremal metric in a class $c_1(L)$, it is natural to try minimizing the Calabi functional. That this is closely related to the algebraic geometry of (M, L) is suggested by the following result, analogous to a theorem due to Atiyah-Bott [5] in the case of vector bundles.

Theorem 4.1 (Donaldson [20]). *Given a polarized manifold (M, L), we have*

$$\inf_{\omega \in c_1(L)} \|S(\omega) - \underline{S}\|_{L^2} \geqslant \sup_{\chi} -c_n \frac{\mathrm{Fut}(\chi)}{\|\chi\|}, \tag{4.1}$$

where the supremum runs over all test-configurations for (M, L) with $\|\chi\| > 0$, and c_n is an explicit dimensional constant.

Donaldson also conjectured that in fact equality holds in (4.1). When M admits an extremal metric $\omega_e \in c_1(L)$, then it is easy to check that

$$\|S(\omega_e) - \underline{S}\|_{L^2} = -c_n \frac{\mathrm{Fut}(\chi_e)}{\|\chi_e\|}, \tag{4.2}$$

where χ_e is the product configuration built from the $\mathbf{C}^*$-action induced by $\nabla S(\omega_e)$. In other words equality holds in (4.1) in this case. When (M, L) admits no extremal metric, there is little known, except for the case of a ruled surface [50] where we were able to perform explicit constructions of metrics and test-configurations to realize equality in (4.1). Note that in the case of vector bundles the analogous conjecture is known to hold (i.e. equality in (4.1)) by Atiyah-Bott [5] over Riemann surfaces, and Jacob [27] in higher dimensions.

To describe our result, let Σ be a genus 2 curve, and $M = \mathbf{P}(\mathcal{O} \oplus \mathcal{O}(1))$, where $\mathcal{O}(1)$ denotes any degree one line bundle over Σ. For any real number $m > 0$, we have a Kähler class Ω_m on M, defined by

$$\Omega_m = [F] + m[S_0], \tag{4.3}$$

where $[F], [S_0]$ denote Poincaré duals to the homology classes of a fiber F and the zero section S_0. Up to scaling we obtain all Kähler classes on M in this way. Depending on the value of m, in [50] we observed 3 qualitatively different behaviors of a minimizing sequence for the Calabi functional in Ω_m. There are explicitly computable numbers $0 < k_1 < k_2$ and minimizing sequences ω_i for the Calabi functional in Ω_m with the following properties:

1. When $m < k_1$, then the ω_i converge to the extremal metric in Ω_m whose existence was shown by Tønnesen-Friedman [57].
2. When $k_1 \leqslant m \leqslant k_2$ then suitable pointed limits of the ω_i are complete extremal metrics on $M \setminus S_0$ and $M \setminus S_\infty$. Here S_∞ is the infinity section, and the volumes of the two complete extremal metrics add up to the volumes of the ω_i.
3. When $m > k_2$, then suitable pointed limits of the ω_i are either $\Sigma \times \mathbf{R}$, or complete extremal metrics on $M \setminus S_0$ or $M \setminus S_\infty$. In the first case a circle fibration collapses, and the sum of the volumes of the two complete extremal metrics is strictly less than the volume of the ω_i. Figure 4.1 illustrates the behavior of the metrics ω_i when restricted to a $\mathbf{P}^1$ fiber.

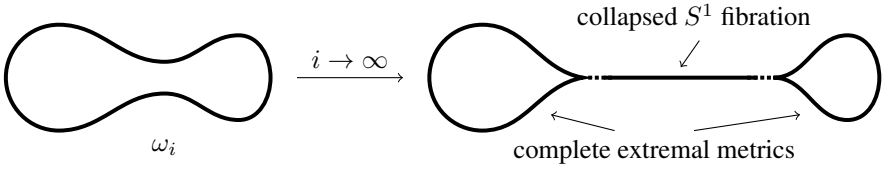

Figure 4.1. The fiber metrics of a minimizing sequence when $m > k_2$.

We interpret cases 2 and 3 as saying that a minimizing sequence breaks the manifold into several pieces. Some of the pieces admit complete extremal metrics, but others display

more complicated collapsing behavior. Having such infinite diameter limits, and possible collapsing is in stark contrast with the case of Fano manifolds that we discussed in Section 3.

The sequences of metrics ω_i above can be written down explicitly using the momentum construction developed in detail by Hwang-Singer [26]. To show that these sequences actually minimize the Calabi energy, one needs to consider the right hand side of (4.1), and construct corresponding sequences of test-configurations χ_i such that

$$\lim_{i\to\infty} \|S(\omega_i) - \underline{S}\|_{L^2} = \lim_{i\to\infty} -c_n \frac{\mathrm{Fut}(\chi_i)}{\|\chi_i\|}. \tag{4.4}$$

For this to make sense we need to assume that m is rational, so that a multiple of Ω_m is an integral class. Such a sequence χ_i can be constructed explicitly, and in the case when $m > k_2$, the exponents of the test-configurations χ_i tend to infinity with i. In other words, we need to embed M into larger and larger projective spaces in order to realize χ_i as a degeneration in projective space. The reason is that the central fiber of χ_i is a normal crossing divisor consisting of a chain of a large number of components isomorphic to M, with the infinity section of each meeting the zero section of the next one. The number of components goes to infinity with i. Figure 4.2 illustrates χ_i restricted to a $\mathbf{P}^1$-fiber of M.

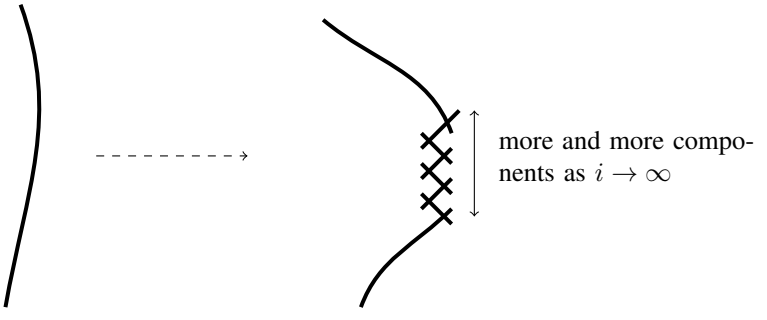

Figure 4.2. The test-configuration χ_i restricted to a $\mathbf{P}^1$ fiber.

From Equation (4.4) together with Theorem 4.1 we obtain the following.

Theorem 4.2. *For the ruled surface M equality holds in Equation 4.1 for any polarization L.*

To conclude this section we point out that already in this example we cannot take a limit of the sequence χ_i in the space of test-configurations, because the exponents go to infinity. However there is a filtration χ, such that χ_i is the induced test-configuration of exponent i, and in this sense the limit of the χ_i exists as a filtration. This filtration achieves the supremum on the right hand side of (4.1) and it is natural to ask whether such a "maximally destabilizing" filtration always exists. In view of the work of Bruasse-Teleman [9] this filtration, if it exists, should be viewed as analogous to the Harder-Narasimhan filtration of an unstable vector bundle.

Acknowledgements. Over the years I have benefited from conversations about extremal metrics with many people. In particular I would like to thank Simon Donaldson, Duong Phong, Julius Ross, Jacopo Stoppa, Richard Thomas and Valentino Tosatti for many useful discussions. The work presented in this survey was partially supported by the NSF.

Ricci flows with unbounded curvature

Peter M. Topping

Abstract. Until recently, Ricci flow was viewed almost exclusively as a way of deforming Riemannian metrics of bounded curvature. Unfortunately, the bounded curvature hypothesis is unnatural for many applications, but is hard to drop because so many new phenomena can occur in the general case. This article surveys some of the theory from the past few years that has sought to rectify the situation in different ways.

Mathematics Subject Classification (2010). Primary 53C44; Secondary 35K55, 58J35.

Keywords. Ricci flow, well-posedness, unbounded curvature, uniformization, geometrization, flowing beyond singularities.

1. Introduction

Since its inception in 1982 [16], Ricci flow has supported the development of a remarkable and elegant theory. The flow has become well-known as a way of deforming a Riemannian metric in order to improve it, or turn it into a special metric that might satisfy a geometrically rigid condition or simply a natural PDE, and indeed up until now, most applications fit within the following general strategy.

- First we take a space that we do not understand very well, perhaps a Riemannian manifold satisfying a curvature condition, or a metric space with some weak geometric structure.
- Next we deform the space under Ricci flow, keeping track of its properties, for example its topology, its curvature or its conformal structure, until it develops into a very special space, for example sometimes one of constant curvature.
- Such special spaces we can hope to classify, and if the Ricci flow can be sufficiently well understood then we can go back and classify or better understand the space with which we started.

As an example, Hamilton's original insight was that a simply connected three-dimensional closed Riemannian manifold of positive Ricci curvature will flow smoothly under a suitably normalised Ricci flow through a family of manifolds of positive Ricci curvature to a manifold of *constant* curvature, which can then be identified as a round sphere. He deduced that the original manifold of positive Ricci curvature must be diffeomorphic to the three-sphere. Dramatic further development of Ricci flow theory by Hamilton and then Perelman ultimately extended this principle to handle all closed three-manifolds, leading to a resolution of the conjectures of Poincaré and Thurston ([19, 23, 27–29]).

Proceedings of the International Congress of Mathematicians, Seoul, 2014

This general strategy has clearly been very effective, but its scope has nevertheless been severely limited by the Ricci flow existence and asymptotics theory only applying in very special cases, meaning that we are only scratching the surface of the potential applicability of the method. In particular, the vast majority of applications require the underlying manifold to be closed, and without that hypothesis we are not even able in general to start the flow going, even for a short time, without imposing further conditions such as boundedness of the curvature that may damage potential applications.

This article surveys part of the programme to extend the theory of Ricci flow to handle general manifolds or even metric spaces. The central point will be the necessity to handle flows with unbounded curvature; until recently we have had no idea how to even start the flow going starting with a manifold of unbounded curvature, let alone understand its long-time existence and asymptotics or uniqueness. In this unrestricted situation, the flow interacts with itself 'at spatial infinity' in an unfamiliar way that is interesting both geometrically and in terms of the pure PDE questions it raises. Since classical solutions to the Ricci flow are characterised as existing until the curvature becomes unbounded, and we want to consider unbounded curvature from the outset, we now need to understand the issue of long-time existence in much more detail. This also brings to the fore the subtle issue of asymptotics of the flow, and we will witness how Ricci flow organises itself to find a special metric, even when there appear to be obstructions.

2. Why is Ricci flow with unbounded curvature so difficult?

We call a smooth one-parameter family of Riemannian metrics $g(t)$ on a manifold $\mathcal{M}$ a Ricci flow when

$$\frac{\partial g}{\partial t} = -2\,\mathrm{Ric}_{g(t)} \tag{2.1}$$

where Ric is the Ricci tensor (see [16, 38]). One should interpret the right-hand side of the equation as some sort of Laplacian of the metric, and thus interpret this equation as some sort of heat equation, although ultimately this is a nonlinear equation, and is even not quite parabolic, which causes problems when trying to establish existence of solutions even to this day, except in relatively simple situations.

One way of trying to pose this flow is to consider an initial Riemannian metric g_0, and then look for a family $g(t)$, $t \in [0, T)$ satisfying (2.1), with $g(0) = g_0$. In due course, we will see that this is rather naive in general, but it works well in special situations such as on closed manifolds (Hamilton [16]) or more generally when the initial metric is complete and of bounded curvature (Shi [36]). The following hybrid of their work also incorporates a uniqueness assertion of Chen-Zhu [4]; the proofs have been clarified and simplified by DeTurck/Hamilton [10, 19] and Kotschwar [24].

Theorem 2.1 (The Hamilton-Shi flow). *Given a smooth, complete Riemannian manifold* $(\mathcal{M}, g_0)$ *of* bounded curvature*, there exist a unique* $T \in (0, \infty]$ *and Ricci flow* $g(t)$ *for* $t \in [0, T)$ *satisfying the equation* (2.1)*, the initial condition* $g(0) = g_0$*, and the properties that the curvature remains bounded for* $t \in [0, T_0]$*, for any* $T_0 \in [0, T)$*, and that if* $T < \infty$ *then*

$$\sup_{\mathcal{M}} |\mathrm{Rm}_{g(t)}| \to \infty \quad \text{as } t \uparrow T,$$

where $\mathrm{Rm}_{g(t)}$ *is the curvature tensor of* $g(t)$*. Moreover,* $(\mathcal{M}, g(t))$ *is complete for all* $t \in [0, T)$.

We will call the Ricci flow whose existence is asserted by this theorem the *Hamilton-Shi* Ricci flow.

The final assertion here that the Ricci flow is complete is more or less obvious. Indeed completeness of a Riemannian manifold is equivalent to the assertion that the length of any smooth proper curve $\gamma : [0, 1) \to \mathcal{M}$ (i.e. any curve heading off to infinity in $\mathcal{M}$) is infinite, but the boundedness of the curvature in this theorem guarantees that lengths of curves can only grow or decrease at most exponentially (see, for example, [38, Lemma 5.3.2]) and so an infinitely long curve at time $t = 0$ will remain infinitely long at a later time $t \in [0, T_0]$. However, this principle emphatically fails for flows of unbounded curvature. Loosely speaking,

Unbounded curvature allows Ricci flow to feel spatial infinity.

In particular, an unbounded curvature Ricci flow can pull 'points at infinity' to within a finite distance in finite time, as we now illustrate.

Theorem 2.2 (Pulling in points at infinity; Special case of [41]). *There exists a smooth Ricci flow for* $t \in [0, \infty)$*, starting at a smooth, complete Riemannian metric of bounded curvature, that is incomplete for all* $t > 0$.

In particular, if T^2 *is a torus equipped with an arbitrary conformal structure,* $p \in T^2$ *is any point, and we write* h *for the unique complete, conformal, hyperbolic metric on* $T^2 \backslash \{p\}$*, then there exists a smooth Ricci flow* $g(t)$ *on* T^2 *for* $t > 0$ *such that* $g(t) \to h$ *smoothly locally on* $T^2 \backslash \{p\}$ *as* $t \downarrow 0$.

Of course, the Ricci flow $g(t)$ on T^2 can be restricted to $T^2 \backslash \{p\}$ to give the desired Ricci flow that starts complete, but instantaneously becomes incomplete. Intuitively the point p is being pulled in from infinity as t lifts off from zero – see Figure 2.1.

This example also illustrates the subtleties of uniqueness in Ricci flow in the presence of possibly unbounded curvature, since we could have flowed the initial manifold $(T^2 \backslash \{p\}, h)$ using the Hamilton-Shi flow instead. In this example that flow would simply dilate the metric, and could be written explicitly as $g(t) = (1 + 2t)h$.

Examples such as this run somewhat counter to the classical intuition in Ricci flow, and the failure to recognise that they can arise in practice has previously led to errors in important parts of the literature – see the discussion in [42]. We will return later to see how incompleteness can be dealt with, and also how to impose a condition at infinity (analogous to a boundary condition) in order to make the problem well posed.

3. A clear picture of Ricci flow on surfaces

Both the nature of the evolution equation and the existence theory above become crystal clear when the dimension of the underlying manifold $\mathcal{M}$ is two.

In this case, the Ricci tensor can be written in terms of the Gauss curvature K as $\mathrm{Ric} = K.g$, so the flow equation is

$$\frac{\partial}{\partial t} g(t) = -2K.g(t).$$

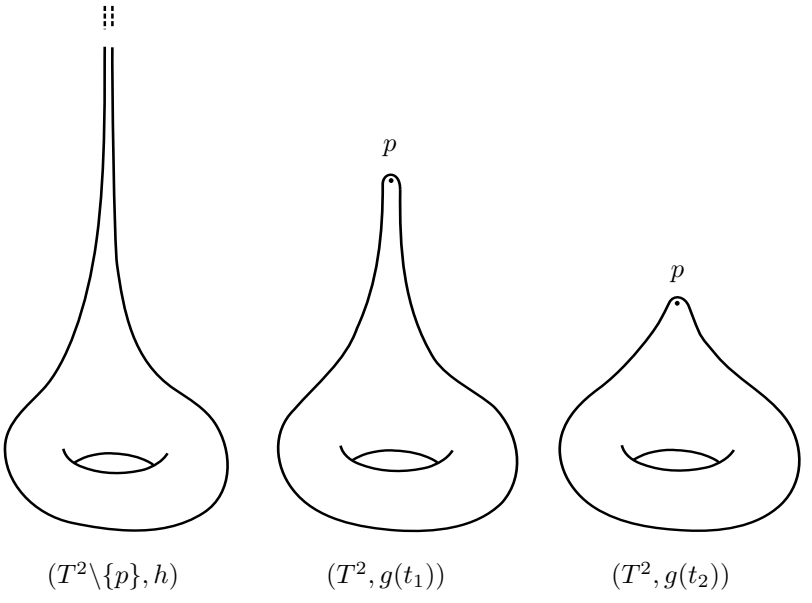

Figure 2.1. Pulling in points at infinity in Theorem 2.2

Thus the flow will always make a conformal deformation of the metric, and we may take local isothermal coordinates x and y, and write the flow $g(t) = e^{2u}|\mathrm{d}z|^2 := e^{2u}(dx^2 + dy^2)$ for some locally-defined, scalar, time-dependent function u, which can then be shown to satisfy the local equation

$$\frac{\partial u}{\partial t} = e^{-2u}\Delta u = -K. \tag{3.1}$$

In particular, in this form, we are dealing with a strictly parabolic PDE. Up to a change of variables, this is the so-called logarithmic fast diffusion equation, which has an extensive literature – see [9, 45] and the references therein.

Theorem 3.1 (Closed surfaces. Hamilton [18], Chow [7]). *Let $\mathcal{M}$ be a closed, oriented surface and g_0 any smooth metric. Define $T = \infty$ unless $\mathcal{M} = S^2$ (topologically) in which case we set $T = \frac{\mathrm{vol}_{g_0}\mathcal{M}}{8\pi}$. Then there exists a unique Ricci flow $g(t)$ on $\mathcal{M}$ for $t \in [0, T)$ so that $g(0) = g_0$. Depending on the genus of $\mathcal{M}$, we have*

$$\begin{aligned}
&\mathcal{M} = S^2: && \frac{g(t)}{2(T-t)} \to G_{+1}, && \textit{a metric of const. curvature } +1, \textit{ as } t \uparrow T.\\
&\mathcal{M} = T^2: && g(t) \to G_0, && \textit{a flat metric, as } t \to \infty.\\
&\mathcal{M} \neq S^2, T^2: && \frac{g(t)}{2t} \to G_{-1}, && \textit{a metric of const. curvature } -1, \textit{ as } t \to \infty.
\end{aligned}$$

The well-posedness theory on closed surfaces was thus completed in the 1980s. An alternative approach to Theorem 3.1 that provides a model for the trickier argument required to prove the Poincaré conjecture can be found in [44].

It is apparent from Theorem 3.1 that Ricci flow *geometrises* a closed surface; more precisely it finds a conformal metric of constant curvature on an arbitrary closed Riemann surface, which is enough to establish the Uniformisation theorem in the restricted case of closed surfaces [6]. It is then a natural question to ask whether Ricci flow performs the same geometrisation task on a general surface. Of course, to be able to even ask this question, we have to be able to start the Ricci flow with a more general metric, and continue it until the flow has had a chance to organise itself into a special metric, whereas the Hamilton-Shi flow from Theorem 2.1 flows restricted metrics, and in general will stop (as we will see) before the flow has achieved anything.

In fact, as we shall demonstrate shortly, Ricci flow is perfectly capable of flowing a completely general surface with possibly unbounded curvature in a uniquely defined way, without even requiring the initial metric to be complete. Before stating the result, we dwell on some issues that such a result must address.

Those unfamiliar with PDE theory often misinterpret existence theory as presumably being obvious. Surely if we are trying to solve an equation $\frac{\partial g}{\partial t} = -2Kg$, then we should simply keep moving g by tiny amounts in the direction $-2Kg$ and a solution should result. The most naive aspect of that suggestion is that it would appear to apply to the problem of solving backwards in time from a given smooth metric, whereas this is certainly not possible. Indeed, Ricci flow has the dramatic smoothing effect of parabolic equations, and immediately makes any metric real analytic [25]. Therefore we could never flow backwards in time starting from a general smooth metric that is not also real analytic.

A more subtle issue that arises once we drop the hypothesis that the underlying manifold is closed, is that we have to worry about boundary conditions. To illustrate this issue, consider simply the problem of starting the Ricci flow on the open disc $D^2 \subset \mathbb{R}^2$ with a metric $g_0 = e^{2u_0}(dx^2 + dy^2)$ that is smooth up to the boundary ∂D^2. From (3.1), this results in the PDE problem

$$\begin{cases} \dfrac{\partial u}{\partial t} = e^{-2u}\Delta u & D^2 \\ u(0) = u_0 & \partial D^2. \end{cases} \tag{3.2}$$

Even amongst solutions that remain continuous up to the boundary at later times, this PDE problem is ill-posed owing to nonuniqueness. Indeed, standard parabolic theory tells us that we are free to specify the restriction of u to ∂D^2 at later times, and only then would we obtain uniqueness. In fact, we will shortly solve the well-posedness problem without resorting to specifying any more data.

A third way we can see that existence theory should be a subtle issue is to consider what it should imply. Geometric flows are typically designed to find special objects, for example constant curvature metrics in the present discussion. On the other hand, it is often possible to give a geometric flow initial data that for some reason cannot be deformed globally and smoothly into a special object – occasionally one does not even exist. Any assertion of global existence of solutions in such cases is also asserting that the geometric flow must organise itself in such a way to resolve this issue, often finding an ingenious way of decomposing the object being flowed into multiple special objects (see [40] and [33, 34] for some other contexts in which this occurs).

We shall shortly see how these issues are resolved in practice by the Ricci flow, but first we give the main well-posedness result in the two-dimensional case. The existence part is joint work with G. Giesen.

Theorem 3.2 (Ricci flows on surfaces, without restriction; [13, 39, 43]). *Let $(\mathcal{M}, g_0)$ be any smooth (connected) Riemannian surface, possibly incomplete and/or with unbounded curvature. Depending on the conformal type, we define $T \in (0, \infty]$ by*[1]

$$T := \begin{cases} \frac{1}{4\pi\chi(\mathcal{M})} \operatorname{vol}_{g_0} \mathcal{M} & \text{if } (\mathcal{M}, g_0) \cong \mathcal{S}^2, \mathbb{C} \text{ or } \mathbb{R}P^2, \\ \infty & \text{otherwise.} \end{cases}$$

Then there exists a smooth Ricci flow $g(t)$ on $\mathcal{M}$, defined for $t \in [0, T)$ such that

(1) *$g(0) = g_0$, and*

(2) *$g(t)$ is instantaneously complete, i.e. complete for all $t \neq 0$ at which it is defined.*

The flow $g(t)$ is unique in the sense that if $\tilde{g}(t)$ is any other smooth Ricci flow, defined now for $t \in [0, \tilde{T})$, satisfying (1) and (2) above, then $\tilde{T} \leq T$ and $g(t) = \tilde{g}(t)$ for all $t \in [0, \tilde{T})$.

In addition, this Ricci flow $g(t)$ is maximally stretched (see Remark 3.3), and the Gauss curvature $K_{g(t)}$ satisfies

$$K_{g(t)} \geq -\frac{1}{2t}$$

for $t \in (0, T)$. If $T < \infty$, then we have

$$\operatorname{vol}_{g(t)} \mathcal{M} = 4\pi\chi(\mathcal{M})(T - t) \ \to \ 0 \quad \text{as } t \uparrow T,$$

and in particular, T is the maximal existence time.

Related results can be found in the literature of the logarithmic fast diffusion literature (e.g. [9, 45]) and the work of Mazzeo, Sesum, Ji and Isenberg [21, 22].

Remark 3.3 ([13] and [15, Remark 1.5]). The *maximally stretched* assertion of the theorem means that $g(t)$ lies 'above' any another Ricci flow with the same or lower initial data. More precisely, if $0 \leq a < b \leq T$ and $\tilde{g}(t)$ is any Ricci flow on $\mathcal{M}$ for $t \in [a, b)$ with $\tilde{g}(a) \leq g(a)$ (with $\tilde{g}(t)$ not necessarily complete or of bounded curvature) then $\tilde{g}(t) \leq g(t)$ for every $t \in [a, b)$.

The mechanism by which this Ricci flow makes an incomplete metric immediately complete is somewhat similar to how the example from Theorem 2.2 made a complete metric immediately incomplete. Unbounded curvature allows points at a finite distance to be sent out to infinity, and vice versa.

Given the unusual nature of these flows, some examples are in order. Although Theorem 3.2 can handle arbitrary initial metrics, with arbitrarily wild behaviour at spatial infinity, we pick the two simplest possible examples [39], both of which start completely flat but have no choice but to have unbounded curvature immediately.

Example 3.4. Let $(\mathcal{M}, g_0)$ be the punctured plane. The metric is incomplete since we can take a curve asymptoting to the origin, of finite length, and the flow will have to do something about this in order to make the metric complete immediately. The flow we construct in Theorem 3.2 deals with this by stretching the metric near the puncture to be asymptotically a hyperbolic cusp, scaled to have Gauss curvature $-\frac{1}{2t}$. See Figure 3.1. (In fact, in this extremely special case, one could compute the flow explicitly as a so-called Ricci soliton, up to the solution of an ODE.)

[1]Note that in the case that $\mathcal{M} = \mathbb{C}$, we set $T = \infty$ if $\operatorname{vol}_{g_0} \mathbb{C} = \infty$. Here $\chi(\mathcal{M})$ is the Euler characteristic.

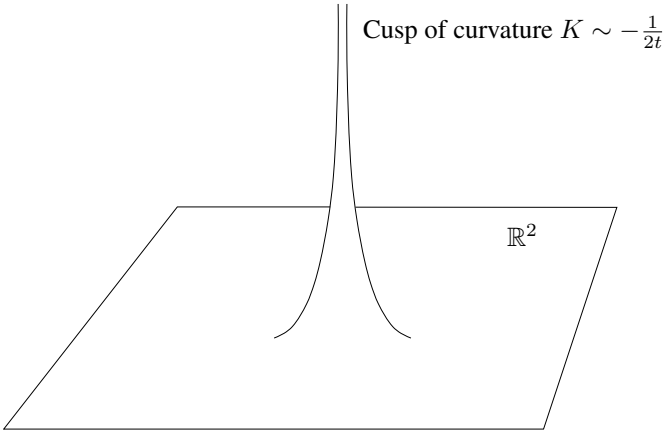

Figure 3.1. Puncture turns into a hyperbolic cusp in Example 3.4

Example 3.5. Now let $(\mathcal{M}, g_0)$ be the Euclidean unit two-dimensional disc. Again, the flow must blow up the metric to make it complete immediately, and it does this by stretching it near to the 'boundary' circle into a Poincaré metric, also scaled to have Gauss curvature $-\frac{1}{2t}$. See Figure 3.2.

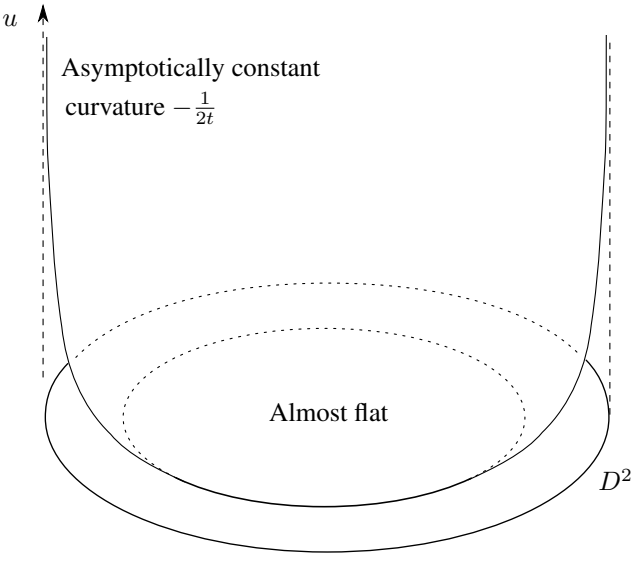

Figure 3.2. Metric stretches at infinity in Example 3.5

This example fits directly into the discussion above on flowing smooth metrics on the disc D^2, where we decided that the addition of boundary data would be the standard way of achieving well-posedness. In Theorem 3.2, the condition on solutions that they are instantaneously complete can be viewed as a substitute for a boundary condition.

Intuitively, the flow from Theorem 3.2 is finding a way of feeding in volume at infinity where the metric is incomplete. The notable feature here is not just that this can be done in order to give a solution, but that it can be done uniquely: If we try to feed in less volume, then the metric will fail to become complete. On the other hand, if we try to feed in more, then the damping within the equation, arising from the e^{-2u} factor in the equation (3.1) is preventing the extra volume from arriving in the interior.

Naively, one might view a common feature of both these examples to be that the conformal factor u in the most obvious, Euclidean coordinates is immediately asymptotically infinity at spatial infinity. However, the conformal factor u depends on the coordinates chosen, and in different coordinates this property will not hold.

Given that Theorem 3.2 makes the metric complete immediately, and also makes the curvature bounded from below, it is reasonable to speculate that maybe the flow also makes the curvature bounded from above immediately, and that therefore after an arbitrarily short time we are in the classical situation of Theorem 2.1 and could make do from then on with the Hamilton-Shi flow. We will see that this suggestion is wrong in two ways. To begin with, we cannot hope ever to be able to construct a complete Ricci flow solution that makes the curvature bounded from above, because our flow is the unique instantaneously complete solution, and carefully chosen initial metrics will have unbounded curvature for all time:

Theorem 3.6 (Ricci flows with unbounded curvature; [14]). *Given any noncompact Riemann surface $\mathcal{M}$, there exists a smooth, complete, conformal metric g_0 such that the unique complete Ricci flow $g(t)$ given by Theorem 3.2 exists for all $t \geq 0$ and $(\mathcal{M}, g(t))$ has unbounded curvature for each $t \geq 0$.*

As we will see in Theorem 4.2, Ricci flows with unbounded curvature at later times were first constructed in higher dimensions in the context of flows with nonnegative complex sectional curvature.

To see a second way in which the classical Hamilton-Shi flow cannot be a substitute for the flow from Theorem 3.2, consider for a moment the restricted situation that $(\mathcal{M}, g_0)$ is both complete and of bounded curvature. We can flow such a metric not only with Theorem 3.2 but also with the Hamilton-Shi flow. By the uniqueness of complete Ricci flows asserted in Theorem 3.2, they must agree – at least while the Hamilton-Shi flow exists. By Theorem 2.1, the Hamilton-Shi flow exists for all time unless the curvature blows up, so one might naively think that this should be when the flow from Theorem 3.2 stops too. However, this more general flow can typically keep going.

Theorem 3.7 (Flowing beyond curvature blow-up; [15]). *There exists a complete surface $(\mathcal{M}, g_0)$ of bounded curvature such that the subsequent Ricci flow $g(t)$ given by Theorem 3.2 exists for all time $t \geq 0$, and that for some times $0 < \tilde{T} < t_0 < \infty$ we have:*

- *The curvature of $g(t)$ is unbounded as $t \uparrow \tilde{T}$, but bounded on $[0, T_0]$ for all $T_0 \in [0, \tilde{T})$.*
- *The curvature is unbounded for each $t \geq t_0$.*

Clearly, the Hamilton-Shi flow will agree with $g(t)$ above until time $\tilde{T}$, when it stops, leaving $g(t)$ to continue alone.

An earlier result of Cabezas-Rivas and Wilking that we state in Theorem 4.2 constructs examples of Ricci flows in dimensions four and higher, with nonnegative complex sectional curvature, with unbounded curvature precisely for $t \geq 1$. In fact, more exotic behaviour can be engineered in which the flow passes back and forth between periods in which the curvature of the flow is unbounded and bounded, such as in the following theorem and Figure 3.3.

Theorem 3.8 (Bursts of unbounded curvature; [15]). *There exists a complete surface $(\mathcal{M}, g_0)$ of bounded curvature such that the subsequent Ricci flow $g(t)$ given by Theorem 3.2 exists for all time $t \geq 0$, and such that for some times $0 < \tilde{T} < t_0 < t_1 < t_2 < \infty$ we have:*

- *The curvature of $g(t)$ is bounded on $[0, T_0]$ for all $T_0 \in [0, \tilde{T})$, but unbounded on $[0, \tilde{T})$.*
- *The curvature is unbounded for each $t \in [t_0, t_1]$.*
- *The curvature is bounded for $t \geq t_2$.*

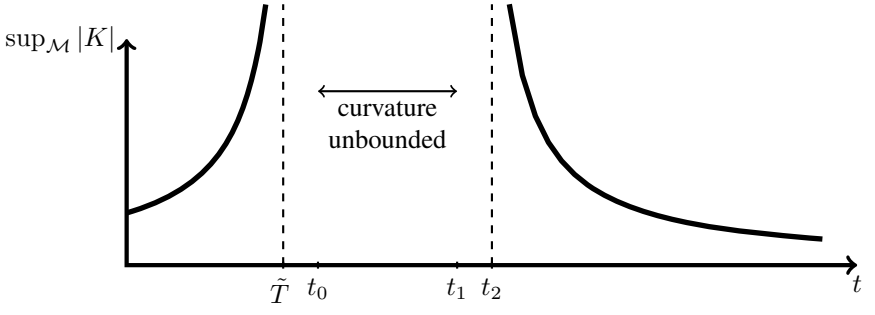

Figure 3.3. The flow in Theorem 3.8 switches back and forth between bounded and unbounded curvature, remaining always complete. The Hamilton-Shi flow ends at $t = \tilde{T}$.

Of course, by uniqueness, the only lever we have to engineer this behaviour is the choice of the initial metric. Once the flow starts, it is determined forever.

Now we have a Ricci flow starting with an arbitrary initial surface, we can return to the question of whether this Ricci flow will geometrise the surface, finding a metric of constant curvature. If we restrict our discussion to initial surfaces $(\mathcal{M}, g_0)$ that are conformal to a hyperbolic metric H, then by definition of T in Theorem 3.2, our Ricci flow must exist for all $t \geq 0$ and we can ask the question as to whether the flow will manage to converge to H. We find that it does:

Theorem 3.9 (Ricci flow geometrises general hyperbolic surfaces; [13]). *If $(\mathcal{M}, g_0)$ has a conformally equivalent, complete, hyperbolic metric H, then the Ricci flow $g(t)$ from Theorem 3.2 exists for all $t \geq 0$ and finds H in the sense that*

$$\frac{g(t)}{2t} \to H$$

smoothly locally as $t \to \infty$.

We view this type of result not as a route to giving an alternative proof of the Uniformisation theorem for general surfaces, but partly as a stepping stone to proving higher-dimensional uniformisation results, partly as a way of comparing the geometry of general metrics to that of conformal constant curvature metrics – for example the determinant of the Laplacian behaves well under Ricci flow [1] – and partly as a means for understanding how Ricci flow organises itself in order to find a special metric. In the latter direction, it is interesting to apply Theorem 3.9 in the case that $\mathcal{M}$ is noncompact (for example, the open disc) and g_0 is a metric supplied from Theorem 3.6. In this case we know on one hand that

$\frac{g(t)}{2t}$ converges to a hyperbolic metric, i.e. one of constant curvature -1, and on the other hand that it remains with unbounded curvature for all time. These two assertions are not contradictory because the convergence to a hyperbolic metric is smooth *local* convergence. In other words, the Ricci flow cannot prevent unbounded curvature, but it does organise itself to force regions of large curvature out towards spatial infinity.

4. Flows with unbounded curvature in higher dimensions

It is interesting to speculate as to how many of the results of the last section generalise to higher dimensions. Certainly the existence theory in Theorem 3.2 cannot possibly be expected to hold in such generality because one can choose smooth, complete, three-dimensional Riemannian manifolds of unbounded curvature that we cannot hope to evolve under Ricci flow, even for a short time. For example, one could take the underlying manifold to be $S^2 \times \mathbb{R}$ and endow it with a warped product metric so that metrically it consists of an infinite chain of three-spheres connected by thinner and thinner (and longer and longer) necks, as in Figure 4.1. However small we take $\varepsilon > 0$, if we pick a neck that is sufficiently thin and long, then the Ricci flow will be inclined to pinch it within time ε. (See [38, §1.3.2] for more about this type of neck-pinch singularity.)

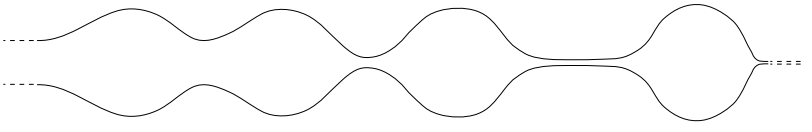

Figure 4.1. $S^2 \times \mathbb{R}$ with thinner and thinner necks

One can, however, hope to flow manifolds of unbounded curvature that also satisfy an appropriate nonnegative curvature condition that can rule out neck-pinch type singularities happening in an arbitrarily short time. An interesting scenario would be to consider complete three-dimensional manifolds of nonnegative Ricci curvature. It is very likely that Ricci flow knows how to flow such manifolds, preserving the nonnegativity of the Ricci curvature, in a unique way.

In 1989, Shi [35] classified complete three manifolds of nonnegative Ricci curvature that have *bounded curvature*. The key step, following Hamilton [17], was to flow forwards using the Ricci flow and prove that either the Ricci curvature becomes strictly positive immediately, or the manifold splits locally as a product. Being able to drop the bounded curvature assumption while still being able to flow even for a short time would have yielded a classification of *all* three manifolds of nonnegative Ricci curvature, which is the most natural class to consider. This classification had to wait over twenty years, and the development of alternative minimal surface techniques by Liu [26]. The natural Ricci flow question of existence with unbounded curvature remains open.

A very natural situation in which the existence side of the theory *has* been successfully developed is the case that we flow manifolds of nonnegative *complex* sectional curvature. This curvature condition implies nonnegative sectional curvature, and is implied by nonnegative curvature operator; it is preserved under Ricci flow [3]. Cabezas-Rivas and Wilking proved existence of solutions in this situation, retaining the curvature condition.

Theorem 4.1 (Cabezas-Rivas and Wilking [3, Theorem 1]). *Given any complete Riemannian manifold $(\mathcal{M}, g_0)$ with nonnegative complex sectional curvature, there exists a Ricci flow $g(t)$ for $t \in [0, \varepsilon)$, some $\varepsilon > 0$, with $g(0) = g_0$ and with $g(t)$ having nonnegative complex sectional curvature for each $t \in [0, \varepsilon)$.*

It is an interesting open question to prove uniqueness of this solution – conceivably there could be many other solutions with the same initial metric. Indeed, *a priori* the Ricci flow could have infinitely many nonunique branches at each instant of time, as is the case for parabolic equations on bounded domains.

Except in low dimensions, the restriction of nonnegative complex sectional curvature does not in itself enforce boundedness of the curvature of a Ricci flow as time advances:

Theorem 4.2 (Cabezas-Rivas and Wilking [3, Theorem 4, Corollary 3]). *There exist Ricci flows with nonnegative complex sectional curvature for $t \in [0, \infty)$ with unbounded curvature for all time, and others with unbounded curvature precisely for $t \geq 1$. On the other hand, if for an n-dimensional Riemannian manifold $(\mathcal{M}, g_0)$ with nonnegative complex sectional curvature there exists $v_0 > 0$ such that*

$$\mathrm{vol}_{g_0}(B_{g_0}(x, 1)) \geq v_0$$

for all $x \in \mathcal{M}$, then we may assume that the curvature of the Ricci flow arising in Theorem 4.1 is bounded above by $\frac{C(n, v_0)}{t}$.

The existence theory above is not explicit about the length of time for which the solution will persist. However, by virtue of the nonnegativity of the complex sectional curvature, a lower bound for the existence time can be read off from the initial geometry of the flow:

Theorem 4.3 (Cabezas-Rivas and Wilking [3, special case of Corollary 5]). *Given an n-dimensional manifold $\mathcal{M}$, there exists $\varepsilon > 0$ depending only on n such that we may assume that a Ricci flow arising from Theorem 4.1 exists for $t \in [0, T)$ where*

$$T = \varepsilon . \sup \left\{ \frac{\mathrm{vol}_{g_0}(B_{g_0}(x, r))}{r^{n-2}} \;\middle|\; x \in \mathcal{M}, r > 0 \right\} \in (0, \infty].$$

Finally we remark that perhaps the most natural context in which one might hope to generalise the results of Section 3 is that of higher dimensional *Kähler* Ricci flow. We leave this discussion for another occasion.

5. Flowing rough metrics or Alexandrov spaces

The entire discussion so far has considered only Ricci flows starting with *smooth* Riemannian metrics. One can also ask whether it is possible to start flowing from a metric that is not smooth, or is possibly not even a Riemannian metric at all, but perhaps a metric space with some basic structure. A Ricci flow arising in this way would generally have unbounded curvature at least in the limit $t \downarrow 0$.

One might naively think that if we can view Ricci flow as a parabolic equation, then it should be irrelevant what the regularity of an initial Riemannian metric is because Ricci flow should instantly smooth it out. However, Ricci flow will *not* smooth in the same quantified

way as the ordinary heat equation. The Harnack inequality, in the sense of [20, Section 1], can be used to prove that positive solutions of the heat equation on, say, Euclidean space must smear out at a certain rate, with the heat kernel being the extreme case. By contrast, the coefficient e^{-2u} in (3.1) can interrupt this behaviour, as is exploited implicitly in the proofs of Theorems 3.6 and 3.8. This effect from a PDE perspective says that a delta-mass for e^{2u} will remain a delta-mass for a while under the evolution equation (3.1), and will not spread out like a heat kernel. See the discussion in [45, Section 8.2].

Nevertheless, there are several situations in which it is possible to start the Ricci flow with a very rough object, perhaps a certain type of metric space. The general principle behind most results of this form, as well as some of the results we have discussed earlier in this survey, is that one approximates the initial data by a sequence of smooth Riemannian manifolds $(\mathcal{M}_i, g_i)$, flows each of these, and then tries to take a limit of these smooth Ricci flows. The real art is to prove uniform estimates on the sequence of smooth Ricci flows and their existence time so that this limit can be taken. A number of estimates of this form could be summarised loosely as

Initial metric g_0 has (i) lower curvature bound, and (ii) noncollapsing hypothesis	$\Longrightarrow$	Curvature decays like $\lvert\mathrm{Rm}_{g(t)}\rvert \leq \frac{C}{t}$

Without the noncollapsing condition (ii), no such uniform estimate can hold as we see by returning to the 'contracting cusp' example of Theorem 2.2 where the curvature decay is expected to be like C/t^2.

Although we do not attempt a complete survey of such results, we do wish to highlight one of the results of M. Simon [37] of this form.

Theorem 5.1 (Special case of [37, Theorem 7.1]). *Given a closed three or two-dimensional manifold $(\mathcal{M}, g_0)$ that satisfies*

(i) $\mathrm{Ric}_{g_0} \geq k \in \mathbb{R}$, *and*

(ii) $\mathrm{vol}_{g_0}(B_{g_0}(x,1)) \geq v_0 > 0$ *for all $x \in \mathcal{M}$,*

there exist constants $T = T(k, v_0) > 0$ and $K = K(k, v_0) > 0$ such that the Ricci flow $g(t)$ with $g(0) = g_0$ exists for $t \in [0, T)$ and satisfies, for each $t \in (0, T)$, the inequalities

(i) $\mathrm{Ric}_{g(t)} \geq -K$,

(ii) $\mathrm{vol}_{g(t)}(B_{g(t)}(x,1)) \geq \frac{v_0}{2}$ *for all $x \in \mathcal{M}$,*

(iii) $\lvert\mathrm{Rm}_{g(t)}\rvert \leq \frac{K}{t}$, *and*

(iv) $e^{K(t-s)} d_{g(s)}(p,q) \geq d_{g(t)}(p,q) \geq d_{g(s)}(p,q) - K(\sqrt{t} - \sqrt{s})$ *for all $s \in (0, t]$ and $p, q \in \mathcal{M}$, where $d_{g(s)}(p,q)$ is the Riemannian distance between p and q with respect to $g(s)$.*

As a consequence, Simon [37] was able to run the Ricci flow for a definite amount of time, starting with any metric space arising as a Gromov-Hausdorff limit of smooth closed three-manifolds satisfying (a) and (b) of Theorem 5.1 uniformly.

Of course, we would like to be able to describe *synthetically* the metric spaces that can be flowed, rather than describe them as limit points under Gromov-Hausdorff convergence. A clean situation in which this can be done was described by T. Richard [31]. The starting

point for his work is the notion of Alexandrov space, which for our purposes is a type of metric space (X, d) that satisfies a very weak notion of curvature bounded below. Such spaces automatically have integral (or infinite) Hausdorff dimension, and we require this dimension to be two. The resulting object turns out to be topologically a surface (possibly with boundary), and we require this surface to be closed. These constraints define the notion of *Alexandrov surface* – see [30] and [2] for a more precise definition and further details.

Following Alexandrov, Richard [30, 31] proved that Alexandrov surfaces can be approximated by smooth Riemannian surfaces satisfying (a) and (b) of Theorem 5.1 uniformly, and hence showed that Ricci flow smooths out an Alexandrov surface. He also proved that it does this in a unique way.

Theorem 5.2 (Flowing Alexandrov surfaces [31]). *Given an Alexandrov surface (X, d) with curvature bounded below by -1, there exists a Ricci flow $g(t)$ on a closed surface $\mathcal{M}$, for $t \in (0, T)$, some $T > 0$, with $K_{g(t)} \geq -1$ and such that the distance function $d_{g(t)} : \mathcal{M} \times \mathcal{M} \to [0, \infty)$ of $g(t)$ converges uniformly to some distance function $d_0 : \mathcal{M} \times \mathcal{M} \to [0, \infty)$ as $t \downarrow 0$, where $(\mathcal{M}, d_0)$ is isometric to (X, d).*

Moreover, the Ricci flow is unique up to isometry in the sense that if $(\hat{\mathcal{M}}, \hat{g}(t))$, defined for $t \in (0, \hat{T})$, is any other Ricci flow with curvature uniformly bounded from below, for which $d_{\hat{g}(t)} \to \hat{d}_0$ as $t \downarrow 0$ with $(\hat{\mathcal{M}}, \hat{d}_0)$ isometric to (X, d), then there exists a smooth map $\varphi : \mathcal{M} \to \hat{\mathcal{M}}$ that is an isometry from $(\mathcal{M}, g(t))$ to $(\hat{\mathcal{M}}, \hat{g}(t))$ for each $t \in (0, \min\{T, \hat{T}\})$.

A curious consequence of this theorem is that Ricci flow knows again how to organise itself, this time to uniquely and instantaneously endow such metric spaces with a conformal structure.

Isoperimetric inequalities and asymptotic geometry

Stefan Wenger

Abstract. The m-th isoperimetric or filling volume function of a Riemannian manifold or a more general metric space X measures how difficult it is to fill m-dimensional boundaries in X of a given volume with an $(m+1)$-dimensional surface in X. The asymptotic growth of the isoperimetric functions provides large scale invariants of the underlying space. They have been the subject of intense research in past years in large scale geometry and especially geometric group theory, where the isoperimetric functions appear as Dehn functions of a group.

In this paper and the accompanying talk, I survey relationships between the asymptotic growth of isoperimetric functions and the large scale geometry of the underlying space and, in particular, fine properties of its asymptotic cones. I will furthermore describe recently developed tools from geometric measure theory in metric spaces and explain how these can be used to study the asymptotic growth of the isoperimetric functions.

Mathematics Subject Classification (2010). Primary 53C23; Secondary 49Q15, 20F65.

Keywords. Isoperimetric inequalities, Dehn functions, Gromov hyperbolicity, non-positive curvature, nilpotent groups, Carnot groups, asymptotic cones, currents in metric spaces, compactness theorems.

1. Introduction

The filling area (or first isoperimetric) function of a simply connected Riemannian manifold M measures, roughly speaking, how difficult it is to fill a closed curve in M by a disk-type surface in M. More precisely, it is defined by

$$\mathrm{FA}_0(M,r) := \sup\left\{\mathrm{Fillarea}_0(\gamma) : \gamma \text{ closed curve in } M \text{ of length} \le r\right\},$$

where $\mathrm{Fillarea}_0(\gamma)$ is the least area of a C^1-smooth (or Lipschitz) disk in M bounding γ. The filling area function is closely related to the important Dehn function widely studied in geometric group theory. Indeed, if a finitely presented group Γ acts properly discontinuously and cocompactly by isometries on a simply connected Riemannian manifold M then the Dehn function δ_Γ of Γ and the filling area function FA_0 have the same growth, thus $\delta_\Gamma(n) \simeq \mathrm{FA}_0(M,n)$, as asserted in [37] and proved in [14], [18]. Here, given functions $f, g\colon [0,\infty) \to [0,\infty)$ one writes $f \preceq g$ if there exists $C > 0$ such that

$$f(r) \le Cg(Cr + C) + Cr + C$$

Proceedings of the International Congress of Mathematicians, Seoul, 2014

for all $r \geq 0$ and one writes $f \simeq g$ if $f \preceq g$ and $g \preceq f$. The Dehn function of a finitely presented group gives a measure of the complexity of the word problem in a given group. Its growth is a quasi-isometry invariant of groups and thus, under suitable conditions, the same holds true for the filling area function. Higher dimensional filling volume (or isoperimetric) functions in M can be defined analogously. If one uses m-spheres in M as boundaries and $(m+1)$-dimensional disk-type surfaces as fillings, one obtains a homotopical filling function $\delta_M^m(r)$, sometimes called m-th order Dehn function of M. If one uses m-cycles as boundaries and $(m+1)$-chains in M one obtains a homological filling volume function $\mathrm{FV}_{m+1}(M,r)$. See Section 2 below for the precise definitions and relationships between $\delta_M^m(r)$ and $\mathrm{FV}_{m+1}(M,r)$. Like their one-dimensional sibling, the higher dimensional filling functions are quasi-isometry invariants under suitable conditions on the underlying space. They have been intensely studied in large scale geometry and in geometric group theory, where they appear as higher Dehn functions.

The purpose of the present article and the accompanying talk is to survey recent results relating the growth of the filling volume functions to the large scale geometry of the underlying space and to fine properties of its asymptotic cones. In particular, I will explain results from [49, 71–73]. The proofs of these results rely on recently developed tools from geometric measure on metric spaces. I will describe some of these tools, including Ambrosio-Kirchheim's theory [5] of metric currents and the main compactness theorem from [74].

In the rest of this introduction, I briefly describe two results in this direction which can be proved with these techniques. The main results will be explained in Sections 3 and 5.

In the seminal paper [37], Gromov proved a fundamental theorem which shows that linear growth of the filling area function for a Riemannian manifold M (or more generally, for a metric space) is equivalent to M having negative curvature on a large scale, that is, to M being hyperbolic in the sense of Gromov. In fact, Gromov even proved that if $\mathrm{FA}_0(M,r) \leq \lambda r^2$ for all sufficiently large r and a sufficiently small constant $\lambda > 0$ then M is Gromov hyperbolic. This shows, in particular, that the filling area function can not have intermediate growth between quadratic and linear. In [71], I proved the following optimal result.

Theorem 1.1 ([71]). *Let M be a Riemannian manifold. If there exist $r_0, \varepsilon > 0$ such that*

$$\mathrm{FA}_0(M,r) \leq \frac{1-\varepsilon}{4\pi} r^2$$

for all $r \geq r_0$ then M is Gromov hyperbolic and, in particular, $\mathrm{FA}_0(M,r) \simeq r$.

The constant $\frac{1}{4\pi}$ is optimal in view of the classical isoperimetric inequality in the Euclidean plane. Theorem 1.1 actually holds in the complete generality of geodesic metric spaces and an analogous version holds for Cayley graphs, see Theorem 3.2 and Corollary 3.3 below.

A class of groups for which the Dehn function has been particularly well-studied is that of nilpotent groups. While many techniques have been developed to obtain upper bounds for the growth of the Dehn function, only few techniques are known to produce lower bounds. A basic question which had remained open for a long time asks whether the Dehn function δ_Γ of every finitely generated nilpotent group Γ grows exactly polynomially, that is, $\delta_\Gamma(n) \simeq n^\alpha$ for some $\alpha \in \mathbb{N}$. In [72], I answered this question in the negative.

Theorem 1.2 ([72]). *There exists a finitely generated nilpotent group Γ such that*

$$n^2 \varrho(n) \preceq \delta_\Gamma(n) \preceq n^2 \log n$$

for a function ϱ satisfying $\varrho(n) \to \infty$ as $n \to \infty$.

The higher filling volume functions have recently also started to attract attention in relationship with large scale geometry and groups. Interesting questions remain, in particular, concerning the relationship between the growth and the existence of flats in Riemannian manifolds of non-positive curvature and more generally $\mathrm{CAT}(0)$-spaces. They have also recently been studied in the context of geometric group theory for various classes of groups, see Sections 3 and 5 for some results.

The proofs of the results above (and further results which I will describe) rely on powerful tools from geometric measure theory in metric spaces, in particular, on Ambrosio-Kirchheim's theory [5] of currents in metric spaces. This theory provides a suitable notion of chains in the generality of complete metric spaces. One of the main observations used in the proofs of the results relating filling volume and asymptotic geometry is a compactness theorem for a sequence of chains in a sequence of metric spaces, see Theorem 4.1. When applied to a sequence M_n of compact, connected and oriented Riemannian m-manifolds, this theorem says that if the diameters, the volumes and the volumes of the boundaries are uniformly bounded, then there exist a subsequence M_{n_j}, a complete metric space Z, and isometric embeddings $\varphi_j \colon M_{n_j} \hookrightarrow Z$ such that the images $\varphi_j(M_{n_j})$, viewed as integral currents, converge with respect to the flat norm to an integral current in Z. This theorem can for example be used to show that if the $(m+1)$-th filling volume function of a metric space X (satisfying a weak non-positive curvature condition) has growth $\mathrm{FV}_{m+1}(X, r) \simeq r^{\frac{m+1}{m}}$ then there is an asymptotic cone of X which contains a copy of a normed space of dimension $m+1$, see Section 5.

The plan of the paper is as follows. In Section 2, I briefly recall the definition of the Dehn and filling volume functions in a metric space, using Lipschitz maps and Lipschitz chains. Section 3 describes some of the main results which I would like to discuss in this talk, including generalizations of the theorems above. Section 4 outlines some of the analytic tools used in the proofs of the main results. Finally, Section 5 explains how the theory of currents and the compactness theorem mentioned above can be used to prove some relationships between the growth of filling volume functions and fine (Lipschitz) properties of asymptotic cones.

2. Filling volume and Dehn functions

There exist various definitions of filling volume functions in a Riemannian manifold or, more generally, in a metric space X. Depending on the type of boundaries and fillings which are admitted one obtains different notions of filling functions. For example, one may use m-dimensional spheres as boundaries and $(m+1)$-dimensional balls as fillings in order to obtain a homotopical filling function. Or one may uses singular m-cycles and singular $(m+1)$-chains in order to obtain a homological filling function. Here, I will define the filling volume functions using Lipschitz spheres and Lipschitz cycles. If X is a simplicial complex, one may alternatively define the filling volume functions using simplicial maps or simplicial chains.

2.1. Volume of Lipschitz maps. Let X be a metric space and Ω an open subset of an m-dimensional Riemannian manifold (e.g. $\mathbb{R}^m$ or S^m). The volume of a Lipschitz map

$\varphi\colon \Omega \to X$ is defined by

$$\mathrm{Vol}(\varphi) = \int_X \#\{z \in \Omega : \varphi(z) = y\}\, d\mathcal{H}^m(y),$$

where $\mathcal{H}^m$ denotes the Hausdorff m-measure on X. If φ is injective then $\mathrm{Vol}(\varphi)$ is just the Hausdorff m-measure of $\varphi(\Omega)$. If $m = 1$ and Ω is an interval then $\mathrm{Vol}(\varphi) = \mathrm{length}(\varphi)$, the length of the Lipschitz curve φ. If X is a Riemannian manifold or simplicial complex with piecewise Riemannian metric then φ is almost everywhere differentiable by Rademacher's theorem. Thus, by the area formula, $\mathrm{Vol}(\varphi)$ is the integral over Ω of the jacobian of the derivative of φ. If X is a general metric space, then φ is "metrically" differentiable almost everywhere and $\mathrm{Vol}(\varphi)$ is the integral over Ω of the jacobian of the metric derivative of φ by [40].

2.2. Homotopical filling functions. The m-th order Dehn function δ_X^m of a metric space X measures how much volume is needed to fill an m-sphere in X by an $(m+1)$-ball. More precisely, it is defined by

$$\delta_X^m(r) := \sup\{\mathrm{Fillvol}_{0,X}(\varphi) : \varphi\colon S^m \to X \text{ Lipschitz}, \mathrm{Vol}(\varphi) \le r\},$$

where $\mathrm{Fillvol}_{0,X}(\varphi)$ is the smallest volume of a Lipschitz map from the $(m+1)$-dimensional unit ball in $\mathbb{R}^{m+1}$ extending φ; respectively, infinity if no Lipschitz extension exists. If $m = 1$ one often uses the more suggestive notation

$$\mathrm{FA}_0(X, r) := \delta_X^1(r).$$

If X is a Riemannian manifold then this is just the filling area function already defined in Section 1.

2.3. Homological filling functions. The $(m+1)$-th filling volume function $\mathrm{FV}_{m+1}(X, r)$ of a metric space X is defined analogously to the function δ_X^m but employs cycles and chains instead of spheres and balls. For many purposes, a suitable notion of chains is given by the singular Lipschitz chains of [36]. In Section 4, a more involved notion of m-chains will be described which gives rise to powerful analytic tools.

By definition, a (singular) Lipschitz m-chain in X is a formal finite sum $c = \sum_{i=1}^k a_i\varphi_i$, where $a_i \in \mathbb{Z}$ and $\varphi_i\colon \Delta^m \to X$ are Lipschitz maps. Here, Δ^m denotes the standard Euclidean m-simplex. The mass (or volume) of c is defined by

$$\mathbf{M}(c) := \sum_{i=1}^k |a_i| \,\mathrm{Vol}(\varphi_i).$$

The boundary of c is the $(m-1)$-chain given by $\partial c = \sum_{i=1}^k a_i\varphi_i|_{\partial\Delta^m}$. If $\partial c = 0$ then c is called cycle. The $(m+1)$-th filling volume function $\mathrm{FV}_{m+1}(X, r)$ of X is then defined by

$$\mathrm{FV}_{m+1}(X, r) := \sup\left\{\mathrm{Fillvol}_X(z) : z \text{ Lip. } m\text{-cycle in } X \text{ with } \mathbf{M}(z) \le r\right\},$$

where $\mathrm{Fillvol}_X(z)$ is the smallest mass of a Lipschitz $(m+1)$-chain c in X with $\partial c = z$; respectively infinity if no such chain exists. We furthermore define the filling area function for curves by Lipschitz 2-chains by

$$\mathrm{FA}(X, r) := \sup\left\{\mathrm{Fillvol}_X(\gamma) : \gamma\colon S^1 \to X \text{ Lipschitz with } \mathrm{length}(\gamma) \le r\right\}.$$

It follows that $\mathrm{FA}(X,r) \le \mathrm{FV}_2(X,r)$ and $\mathrm{FA}(X,r) \le \mathrm{FA}_0(X,r)$. The notation used here differs from the notation used in some of the existing literature.

Suppose that X has the structure of a finite-dimensional simplicial complex with finitely many isometry types of cells. Then one may equivalently define the $(m+1)$-th filling volume function of X by using simplicial chains instead of Lipschitz chains. This results in a function whose growth is $\simeq$-equivalent to that of $\mathrm{FV}_{m+1}(X,r)$ by the deformation theorem of geometric measure theory [27], see also [26].

If X is an m-connected Riemannian manifold or simplicial complex then the Dehn and filling volume functions are related as follows. One has

$$\delta^2_X(r) \preceq \mathrm{FV}_3(X,r)$$

and

$$\delta^m_X(r) \simeq \mathrm{FV}_{m+1}(X,r)$$

when $m \ge 3$, see [13, 36, 76]. For $m \le 2$ the two functions are different in general, by the results in [1, 77].

2.4. Filling in a larger space. Various notions of coarse filling functions exist in the literature. Their purpose is to make sense of filling functions which are independent of the local structure of a given space. One may take a somewhat different approach to coarse filling functions by allowing fillings in a suitably enlarged space as follows. Let X and Y be metric spaces and $\iota\colon X \hookrightarrow Y$ an isometric (i.e. distance preserving) embedding. The generalized filling area function (by disks) of X with respect to Y is defined by

$$\mathrm{FA}_0(X,Y,r) := \sup\{\mathrm{Fillvol}_{0,Y}(\iota\circ\gamma) : \gamma\colon S^1 \to X \text{ Lipschitz}, \mathrm{length}(\gamma) \le r\}.$$

One may define generalized higher order Dehn functions analogously but they will not appear in this paper. Note that the space X isometrically embeds into the Banach space $\ell^\infty(X)$ of bounded functions on X, endowed with the supremum norm, via a Kuratowski embedding. Since $\ell^\infty(X)$ is an injective metric space it follows that

$$\mathrm{FA}_0(X,\ell^\infty(X),r) \le \mathrm{FA}_0(X,Y,r) \le \mathrm{FA}_0(X,r) \tag{2.1}$$

for every $r \ge 0$ and every metric space Y into which X embeds isometrically. Moreover, one has

$$\mathrm{FA}_0(X,\ell^\infty(X),r) \le \frac{1}{2\pi}r^2 \tag{2.2}$$

for every $r \ge 0$ and every metric space X. Note that X itself need not admit "fillings" of Lipschitz curves. Inequality (2.2) applies, in particular, to the Cayley graph of a finitely presented group. One defines analogously

$$\mathrm{FA}(X,Y,r) := \sup\left\{\mathrm{Fillvol}_Y(\iota\circ\gamma) : \gamma\colon S^1 \to X \text{ Lipschitz with } \mathrm{length}(\gamma) \le r\right\}$$

and obtains $\mathrm{FA}(X,Y,r) \le \mathrm{FA}_0(X,Y,r)$ and the inequalities in (2.1) hold with FA_0 replaced by FA. The generalized higher filling volume functions are defined by

$$\mathrm{FV}_{m+1}(X,Y,r) := \sup\left\{\mathrm{Fillvol}_Y(\iota_\# z) : z \text{ Lip. } m\text{-cycle in } X \text{ with } M(z) \le r\right\},$$

where $\iota_\# z$ is z when viewed as a Lipschitz cycle in Y. One obtains again (2.1) with FA_0 replaced by FV_{m+1}.

2.5. Dehn functions of groups. As already mentioned in the introduction, the filling area function FA_0 is closely related to the Dehn function from geometric group theory. Given a finitely presented group Γ with presentation $\Gamma = \langle a_1, \dots, a_d \mid r_1, \dots, r_s \rangle$, the Dehn function of Γ is defined by

$$\delta_\Gamma(n) := \max \delta(\omega),$$

where the maximum is taken over all words ω in the letters a_i of length at most n representing the identity in Γ. Furthermore, the "area" $\delta(\omega)$ of ω is the smallest number k such that ω can be written as

$$\omega = \prod_{i=1}^{k} g_i r_{j_i}^{\pm 1} g_i^{-1}$$

for some g_i and r_{j_i}, where equality is taken to be in the free group generated by the a_i. A different presentation results in a function whose growth is $\simeq$-equivalent to δ_Γ. If Γ is a group acting properly discontinuously and cocompactly by isometries on a simply connected Riemannian manifold M then $\mathrm{FA}_0(M, n) \simeq \delta_\Gamma(n)$, see [14] and [18]. The Dehn function can also be seen as a generalized filling function $\mathrm{FA}_0(X, Y, r)$ as follows. Let X be the Cayley graph of Γ with respect to the presentation above, endowed with the length metric, and let Y be the universal cover of the 2-presentation complex of Γ. Endow Y with a metric such that each 2-cell is a spherical cap. Then Y is a thickening of X, that is, Y contains X isometrically and is at finite Hausdorff distance from X. The Dehn function of Γ then has the same growth as the generalized filling function $\mathrm{FA}_0(X, Y, r)$.

Higher dimensional analogs of the Dehn function of a group can be defined for groups satisfying certain finiteness properties. The m-th order Dehn function δ_Γ^m can be defined for any group Γ of type $\mathcal{F}_{m+1}$, that is, so that Γ has a $K(\Gamma, 1)$ with finitely many $(m+1)$-cells. Roughly speaking, $\delta_\Gamma^m(n)$ measures how many $(m+1)$-cells are needed to fill (by a cellular $(m+1)$-ball) a cellular m-sphere in a $K(\Gamma, 1)$ made of at most n cells of dimension m. See [4, 14], and [13] for a precise definition and [33, 34] for a comparison with the homotopical and homological filling functions defined above.

3. Growth of filling volume functions

This section describes results which relate the growth of the filling volume and Dehn functions to the large scale geometry of the underlying space. Some more general results in this direction will also be given in Section 5.

3.1. Gromov hyperbolic spaces. The concept of δ-hyperbolicity of a metric space was first introduced and studied by Gromov in his seminal article [37]. It provides a notion of negative curvature on a large scale. A geodesic metric space X is called δ-hyperbolic if every geodesic triangle in X is δ-slim, that is, if each side of the triangle is contained in the δ-neighborhood of the two other sides. A geodesic metric space is called Gromov hyperbolic if it is δ-hyperbolic for some $\delta \geq 0$. Every geodesic metric space of finite diameter is Gromov hyperbolic. So is every simply connected Riemannian manifolds of sectional curvature bounded above by some $\kappa < 0$. Gromov proved in [37] that δ-hyperbolic metric spaces are characterized by having a filling area function which grows linearly. In fact, he proved that if X is a δ-hyperbolic metric space and $\mathrm{FA}_0(X, 100\delta) < \infty$ then $\mathrm{FA}_0(X, r) \simeq r$. Gromov furthermore established a far-reaching converse in [37]. He showed that if the filling area

function of a geodesic metric space X satisfies

$$\mathrm{FA}_0(X,r) \leq \frac{1}{4000} r^2$$

for all sufficiently large r then X is Gromov hyperbolic and thus $\mathrm{FA}_0(X,r) \simeq r$. In particular, there are no geodesic metric spaces with filling area function having growth between linear and quadratic. This result inspired many different proofs, see e.g. [52], [62], [11], [56], [24]. Using methods from geometric measure theory, I improved in [71] Gromov's result to yield the optimal possible constant.

Theorem 3.1 ([71]). *Let X be a geodesic metric space. If there exist $\varepsilon, r_0 > 0$ such that*

$$\mathrm{FA}(X,r) \leq \frac{1-\varepsilon}{4\pi} r^2 \tag{3.1}$$

for every $r \geq r_0$ then X is Gromov hyperbolic.

The constant $\frac{1}{4\pi}$ is optimal as follows from the classical isoperimetric inequality in the Euclidean plane. Previously, the best known constant was $\frac{1}{4000}$ in the case of geodesic metric spaces and $\frac{1}{16\pi}$ for a certain class of Riemannian manifolds, called 'reasonable' in [37]. Theorem 3.1 is thus already new in the case that X is a Riemannian manifold.

Even though optimal, the above theorem is not quite satisfactory in a certain sense. Namely, local deformations of the metric might result in a much bigger isoperimetric constant, destroying (3.1) without changing the large scale structure of X. Moreover, the theorem does not apply to spaces such as Cayley graphs of finitely presented groups. The following more general result remedies some of these deficiencies.

Theorem 3.2 ([71]). *Let X be a geodesic metric space such that $\mathrm{FA}(X,r) \preceq r^2$. If there exist $\varepsilon, r_0 > 0$ such that*

$$\mathrm{FA}(X, \ell^\infty(X), r) \leq \frac{1-\varepsilon}{4\pi} r^2 \tag{3.2}$$

for every $r \geq r_0$ then X is Gromov hyperbolic.

The condition that $\mathrm{FA}(X,r) \preceq r^2$ may be replaced by $\mathrm{FA}(X,Y,r) \preceq r^2$ for some thickening Y of X or by a quadratic bound on a coarse filling area function. Compare (3.2) with the bound (2.2) which holds for every metric space X.

In [71], Theorem 3.2 was stated with $\mathrm{FA}(X, \ell^\infty(X), r)$ replaced by the possibly larger function $\mathrm{FA}_0(X, \ell^\infty(X), r)$. The version above follows from the same arguments as in the proof of [71, Theorem 5.1] together with the fact, recently proven in [17], that the Hausdorff 2-measure is semi-elliptic.

From Theorem 3.2 and (2.2) one obtains the following purely group theoretic result.

Corollary 3.3. *Let $\Gamma = \langle S \mid R \rangle$ be a finitely presented group. Suppose there exist $\varepsilon > 0$ and $n_0 \in \mathbb{N}$ such that the Dehn function of Γ with respect to the presentation $\langle S \mid R \rangle$ satisfies*

$$\delta_\Gamma(n) \leq \frac{1-\varepsilon}{2\pi L} n^2$$

for every $n \geq n_0$, where $L := \max\{|r|^2 : r \in R\}$. Then Γ is Gromov hyperbolic and thus has a linear Dehn function.

It is not clear to me what the best constant is for Gromov hyperbolicity for the Dehn function of finitely presented groups.

As already mentioned, there is no group whose Dehn function grows like r^α for some $\alpha \in (1,2)$. In [12] it was proved that the set of $\alpha \geq 2$ for which there exists a finitely presented group Γ with $\delta_\Gamma(n) \simeq n^\alpha$ is dense in the interval $[2,\infty)$. Thus, there is no other gap than $(1,2)$ in the isoperimetric spectrum for the Dehn function. A similar result for surfaces of revolution can be found in [32]. As regards the higher filling volume functions it is known that geodesic Gromov hyperbolic spaces satisfying suitable conditions on the geometry on small scales have linear filling volume functions $\mathrm{FV}_{m+1}(X,r)$ for all $m \geq 1$. This was shown, in a simplicial setup, in [44]. For filling functions defined with chains with real coefficients in finitely presented groups, this was proved in [51].

3.2. Metric spaces of non-positive curvature. In this section, I describe what is known about the growth of the filling volume functions in $\mathrm{CAT}(0)$-spaces, that is, geodesic metric spaces of non-positive curvature in the sense of Alexandrov. This notion of global non-positive curvature is based on the comparison of geodesic triangles with Euclidean comparison triangles. For precise definitions and an account of the theory of $\mathrm{CAT}(0)$-spaces see e.g. [15] or [16].

In [61], it was proved that if X is a $\mathrm{CAT}(0)$-space then

$$\mathrm{FA}_0(X,r) \leq \frac{1}{4\pi} r^2 \tag{3.3}$$

for every $r \geq 0$. Lytchak and I have recently proved in [49] that (3.3) in fact characterizes $\mathrm{CAT}(0)$-spaces.

Theorem 3.4 ([49]). *Let X be a proper geodesic metric space such that* (3.3) *holds for all $r \geq 0$. Then X is a* $\mathrm{CAT}(0)$*-space.*

The only geodesic metric spaces satisfying (3.3) with $\frac{1}{4\pi}$ replaced by a strictly smaller constant are metric trees, that is, they are such that every geodesic triangle is isometric to a tripod. More precisely, if X is a geodesic metric space satisfying $\mathrm{FA}(X,r) \leq Cr^2$ for some $C < \frac{1}{4\pi}$ and all $r \geq 0$ then X is a metric tree and hence $\mathrm{FA}_0(X,r) = 0$. This follows from the same methods as used in the proof of Theorem 3.1.

We turn to the higher filling volume functions in the setting of $\mathrm{CAT}(0)$-spaces. In his seminal paper [36], Gromov showed that if X is a Hadamard manifold, that is, a complete simply connected Riemannian manifold of non-positive sectional curvature, then for every $m \geq 1$ we have

$$FV_{m+1}(X,r) \leq C_m r^{\frac{m+1}{m}} \tag{3.4}$$

for all $r \geq 0$ and for some constant C_m depending only on m. In [67, 70], I proved that this holds true for general $\mathrm{CAT}(0)$-spaces and, with an appropriate notion of chains, even for metric spaces admitting cone type inequalities, see Section 5 below. The optimal isoperimetric constant in (3.4) is only known in a few cases. In [3] it was found for Euclidean space $X = \mathbb{R}^n$ and all m. For Hadamard manifolds of dimension n, the isoperimetric inequality for domains (i.e. for $m = n-1$) with optimal Euclidean isoperimetric constant was proved in [19] for $n = 4$ and in [41] for $n = 3$.

If X is a $\mathrm{CAT}(\kappa)$-space with $\kappa < 0$, that is, X has a strictly negative upper curvature bound, then it is not difficult to show that

$$\mathrm{FV}_{m+1}(X,r) \leq Cr$$

for all r and for some constant C, see [68]. In general, it is a difficult problem to determine the growth of the filling volume functions for $\mathrm{CAT}(0)$-spaces, even when restricted to Hadamard manifolds. The following conjecture appears somewhat implicitly in [38, p. 128].

Conjecture 3.5. *If X is a proper cocompact $\mathrm{CAT}(0)$-space of Euclidean rank k then for every $m \geq k$ there exists C such that*

$$\mathrm{FV}_{m+1}(X, r) \leq Cr \tag{3.5}$$

for all $r \geq 0$.

Recall that the Euclidean rank of X is the maximal dimension of an isometrically embedded copy of Euclidean space in X. The intuition behind this conjecture comes from a general guiding principle in the theory of non-positively curved spaces which states that above the Euclidean rank a proper cocompact $\mathrm{CAT}(0)$-space should exhibit hyperbolic behavior. Instead of assuming X to be proper, cocompact and of Euclidean rank k, one may more generally formulate the conjecture for the larger class of $\mathrm{CAT}(0)$-spaces all of whose asymptotic cones have geometric dimension at most k, see also Section 5. The conjecture is known to be true in the following cases. If X is a proper cocompact $\mathrm{CAT}(0)$-space X of Euclidean rank $k = 1$ then X is Gromov hyperbolic and thus (3.5) follows from [44] together with the Lipschitz extension results of [46]. As regards the case $k > 1$, the conjecture is known to hold for symmetric spaces of non-compact type. This was asserted in [38], where a proof using projections onto maximal flats was proposed. Recently, a proof which is similar in spirit to the argument outlined in [38] but which uses projections onto suitable horospheres was given in [48]. It seems that the above conjecture remains unanswered for most cases even in the context of Hadamard manifolds.

A consequence of the above conjecture would be that isoperimetric inequalities detect the Euclidean rank. This also follows from [73], where I showed that the $(m+1)$-th filling volume function (defined using metric integral currents) have sub-Euclidean growth $o(r^{\frac{m+1}{m}})$ when m is at least the Euclidean rank. This holds more generally true for metric spaces admitting cone type inequalities, see Theorem 5.4 below. In [58], it was showed that for a simplicial complex X with $H_1(X) = H_2(X) = 0$ and for which every extremal 2-cycle for FV_3 has genus at most some fixed $g \in \mathbb{N}$, the following holds: if $\mathrm{FA}(X, r) \leq Cr^2$ and if $\mathrm{FV}_3(X, r) = o(r^{\frac{3}{2}})$ then for every $\varepsilon > 0$ there exists D_ε such that

$$\mathrm{FV}_3(X, r) \leq D_\varepsilon r^{1+\varepsilon}$$

for every $r \geq 1$. It is unknown at present, whether in $\mathbb{R}^3$, endowed with a non-positively curved metric, extremal 2-cycles have a uniform bound on their genus.

3.3. Nilpotent groups. A class of groups (resp. spaces) for which the Dehn and filling volume functions have been particularly well-studied is that of nilpotent (Lie) groups. While many results on upper bounds have been established, fewer techniques for lower bounds are known. After recalling some well-known results I will focus on the main result of [72], which provided a new lower bound for the Dehn function and helped answering a long-standing open question concerning the possible growth of Dehn functions for nilpotent groups.

Recall that a group G is nilpotent if its lower central series terminates in the trivial subgroup after finitely many steps,

$$G = G_0 > G_1 > \ldots G_c > G_{c+1} = \{e\},$$

where $G_{i+1} = [G, G_i]$ is the subgroup generated by commutators $[g, h]$ with $g \in G$ and $h \in G_i$. The smallest number c such that $G_{c+1} = \{e\}$ is called the class or step of G. A special class of nilpotent Lie groups is given by the so-called homogeneous nilpotent Lie groups or Carnot groups. By definition, a connected and simply connected nilpotent Lie group G of step c is called Carnot group if its Lie algebra $\mathfrak{g}$ admits a decomposition

$$\mathfrak{g} = V_1 \oplus \cdots \oplus V_c$$

such that $[V_1, V_i] = V_{i+1}$ for all $i = 1, \ldots, c-1$ and $[V_1, V_c] = \{0\}$. Here, $[V_1, V_i]$ denotes the smallest subspace of $\mathfrak{g}$ spanned by brackets of the form $[v, w]$ with $v \in V_1$ and $w \in V_i$. The subspace V_i is called the i-th layer of $\mathfrak{g}$. Every connected and simply connected nilpotent Lie group G of step 2 is a Carnot group. When endowed with a left-invariant Riemannian metric d_0, a Carnot group G is locally but not globally biLipschitz homeomorphic to Euclidean space. In fact, on the large scale the metric d_0 behaves like a Carnot-Carathéodory metric by [55]. Carnot groups admit scaling automorphisms. On the basis of the Lie algebra these are given by $s_t(v) = t^i v$ for $v \in V_i$ and $t \geq 0$. When endowed with a left-invariant Riemannian metric in such a way that the subspaces $V_i \subset T_e G$ are pairwise orthogonal, the differential of s_t stretches vectors in the left-translates of V_i by a factor t^i. In what follows, all nilpotent Lie groups will be endowed with a left-invariant Riemannian metric.

Recall that the n-th Heisenberg group $\mathbb{H}^n$ is the nilpotent Lie group $\mathbb{R}^{2n+1} = \mathbb{R}^n \times \mathbb{R}^n \times \mathbb{R}$ with multiplication given by

$$(x, y, t) \star (x', y', t') = (x + x', y + y', t + t' + \langle x, y' \rangle).$$

Note that $\mathbb{H}^n$ is of step 2 and has grading of the Lie algebra given by $\mathfrak{h}_n = V_1 \oplus V_2 = \mathbb{R}^{2n} \times \mathbb{R}$. It was proved in [26] and [29] that the first Heisenberg group $\mathbb{H}^1$ has cubic filling area functions:

$$\mathrm{FA}(\mathbb{H}^1, r) \simeq \mathrm{FA}_0(\mathbb{H}^1, r) \simeq r^3.$$

In [31] it was proved that if Γ is a finitely generated nilpotent group of step c then its Dehn function is bounded by $\delta_\Gamma(r) \preceq r^{c+1}$. Previously, it had been shown in [38, $5.A_2'$], [59] that every Carnot group G of step c satisfies $\mathrm{FA}_0(G, r) \preceq r^{c+1}$. This relies essentially on the fact that the curves $t \mapsto s_t(x)$ with $t \in [0, 1]$ have length $\preceq d_0(x, e)^c$, where e is the identity, and stay at bounded distance from each other in the sense that

$$d_0(s_t(x), s_t(x')) \leq t d_0(x, x'),$$

where d_0 is the left-invariant Riemannian metric on G. In [38, $5.A_5$] a strategy has been proposed how to extend this to all simply connected nilpotent Lie groups. The upper growth of r^{c+1} is optimal. Indeed, the Dehn function of every free nilpotent group Γ of step c satisfies $\delta_\Gamma(n) \simeq n^{c+1}$ by [9] and [30]. However, not every nilpotent group of step c has Dehn function growing like r^{c+1}. Indeed, it was proved in [39], and later in [2, 53], that the higher Heisenberg groups $\mathbb{H}^n$, $n \geq 2$, have quadratic filling area functions:

$$\mathrm{FA}(\mathbb{H}^n, r) \simeq \mathrm{FA}_0(\mathbb{H}^n, r) \simeq r^2.$$

In particular, the n-th integer Heisenberg group has quadratic Dehn function whenever $n \geq 2$. Very roughly speaking, the fact that the first layer V_1 of the Lie algebra $\mathfrak{h}_n = V_1 \oplus V_2$ of $\mathbb{H}^n$ contains many 2-dimensional Lie subalgebras is responsible for the quadratic upper

bound. More generally, the n-th central power of any free nilpotent Lie group of step 2 has quadratic filling area functions for $n \geq 2$. This was asserted in [53] and proved in [78]. Recall that if G is a Carnot group of step 2 with grading $\mathfrak{g} = V_1 \oplus V_2$ of its Lie algebra then the n-th central power $G_{Z,n}$ of G is the Carnot group of step 2 whose Lie algebra has grading $\mathfrak{g}_{Z,n} = V_1' \oplus V_2$, where $V_1' := V_1 \oplus \cdots \oplus V_1$ is the n-fold direct sum of copies of V_1, and where the Lie bracket on $\mathfrak{g}_{Z,n}$ is given by

$$[v, w]' = [v_1, w_1] + \cdots + [v_n, w_n]$$

for $v, w \in \mathfrak{g}_{Z,n}$ of the form $v = v_1 + \ldots v_n + \bar{v}$ and $w = w_1 + \ldots w_n + \bar{w}$ with v_i, w_i in the i-th copy of V_1 in V_1' and $\bar{v}, \bar{w} \in V_2$. For example, the n-th Heisenberg group $\mathbb{H}^n$ is the n-th central power of the first Heisenberg group $\mathbb{H}^1$.

A basic question which had remained open for a long time asks whether the Dehn function $\delta_\Gamma(n)$ of every finitely generated nilpotent group Γ has exactly polynomial growth, that is, $\delta_\Gamma(n) \simeq n^\alpha$ for some $\alpha \in \mathbb{N}$. In [72], I answered this question in the negative by proving the following result.

Theorem 3.6 ([72]). *There exists a finitely generated nilpotent group Γ of step 2 with*

$$n^2 \varrho(n) \preceq \delta_\Gamma(n) \preceq n^2 \log n, \tag{3.6}$$

where ϱ is a function satisfying $\varrho(n) \to \infty$ as $n \to \infty$.

One can construct a whole family of such groups and they can be chosen to be lattices of Carnot groups of step 2. The super-quadratic lower bound is proved using methods from geometric measure theory in metric spaces, see Sections 4 and 5. The proof relies among other things on a compactness theorem. Consequently, the precise growth of the function ϱ is not known. The upper bound comes from [53], [78]. More precisely, let G be a Carnot group of step 2 with grading of the Lie algebra $\mathfrak{g} = V_1 \oplus V_2$. Given a subspace $W \subset V_2$ denote by G_W the Carnot group of step 2 whose Lie algebra is $\mathfrak{g}_W = V_1 \oplus (V_2/W)$. If $\mathrm{FA}_0(G, r) \simeq r^2$ then G_W satisfies

$$\mathrm{FA}_0(G_W, r) \preceq r^2 \log r. \tag{3.7}$$

This was asserted in [53] and proved in [78]. Moreover, if W is spanned by elements of the form $[v, v']$ with $v, v' \in V_1$ then $\mathrm{FA}_0(G_W, r) \simeq r^2$ by [78]. In [72], I proved the following lower bound which complements (3.7) and can be used to prove Theorem 3.6.

Theorem 3.7 ([72]). *Let G be a Carnot group of step 2 with grading $\mathfrak{g} = V_1 \oplus V_2$ of its Lie algebra. If $W \subset V_2$ is a non-trivial subspace satisfying*

$$W \cap \{[v, v'] : v, v' \in V_1\} = \{0\} \tag{3.8}$$

then the Carnot group G_W of step 2 whose Lie algebra is $\mathfrak{g}_W = V_1 \oplus (V_2/W)$ satisfies

$$\frac{\mathrm{FA}(G_W, r)}{r^2} \to \infty \quad \text{as } r \to \infty.$$

Note that if G is as in the theorem and if $\dim V_2 \geq 2 \dim V_1$ then there always exists a non-trivial subspace $W \subset V_2$ satisfying (3.8). In [72], the theorem above was only stated for the case that W is 1-dimensional. However, the exact same proof yields the version above.

One can now easily construct finitely generated nilpotent groups Γ satisfying (3.6) as lattices of Carnot groups G_W as above. A concrete example is given as follows. Let $\mathfrak{h} = V_1 \oplus V_2$ be the free nilpotent Lie algebra of step 2 with $\dim V_1 = 6$. Then there exist bases $\{e_1, \dots, e_6\}$ of V_1 and $\{e_{i,j} : 1 \le i < j \le 6\}$ of V_2 such that the Lie bracket on $\mathfrak{h}$ satisfies $[e_i, e_j] = e_{i,j}$ for all $i < j$. Then $u := e_{1,2} + e_{3,4} + e_{5,6}$ satisfies $u \neq [v_1, w_1] + [v_2, w_2]$ for all $v_i, w_i \in V_1$. Denote by H the Carnot group whose Lie algebra is $\mathfrak{h}$ and by G the 2nd central power of H. Then $\mathrm{FA}_0(G, r) \simeq r^2$ and Theorem 3.7 together with (3.7) imply that

$$r^2 \varrho(r) \le \mathrm{FA}(G_{\langle u \rangle}, r) \le \mathrm{FA}_0(G_{\langle u \rangle}, r) \le C r^2 \log r$$

for all sufficiently large r, where $\varrho(r)$ is a function satisfying $\varrho(r) \to \infty$ as $r \to \infty$. Since $G_{\langle u \rangle}$ has rational structure constants it contains a cocompact lattice Γ and hence $\delta_\Gamma(n) \simeq \mathrm{FA}_0(G_{\langle u \rangle}, n)$. Thus Γ satisfies (3.6).

Theorem 3.7 together with the results preceding it moreover yield the following characterization. Let G be a Carnot group of step 2 with grading $\mathfrak{g} = V_1 \oplus V_2$ of its Lie algebra and such that $\mathrm{FA}_0(G, r) \simeq r^2$. Let $W \subset V_2$ be a non-trivial subspace. Then G_W satisfies $\mathrm{FA}_0(G_W, r) \simeq r^2$ if and only if

$$W = \mathrm{span}\{[v, v'] : v, v' \in V_1, [v, v'] \in W\}.$$

Not so much is known yet about the higher filling functions in Carnot groups, except in the top-dimensional case and in the case of the Heisenberg groups. Let G be a Carnot group of step c and of topological dimension n with grading of the Lie algebra given by $\mathfrak{g} = V_1 \oplus \cdots \oplus V_c$. Then $\mathrm{FV}_n(G, r) \simeq r^{\frac{Q}{Q-1}}$, where Q is the homogeneous dimension defined by $Q = \sum_i i \dim V_i$. The upper bound was proved in [54] for $G = \mathbb{H}^1$ and in [66] for general G, see also [20]. The lower bound follows from the volume growth of balls [55].

The growth of the filling volume functions are known for the Heisenberg groups. Indeed, in [78] and [79] it was proved that for $m \le n - 1$ the $(m+1)$-th filling volume function in $\mathbb{H}^n$ is Euclidean,

$$\mathrm{FV}_{m+1}(\mathbb{H}^n, r) \simeq r^{\frac{m+1}{m}}, \tag{3.9}$$

while for $m = n$ it is super-Euclidean,

$$\mathrm{FV}_{n+1}(\mathbb{H}^n, r) \simeq r^{\frac{n+2}{n}},$$

and for $n < m \le 2n$ it is sub-Euclidean,

$$\mathrm{FV}_{m+1}(\mathbb{H}^n, r) \simeq r^{\frac{m+2}{m+1}}.$$

This was previously conjectured in [38]. In [78], it was proved that (3.9) holds more generally for the jet space Carnot groups $J^k(\mathbb{R}^n)$ for $m \le n - 1$ and that $\mathrm{FV}_{n+1}(J^k(\mathbb{R}^n), r) \simeq r^{\frac{n+k+1}{n}}$. For general Carnot groups G of step c the only known upper bound seems to be the following which I proved in [73]:

$$\mathrm{FV}_{m+1}(G, r) \preceq r^{1 + \frac{c^m}{1 + c + \cdots + c^{m-1}}}.$$

It remains a challenging problem to determine the (possible) growth of the filling area and filling volume functions in Carnot groups.

4. Currents in metric spaces and compactness

In this section, I discuss some of the tools used in the proofs of the theorems stated in Section 3 and of the results which will be described in Section 5. One of the main ingredients is a general compactness result, Theorem 4.1, for sequences of m-chains in a sequence of metric spaces. This theorem can be used to show, in particular, that Euclidean growth of the filling volume function $\mathrm{FV}_{m+1}(X,\cdot)$ is reflected in the $(m+1)$-dimensional Lipschitz geometry of the asymptotic cones of X. Singular Lipschitz chains are not suitable to formulate and prove such a compactness theorem since such chains do not enjoy a compactness property even in the setting of a compact ball in Euclidean space.

4.1. Currents in metric spaces. A suitable theory of chains in the generality of complete metric spaces is provided by Ambrosio-Kirchheim's theory [5] of currents in metric space. This theory, based on ideas of De Giorgi [22], generalizes the well-known Federer-Fleming theory [27] of normal and integral currents in Euclidean space to the setting of complete metric spaces. Ambrosio-Kirchheim's theory has been further developed for example in [7, 8, 21, 23, 45, 47, 67, 69, 74].

As is well-known, m-dimensional currents of finite mass in Euclidean space $\mathbb{R}^N$ in the sense of Federer-Fleming [27] are continuous linear functionals on the space $\mathcal{D}^m(\mathbb{R}^N)$ of compactly supported differential m-forms in $\mathbb{R}^N$. In the generality of a complete metric space X, differential forms do not exist. Ambrosio-Kirchheim's theory [5] employs instead $(m+1)$-tuples of real-valued Lipschitz functions on X as a substitute for differential m-forms. More precisely, the space of generalized m-forms on X is defined by

$$\mathcal{D}^m(X) := \{(f,\pi_1,\dots,\pi_m) : f,\pi_i \in \mathrm{Lip}(X),\ f \text{ bounded}\},$$

where $\mathrm{Lip}(X)$ denotes the space of real-valued Lipschitz functions on X. As a rough guiding principle, a tuple $(f,\pi_1,\dots,\pi_m)$ may be thought of as corresponding to the differential form $f d\pi_1 \wedge \cdots \wedge d\pi_m$ whenever $X = \mathbb{R}^N$ and when the f,π_i are smooth. A metric m-current T in the sense of Ambrosio-Kirchheim [5] is a multi-linear functional on $\mathcal{D}^m(X)$ satisfying three conditions. Firstly, a continuity condition requiring T to be continuous along sequences $(f,\pi_1^k,\dots,\pi_m^k)$ such that $\pi_i^k \longrightarrow \pi_i$ pointwise as $k\to\infty$ with bounded Lipschitz constants; secondly, a locality condition which forces $T(f,\pi_1,\dots,\pi_m)$ to depend on the "derivatives" of π_i rather than the π_i themselves; thirdly, a finite mass condition which asks for the existence of a finite Borel measure μ on X such that

$$|T(f,\pi_1,\dots,\pi_m)| \le \int_X |f|\, d\mu$$

for every $(f,\pi_1,\dots,\pi_m) \in \mathcal{D}^m(X)$ such that all π_i are 1-Lipschitz. The smallest such μ is called the mass of T and denoted $\|T\|$. The support of T, denoted $\mathrm{spt}\, T$, is the support of $\|T\|$. One also calls mass of T the number $\mathbf{M}(T) := \|T\|(X)$. An elementary but important example of a metric m-current in $\mathbb{R}^m$, associated to a function $\theta \in L^1(\mathbb{R}^m)$, is given by

$$[\![\theta]\!](f,\pi_1,\dots,\pi_m) := \int_{\mathbb{R}^m} f\theta \det\left(\frac{\partial \pi_i}{\partial x_j}\right) d\mathcal{H}^m.$$

Recall that the boundary and push-forward of a Federer-Fleming current in $\mathbb{R}^N$ are defined by duality with differential forms. In view of the guiding principle above it is thus natural

to define the boundary and push-forward of a metric current as follows. The boundary of a metric m-current T is the functional ∂T on $\mathcal{D}^{m-1}(X)$ defined by

$$(\partial T)(f, \pi_1, \dots, \pi_{m-1}) := T(1, f, \pi_1, \dots, \pi_{m-1}).$$

This functional satisfies all the conditions of a metric current, except maybe the finite mass condition. If ∂T also satisfies the finite mass condition then T is called a normal current. The push-forward of T under a Lipschitz map $\varphi : X \to Y$ is the m-current in Y defined by

$$\varphi_\# T(g, \tau_1, \dots, \tau_m) := T(g \circ \varphi, \tau_1 \circ \varphi, \dots, \tau_m \circ \varphi)$$

for all $(g, \tau_1, \dots, \tau_m) \in \mathcal{D}^m(Y)$.

In general, a normal m-current T in X has little to do with an m-dimensional surface in X, even when $X = \mathbb{R}^N$, since $\|T\|$ may be diffused. The space of integral m-currents in X, denoted $\mathbf{I}_m(X)$, identifies a suitable subclass of normal currents coming from generalized oriented surfaces in some sense. Roughly, a normal m-current T in X is an integral current if it can be written as the countable sum $\sum \varphi_{i\#}[\![\theta_i]\!]$ for some Lipschitz maps $\varphi_i \colon K_i \subset \mathbb{R}^m \to X$ and $\theta_i \in L^1(K_i, \mathbb{Z})$. Thus, T may be thought of as (being induced by) a generalized m-dimensional surface Σ in X with integer multiplicities, where Σ is made of countably many oriented m-dimensional Lipschitz pieces. By the important boundary rectifiability theorem, proved in [5], the boundary of an integral m-current is an integral $(m-1)$-current, that is, can again be written in the form above. Every singular Lipschitz chain $c = \sum_{k=1}^L a_k \varphi_k$ in X induces an integral m-current by $T_c := \sum_{k=1}^L \varphi_{k\#}[\![a_k 1_{\Delta^m}]\!]$. If the φ_k are injective, with pairwise almost disjoint images, then

$$D^{-1}\mathbf{M}(c) \le \mathbf{M}(T_c) \le D\mathbf{M}(c)$$

for some constant $D \ge 1$ only depending on m. The reason for having a constant is that mass measure uses the Gromov mass*-measure rather than the Hausdorff measure used to define $\mathbf{M}(c)$. One of the fundamental results proved in [5] is the closure theorem, which generalizes the corresponding Euclidean result [27] to the setting of general complete metric spaces X. It asserts that if a sequence (T_n) of integral m-currents in X converges weakly (i.e. pointwise) to some normal m-current T and if (T_n) is bounded in the sense that

$$\sup\,[\mathbf{M}(T_n) + \mathbf{M}(\partial T_n)] < \infty \tag{4.1}$$

then T is again an integral current. Another important result proved [5] is a compactness theorem which shows that if (T_n) is a bounded sequence of integral m-currents in a compact metric space X then a subsequence converges weakly to some integral current in X. As a direct consequence of this theorem and the lower semi-continuity of mass under weak convergence, one obtains a solution of the Plateau problem in compact metric spaces X. That is, for every $S \in \mathbf{I}_m(X)$ there exists $S_0 \in \mathbf{I}_m(X)$ such that $\partial S_0 = \partial S$ and

$$\mathbf{M}(S_0) = \inf\{\mathbf{M}(S') : S' \in \mathbf{I}_m(X), \partial S' = \partial S\}.$$

Ambrosio-Kirchheim [5] furthermore solved the Plateau problem for compact boundaries in some infinite dimensional Banach spaces. Using an idea of U. Lang, I solved the Plateau problem for compact boundaries in all Hadamard spaces (i.e. $\mathrm{CAT}(0)$-spaces which are complete) and all dual Banach spaces in [67]. Using Theorem 4.1 below, I extended this in [75] to non-compact boundaries, generalizing recent results in [7].

4.2. Filling volume functions via integral currents. Instead of using singular Lipschitz chains one may use integral currents in order to define the filling volume functions. More precisely, let X and Y be complete metric spaces and $\iota\colon X \hookrightarrow Y$ an isometric embedding. The filling volume in Y of an element $T \in \mathbf{I}_m(Y)$ with $\partial T = 0$ is defined to be

$$\mathrm{Fillvol}^{\mathbf{I}}_Y(T) := \inf\{\mathbf{M}(S) : S \in \mathbf{I}_{m+1}(Y), \partial S = T\}.$$

The filling area function in X with respect to Y using integral currents is defined by

$$\overline{\mathrm{FA}}(X, Y, r) := \sup\left\{\mathrm{Fillvol}^{\mathbf{I}}_Y(\iota_\# T_c) : c \text{ closed Lip. curve in } X, \mathrm{length}(c) \le r\right\}.$$

Here, T_c denotes the integral 1-current in X induced by c, that is, $T_c := c_\#[\![1_{[a,b]}]\!]$ if c is parametrized on $[a, b]$. Then $\overline{\mathrm{FA}}(X, Y, r) \le D\,\mathrm{FA}(X, Y, r)$ for a universal constant $D \ge 1$. If X is a Riemannian manifold then

$$\overline{\mathrm{FA}}(X, r) = \mathrm{FA}(X, r).$$

We furthermore define the $(m + 1)$-th filling volume function using integral currents by

$$\overline{\mathrm{FV}}_{m+1}(X, Y, r) := \sup\left\{\mathrm{Fillvol}^{\mathbf{I}}_Y(\iota_\# T) : T \in \mathbf{I}_m(X), \partial T = 0, \mathbf{M}(T) \le r\right\}$$

for all $r \ge 0$. We abbreviate $\overline{\mathrm{FV}}_{m+1}(X, r) := \overline{\mathrm{FV}}_{m+1}(X, X, r)$. Let X be a Riemannian manifold. Then one can approximate a cycle $T \in \mathbf{I}_m(X)$ by a singular Lipschitz cycle with almost the same mass, see [28, 4.2.19], and hence

$$\overline{\mathrm{FV}}_{m+1}(X, Y, r) \le D\,\mathrm{FV}_{m+1}(X, Y, r)$$

for almost every $r \ge 0$ and some constant D only depending on m; moreover,

$$\overline{\mathrm{FV}}_{m+1}(X, r) = \mathrm{FV}_{m+1}(X, r)$$

for almost every $r \ge 0$.

4.3. A general compactness theorem. The compactness theorem below, which I proved in [74], can be used to obtain relationships between the growth of the filling volume functions in a metric space and the "Lipschitz geometry" of its asymptotic cones. The result combines features of two powerful existing compactness results: Gromov's theorem for uniformly compact sequences of metric spaces and Ambrosio-Kirchheim's compactness result described above.

In order to state the result, recall the definition of the flat norm for currents, which can be thought of as the analog of the filling volume for an integral current with boundary. For given $T \in \mathbf{I}_m(X)$ it is defined by

$$\mathcal{F}_X(T) := \inf\{\mathbf{M}(R) + \mathbf{M}(S) : R \in \mathbf{I}_m(X), S \in \mathbf{I}_{m+1}(X), T = R + \partial S\}. \tag{4.2}$$

If $\partial T = 0$ then $\mathcal{F}_X(T) \le \mathrm{Fillvol}^{\mathbf{I}}_X(T)$. Convergence with respect to the flat norm implies weak (i.e. pointwise) convergence. If the ambient space X admits cone type inequalities in the sense of Definition 5.2 below then the converse is true for bounded sequences (i.e. those satisfying (4.1)) of integral currents, as I showed in [69]. The general compactness theorem alluded to above can be stated as follows.

Theorem 4.1 ([74]). *Let (X_n) be a sequence of complete metric spaces and $T_n \in \mathbf{I}_m(X_n)$ for $n \geq 1$ such that*

$$\sup_n [\operatorname{diam}(\operatorname{spt} T_n) + \mathbf{M}(T_n) + \mathbf{M}(\partial T_n)] < \infty.$$

Then there exist a subsequence (n_j), a complete metric space Z, $T \in \mathbf{I}_m(Z)$, and isometric embeddings $\varphi_j \colon X_{n_j} \hookrightarrow Z$ such that

$$\mathcal{F}_Z(T - \varphi_{j\#} T_{n_j}) \to 0.$$

Moreover, if $\partial T_n = 0$ for all n then $\operatorname{Fillvol}^{\mathbf{I}}_Z(T - \varphi_{j\#} T_{n_j}) \to 0$ as $j \to \infty$.

When applied to a sequence M_n of compact, connected and oriented Riemannian m-manifolds, possibly with boundary, Theorem 4.1 says that if the diameters, the volumes and the volumes of the boundaries are uniformly bounded, then there exist a subsequence M_{n_j}, a complete metric space Z, and isometric embeddings $\varphi_j \colon M_{n_j} \hookrightarrow Z$ such that the images $\varphi_j(M_{n_j})$, viewed as integral currents, converge with respect to the flat norm to an integral current in Z.

In general, it can be shown that the support of the limit T in Theorem 4.1 isometrically embeds into any ultralimit of the sequence (X_{n_j}, x_j), where $x_j \in \operatorname{spt} T_{n_j}$ is an arbitrary point. If the supports $\operatorname{spt} T_{n_j}$ happen to converge in the Gromov-Hausdorff sense to a metric space Y then $\operatorname{spt} T$ may be viewed as an isometric subset of Y. The inclusion $\operatorname{spt} T \subset Y$ may be strict, due to collapsing and cancellation effects. In [63], see also [64], Sormani and I exhibited sufficient conditions on the local "geometry" of the T_n which guarantee that $\operatorname{spt} T = Y$ holds.

Note that, unlike in Ambrosio-Kirchheim's compactness theorem or Gromov's compactness theorem for a sequence of metric spaces, there is no assumption on compactness or bounded "complexity" on the (supports of the) T_n in Theorem 4.1. In the special case that (X_n) is a uniformly compact sequence of metric spaces, Theorem 4.1 is a consequence of Gromov's and Ambrosio-Kirchheim's compactness theorems together with the results in [69]. The rough idea behind the proof of Theorem 4.1 in full generality is to decompose a given current T_n into the sum $T_n = \sum T_n^i$ of integral currents T_n^i such that each T_n^i has a lower bound on the mass of balls up to a certain radius, where the lower bound and the radius bound depend on i but not on n. This kind of thick-thin decomposition is inspired by the arguments in [36] and [67]. The lower bounds on the mass of balls yields uniform compactness of the sequences $(T_n^i)_n$ for fixed i and thus for each of these sequences the compactness theorems of Gromov and of Ambrosio-Kirchheim can be used.

In [47], Lang and I proved a pointed version of Theorem 4.1 for integral currents of finite mass in bounded balls, generalizing the above theorem.

5. Filling volume and asymptotic cones

The theory of metric currents and the compactness theorems mentioned above can be used to obtain relationships between the growth of the filling volume functions in a metric space and fine metric properties of its asymptotic cones. These relationships play a key role in the proofs of the results in Section 3 and of related results described below.

Let (X, d) be a metric space. An asymptotic cone of X is a metric space which one obtains, roughly speaking, by looking at X from infinitely far away. For each choice of a sequence $(p_n) \subset X$ of base points, each sequence (r_n) of scaling factors of the metric with $r_n \to \infty$, as well as each choice of a non-principal ultrafilter ω on $\mathbb{N}$ there is an associated asymptotic cone denoted by $X_\omega = (X, r_n^{-1}d, p_n)_\omega$. Elements of X_ω are equivalence classes of sequences $(x_n) \subset X$ such that the sequence of real numbers $r_n^{-1}d(x_n, p_n)$ is bounded; the distance between two points $[(x_n)]$ and $[(y_n)]$ is the ultralimit, chosen by the non-principal ultra-filter ω, of the bounded sequence of real numbers $r_n^{-1}d(x_n, y_n)$. Asymptotic cones were introduced in [65]. For properties see for example [25]. Asymptotic cones form an ideal tool in the study of the large scale geometry of a space as the local geometry of X disappears in the limit. If X and Y are quasi-isometric metric spaces then, for the same choice of parameters and appropriate choices of base points, the asymptotic cones of X and Y are biLipschitz homeomorphic. A geodesic metric space is Gromov hyperbolic if and only if all its asymptotic cones are metric trees by [37] and [38]. If X is a symmetric space of non-compact type then every asymptotic cone of X is a Euclidean building by [43]. If G is a Carnot group, endowed with left-invariant Riemannian metric d_0, then $(G, r^{-1}d_0, 0)$ converges in the pointed Gromov-Hausdorff distance to (G, d_c), where d_c is the Carnot-Carathéodory metric associated with d_0. This follows from [55]. In particular, (G, d_c) is the unique asymptotic cone of (G, d_0).

The following result, which I proved in [72], shows that admitting a quadratic isoperimetric inequality for curves is preserved in the asymptotic cones.

Theorem 5.1 ([72]). *Let X be a complete length metric space. If $\overline{\mathrm{FA}}(X, r) \preceq r^2$ then every asymptotic cone X_ω of X satisfies*

$$\overline{\mathrm{FA}}(X_\omega, r) \leq C' r^2$$

for all $r \geq 0$ and some constant C'.

The condition $\overline{\mathrm{FA}}(X, r) \preceq r^2$ may be replaced by $\overline{\mathrm{FA}}(X, Y, r) \preceq r^2$ for some thickening Y of X or by a quadratic bound for a coarse filling function. In particular, if G is a finitely presented group with quadratic Dehn function then every asymptotic cone G_ω of G admits a quadratic isoperimetric inequality for integral 1-currents, that is, $\overline{\mathrm{FA}}(G_\omega, r) \leq Cr^2$ for every $r \geq 0$. Previously, it was shown in [57] that every asymptotic cone G_ω of a finitely presented group with quadratic Dehn function is simply connected. Theorem 5.1 does not give simply connectedness but yields strong metric information of G_ω instead. This can be used to prove that certain groups cannot admit a quadratic Dehn function, for example to obtain Theorem 3.6. Note that many groups have simply connected asymptotic cones without having a quadratic Dehn function.

The proofs of Theorems 3.2 and 3.7 rely on Theorem 5.1. The proof of Theorem 3.2 is by condradiction. If X is not Gromov hyperbolic then there exists an asymptotic cone X_ω of X which is not a metric tree and hence contains a non-trivial closed Lipschitz curve c. Since X_ω has quadratic filling area function by Theorem 5.1 the curve c bounds an integral 2-current in X_ω, which is non-zero because the current associated with c is non-zero. Since integral currents are made of Lipschitz pieces it follows that X_ω receives a Lipschitz piece of $\mathbb{R}^2$ with positive Hausdorff 2-measure. By the metric differentiability [40] of Lipschitz maps and after possibly replacing X_ω by a different asymptotic cone of X, one may assume that X_ω contains an isometric copy of a 2-dimensional normed space. Since the isoperimetric constant with respect to the Hausdorff measure for curves in 2-dimensional normed spaces

is $\geq \frac{1}{4}$ and the Hausdorff 2-measure is semi-elliptic one can use (3.2) to produce a contradiction and to complete the proof. As for the proof of Theorem 3.7, one uses (3.8) together with Pansu's differentiability theorem for Lipschitz maps into Carnot groups to show that there exists a closed Lipschitz curve in (G_W, d_c) which does not bound an integral 2-current. Here, d_c denotes the Carnot-Carathéodory metric associated to a left-invariant Riemannian metric d_0 on G_W. In particular, it follows that (G_W, d_c) cannot have a quadratic filling area function and thus, by Theorem 5.1, (G_W, d_0) cannot have a quadratic filling area function either. Consequently, the filling area function of (G_W, d_0) must have super-quadratic growth, completing the proof of Theorem 3.7.

The main construction in the proof of Theorem 5.1 can be described as follows, see [72] for details.

Outline of proof. After possibly replacing X by a suitable thickening of X, one may assume that $\overline{\mathrm{FA}}(X, r) \leq Cr^2$ for all $r \geq 0$ and some constant C. Let $X_\omega = (X, r_n^{-1} d, p_n)_\omega$ be an asymptotic cone of X and let $x^1, \dots, x^k \in X_\omega$ be a chain of points such that $x^k = x^1$. We will construct $S \in \mathbf{I}_2(X_\omega)$ such that ∂S is the current induced by a piece-wise geodesic loop c connecting x^i with x^{i+1}, $i = 1, \dots, k-1$, and such that

$$\mathbf{M}(S) \leq C \operatorname{length}(c)^2.$$

Note first that each x^i comes from a sequence $(x_n^i) \subset X$. Fix a partition $0 = t_0 < t_1 < \cdots < t_k = 1$ and let $c_n : [0,1] \to X$ be such that $c_n|_{[t_i, t_{i+1}]}$ connects x_n^i with x_n^{i+1} by a piece-wise almost geodesic, parametrized proportional to arc-length. For n sufficiently large, there exists $S_n \in \mathbf{I}_2(X)$ with boundary c_n such that $\mathbf{M}(S_n) \leq C \operatorname{length}(c_n)^2$ and such that $\|S_n\|$ satisfies

$$\|S_n\|(B(x, r)) \geq \delta r^2 \tag{5.1}$$

for all $0 < r < \operatorname{dist}(x, c_n)$, where $\delta > 0$ is a constant only depending on C. An area-minimizing integral current with boundary c_n would for example satisfy this. In general, one cannot expect the existence of an area-minimizer. Nevertheless, the completeness of $\mathbf{I}_m(X)$ with respect to the mass norm allows one to prove the existence of a quasi-minimizing integral current and such a current still satisfies (5.1), as already proved in [5]. It follows that the sequence of metric spaces given by

$$Z_n := (\operatorname{spt}(S_n) \cup c_n([0,1]), r_n^{-1} d)$$

is a uniformly compact sequence. Hence, by Gromov's theorem, there exists a compact metric space Z and isometric embeddings $\varphi_n : Z_n \hookrightarrow Z$ for every n. By Ambrosio-Kirchheim's compactness theorem there exists a subsequence (n_j) such that $\varphi_{n_j \#} S_{n_j}$ converges to some $S \in \mathbf{I}_2(Z)$. Furthermore, we may assume that $\varphi_{n_j} \circ c_{n_j}$ converges uniformly to some piecewise geodesic loop c. It follows that $\partial S = c$ and

$$\mathbf{M}(S) \leq \liminf_{j \to \infty} \mathbf{M}(\varphi_{n_j \#} S_{n_j}) \leq C \liminf_{j \to \infty} \operatorname{length}(c_{n_j})^2 = C \operatorname{length}(c)^2.$$

The image of c and the support of S both lie in the ultralimit A of the sequence of subsets $\varphi_n(Z_n)$. Since A isometrically embeds into X_ω it follows that c and S isometrically embed into X_ω, moreover, $c(t_i) = x^i$. Using this construction and a suitable approximation of a given Lipschitz loop in X_ω one proves Theorem 5.1. □

If X is a Carnot group, endowed with a left-invariant Riemannian metric, and if $\overline{\mathrm{FV}}_{m+1}(X,r) \preceq r^{\frac{m+1}{m}}$ then the asymptotic cone X_ω of X satisfies $\overline{\mathrm{FV}}_{m+1}(X_\omega, r) \le Cr^{\frac{m+1}{m}}$ for some constant C and all $r \ge 0$ by [72]. It is not known in which generality Euclidean growth of the filling volume functions passes to the asymptotic cones for more general metric spaces.

For a large class of spaces, Euclidean growth of the filling volume functions results in non-trivial biLipschitz pieces in some of its asymptotic cones. The class of spaces is the following.

Definition 5.2. A complete metric space X is said to admit a cone type inequality for $\mathbf{I}_m(X)$ if there exists $C \ge 0$ such that

$$\mathrm{Fillvol}^{\mathbf{I}}_X(T) \le C \operatorname{diam}(\operatorname{spt} T)\mathbf{M}(T) \tag{5.2}$$

for every $T \in \mathbf{I}_m(X)$ with $\partial T = 0$.

Banach spaces, Hadamard spaces, and complete metric spaces X with a convex metric all admit cone type inequalities for $\mathbf{I}_m(X)$ for all m. This is more generally true for all complete metric spaces X admitting a bounded combing in the following sense. There exist C and $Cd(x,y)$-Lipschitz curves $c_{x,y}\colon [0,1] \to X$ from x to y for all $x, y \in X$ such that

$$d(c_{x,y}(t), c_{x,z}(t)) \le Cd(y,z)$$

for all triples $x, y, z \in X$ and all $t \in [0,1]$. Finally, if X is an m-connected Riemannian manifold or finite dimensional simplicial complex on which a combable group acts properly discontinuously and cocompactly by isometries then X admits a cone type inequality for $\mathbf{I}_m(X)$, see [26]. Admitting a cone type inequality for $\mathbf{I}_1(X)$ is equivalent to admitting a quadratic isoperimteric inequality for $\mathbf{I}_1(X)$, that is,

$$\overline{\mathrm{FA}}(X,r) \le C'r^2$$

for all $r \ge 0$. In [67], I showed that if a complete metric space X satisfies cone type inequalities for $\mathbf{I}_k(X)$ for $k = 1, \dots, m$ then

$$\overline{\mathrm{FV}}_{m+1}(X,r) \le C'r^{\frac{m+1}{m}} \tag{5.3}$$

for every $r \ge 0$, where C' only depends on the constants of the cone type inequalities. For Riemannian manifolds admitting cone type inequalities (for Lipschitz chains) this was previously proved in [36].

For spaces admitting cone type inequalities, the filling volume functions detect the asymptotic rank, defined as follows, see [73].

Definition 5.3. The asymptotic rank of a metric space X, denoted by $\mathrm{Asrk}(X)$, is the supremum over $n \in \mathbb{N}$ such that there exists an asymptotic cone X_ω of X and a biLipschitz embedding $\varphi : K \hookrightarrow X_\omega$ for some compact subset $K \subset \mathbb{R}^n$ with $\mathcal{H}^n(K) > 0$.

The asymptotic rank is a quasi-isometry invariant of metric spaces, see [73]. For a general metric space X one has the bounds

$$\mathrm{Asrk}(X) \le \sup\{\mathrm{Topdim}(C) : C \subset X_\omega \text{ cpt}, X_\omega \text{ an asymptotic cone of } X\}$$

and

$$\mathrm{Asrk}(X) \ge \sup\{n \in \mathbb{N} : \exists \psi : \mathbb{R}^n \to X \text{ quasi-isometric}\}.$$

In the above, $\mathrm{Topdim}(C)$ denotes the topological dimension of C. If X is a Hadamard space then $\mathrm{Asrk}(X)$ is the maximal geometric dimension of an asymptotic cone of X. If X is moreover proper and cocompact then $\mathrm{Asrk}(X)$ coincides with its Euclidean rank. More generally, if X is a proper cocompact length space with a convex metric then

$$\mathrm{Asrk}(X) = \sup\{n \in \mathbb{N} : \exists V \text{ } n\text{-dim. normed space and } \psi : V \to X \text{ isometric}\}.$$

This follows from [42]. If X is a Carnot group, endowed with a left-invariant Riemannian or Carnot-Carathéodory metric, then $\mathrm{Asrk}(X)$ is the highest dimension of a Lie subalgebra contained in the first layer. This follows from [6, 50], and [55]. If X is the mapping class group of a surface of finite type then $\mathrm{Asrk}(X)$ is the maximal rank of an abelian subgroup. This follows from [10] and the inequalities above.

The following theorem, which I proved in [73], shows that the filling volume functions detect the asymptotic rank for a large class of metric spaces. Recall that a metric space (X, d) is said to be quasi-convex if there exists C such that any two points $x, y \in X$ can be joined by a curve of length at most $Cd(x, y)$.

Theorem 5.4 ([73]). *Let X be a complete quasi-convex metric space and $m \geq 1$. Suppose X admits cone type inequalities for $\mathbf{I}_k(X)$ for $k = 1, \dots, m$. Then:*

(i) *If $m < \mathrm{Asrk}(X)$ then there exists $\varepsilon > 0$ such that*

$$\overline{\mathrm{FV}}_{m+1}(X, r) \geq \overline{\mathrm{FV}}_{m+1}(X, \ell^\infty(X), r) \geq \varepsilon r^{\frac{m+1}{m}}$$

for all $r > 0$ large enough.

(ii) *If $m \geq \mathrm{Asrk}(X)$ then*

$$\limsup_{r\to\infty} \frac{\overline{\mathrm{FV}}_{m+1}(X, r)}{r^{\frac{m+1}{m}}} = 0.$$

The proof of part (ii) of Theorem 5.4 is by contradiction and uses the general compactness theorem, Theorem 4.1. The proof can be outlined as follows.

Outline of proof. Suppose there exists a sequence $(T_n) \subset \mathbf{I}_m(X)$ of cycles such that $\mathbf{M}(T_n) \to \infty$ and

$$\liminf_{n\to\infty} \frac{\mathrm{Fillvol}^{\mathbf{I}}_X(T_n)}{\mathbf{M}(T_n)^{\frac{m+1}{m}}} > 0. \tag{5.4}$$

By a thick-thin decomposition procedure, applied to T_n, one obtains a new cycle $T'_n \in \mathbf{I}_m(X)$ such that (5.4) holds for T_n replaced with T'_n and such that

$$\mathrm{diam}(\mathrm{spt}\, T'_n) \leq E\mathbf{M}(T'_n)^{\frac{1}{m}}$$

for every n, where E is a constant independent of n. By the isoperimetric inequality (5.3), there exists $S_n \in \mathbf{I}_{m+1}(X)$ such that $\partial S_n = T'_n$ and such that $\mathbf{M}(S_n) \leq C\mathbf{M}(T'_n)^{\frac{m+1}{m}}$. The S_n can be chosen such that

$$\mathrm{diam}(\mathrm{spt}\, S_n) \leq E'\mathbf{M}(S_n)^{\frac{1}{m+1}}$$

for every n, where E' is a constant independent of n. This can be proved with the same arguments as in the outline of the proof of Theorem 5.1. Define a metric space by $X_n =$

$(X, r_n^{-1}d)$, where $r_n := \mathbf{M}(T'_n)^{\frac{1}{m}}$, and view S_n as a current in X_n. Then (X_n) and S_n satisfy the hypotheses of Theorem 4.1. There thus exists a subsequence (n_j) and a metric space Z such that X_{n_j} embeds isometrically into Z and S_{n_j}, when viewed as a current in Z, converges to some $S \in \mathbf{I}_{m+1}(Z)$ with respect to the flat norm. Since X admits cone type inequalities, the results in [69] and the fact that (5.4) imply that $S \neq 0$. Since $\operatorname{spt} S$ isometrically embeds into some asymptotic cone of X and since S is "made of" biLipschitz pieces from $\mathbb{R}^{m+1}$ it follows that $\operatorname{Asrk}(X) \geq m+1$, a contradiction. □

In view of Conjecture 3.5 it is natural to ask the following question.

Question 5.5. *Let X be a complete quasi-convex metric space admitting cone type inequalities for $\mathbf{I}_k(X)$ for $k = 1, \ldots, m$. Is it true that $\overline{\mathrm{FV}}_{m+1}(X, r)$ grows at most linearly if $m \geq \operatorname{Asrk}(X)$?*

Acknowledgments. I would like to thank Ruth Kellerhals for useful comments and suggestions concerning the presentation of the results.

The cubical route to understanding groups

Daniel T. Wise

Abstract. We survey the methodology and key results used to understand certain groups from a cubical viewpoint, and describe the ideas linking 3-manifolds, cube complexes, and right-angled Artin groups. We close with a collection of problems focused on groups acting on CAT(0) cube complexes.

Mathematics Subject Classification (2010). 20F67, 57M99.

Keywords. CAT(0) cube complexes, right-angled Artin groups, 3-manifolds.

1. Introduction

This survey presents some of the ingredients in a strategy for understanding groups using cube complexes. Developing and applying this has been my research agenda and its details have become increasingly explicit over the past decade. In the hyperbolic case this research program has recently arrived at a major goal: the virtual Haken problem for hyperbolic cube complexes which was completed by Agol, and its associated application towards closed hyperbolic 3-manifolds which was enabled by the closed surfaces of Kahn and Markovic. Some of these developments were precipitated by my use of cubes to understand the underlying structure of hyperbolic groups with a quasiconvex hierarchy, which was in turn partially aimed at the analogous conclusions for cusped hyperbolic manifolds. I describe here some of the tools leading to these developments, mentioning especially work of and with Bergeron, Haglund, Hruska, Hsu, and Sageev. Many of the issues summarized here are treated in a sketchy but intuitive fashion in [67], and in a more dense traditional fashion in [60]. There is still much to do in the cubical realm and we close the survey with a collection of related problems.

Our strategy to understand a group G follows the following scheme:

- Find codimension-1 subgroups and obtain an action of G on the dual cube complex $\widetilde{X}$.
- If the codimension-one subgroups are nice enough then G acts on $\widetilde{X}$ with good finiteness properties.
- Find a finite index subgroup $G' \subset G$ such that $G'\backslash\widetilde{X}$ is very organized in the sense that it is a "special cube complex".
- Obtain an embedding $G' \subset A(\Gamma)$ into a raag, and conclude that G has many nice properties since raags are very nice groups.

Proceedings of the International Congress of Mathematicians, Seoul, 2014

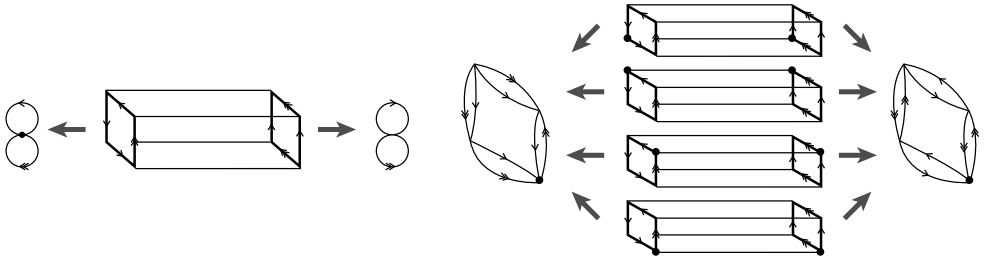

Figure 1.1. A clean cover corresponding to the splitting of $\langle a, b, c, d \mid aaab = cdc^{-1}d^{-1}\rangle$ as an amalgamated free product. The analogous situation for the HNN extension $\langle a, b, c, d, t \mid (aaab)^t = cdc^{-1}d^{-1}\rangle$ is harder.

My trek into this topic began with an interest in residual finiteness that was influenced by the values of the combinatorial group theorists active in the 1960s, and stirred by curiosity about subgroup separability and surfaces in 3-manifolds. In the early 1990s, the simplest examples whose residual finiteness was not understood were cyclic HNN extensions of free groups. These are groups of the form: $\langle a, b, t \mid t^{-1}Ut = V\rangle$ where U, V represent elements of $\langle a, b\rangle$ that do not have conjugate powers. I approached the problem by thinking of covering spaces of a space X that decomposes as a graphs of spaces (see Figure 1.1 for the analogous situation of a free product of two free groups amalgamating a cyclic subgroup). Such a decomposition arises when X is a nonpositively curved square complex with a $\mathcal{VH}$*-structure* in the sense that each of its 1-cells is either "vertical" or "horizontal" and the attaching map of each square alternates between vertical and horizontal edges. The graph of space structure arises from a singular foliation by vertical leaves formed from line segments parallel to the vertical edges. The simplest scenario is where U, V are cyclically reduced words of the same length, in which case the group is the fundamental group of a graph of spaces whose vertex space is a bouquet of circles, and whose edge space is an attached cylinder corresponding to $t^{-1}Ut = V$ that is divided into squares by adding 1-cells parallel to the t edges at the top and bottom. The strategy, as executed in [61], was to first pass to a finite cover $\widehat{X} \to X$ that is *clean* in the sense that the attaching maps of its edge spaces are embeddings. It is straightforward to see that the fundamental groups of these clean graphs of spaces are residually finite. Moreover, there is considerable flexibility in producing finite covering spaces of clean complexes, and this enables one to show that every f.g. subgroup of $\pi_1\widehat{X}$ and hence $\pi_1 X$ is separable. Indeed, this generalizes the ease with which finite covering spaces of graphs can be produced. We refer to Figure 1.1 for a clean cover of the graph of spaces corresponding to the free product of two free groups amalgamating a cyclic subgroup.

These separability ideas were subsequently generalized to arbitrary compact clean $\mathcal{VH}$ square complexes X with $\pi_1 X$ hyperbolic relative to abelian subgroups [64]. A promising application was towards the Dehn complexes of prime alternating links, which are compact nonpositively curved $\mathcal{VH}$ square complexes. A computer experiment showed that many of these Dehn complexes have clean finite covers, and so it became a mission to understand that all Dehn complexes of prime alternating links are virtually clean. In 1997 it seemed that this had introduced a rather new idea towards understanding separability that followed in the footsteps of Hall's work [28], but we now understand in retrospect that it was also an analogue of Scott's right-angled reflection group idea that was used to understand separability

of surface groups [57].

An intriguing early step forward was to show that negatively curved $\mathcal{VH}$-complexes are virtually clean [62]. But although there was an outline of a proof based on the height of an edge group in the splitting, a complete argument that applied to every prime alternating link Dehn complex was unavailable for many years - the malnormal special quotient theorem was the key missing ingredient. I was hopeful that all knot groups were (virtually) fundamental groups of nonpositively curved ($\mathcal{VH}$) square complexes, and went on a fruitless search to generalize the Dehn complex. In another direction, I hoped there was a prospect of generalizing the ideas by showing that there is always a finite index subgroup that acted freely on the product of trees.

Forays into understanding residual finiteness in small-cancellation groups in 1999 led to the study of certain codimension-one subgroups arising from immersed codimension-one graphs. It was then natural to apply Sageev's work [53] on the dual cube complex to cubulate small-cancellation groups [63]. This was an eye-opener for me, as Sageev's construction provided access to a combinatorial geometric structure from ingredients I already had experience with. With Hsu, we cubulated graphs of free groups with cyclic edge groups, and then set out to understand groups with more general splittings [31, 34]. With Hruska, we then made a detailed study of the finiteness properties with papers focusing on the finiteness properties in [29, 30] and generalizing finiteness properties observed in [18, 47, 54, 63].

We began studying raags with Hsu, first showing that they are subgroups of Coxeter groups and hence embed in $SL_n(\mathbb{Z})$ [13, 32], and then examining the separability of the quasi-isometrically embedded subgroups of the raag $\langle\ a, b, c, d \mid [a, b], [b, c], [c, d]\ \rangle$ corresponding to the complement in S^3 of a length 4 chain [33]. Although our proof was not written in that generality, we noticed the separability of complexes that map by a local isometry, but our effort to prove the separability of arbitrary quasi-isometrically embedded subgroups was frustrated.

In 2002, Haglund and I generalized the idea of "clean square complexes" to "special cube complexes" and this dropped the $\mathcal{VH}$ restriction and allowed arbitrary dimensions. The goal of our definition was to obtain separability by extending the notion of canonical completion and retraction to higher dimensions [25]. Surprisingly, this definition magically coincided with the definition of a local isometry to the cube complex of a raag. We immediately set out to generalize the work in [62] to higher dimensions - although it took many years until we finally completed this in [27]. In view of the dual cube complex construction, special cube complexes opened the possibility of reaping algebraic consequences from the hidden cubical geometry of many groups.

2. CAT(0) cube complexes and npc cube complexes

An *n-cube* is a copy of $[-1, 1]^n$. Its *subcubes* are the subspaces obtained by restricting some coordinates to either $+1$ or -1. A *cube complex* is a complex built from cubes glued together along subcubes. The data describing a cube complex is entirely combinatorial; we require that the gluing maps be modeled by (local) isometries where we regard n-cubes as being isometric copies of the corresponding subspaces of $\mathbb{E}^n$.

A *flag complex* S is a simplicial complex with the property that $n + 1$ vertices span an n-simplex if and only if they are pairwise adjacent. Thus a flag complex is determined completely by its 1-skeleton: We can reconstruct S from S^1 by adding an n-simplex for

each complete graph $K(n)$ in S. For instance, a graph S is a flag complex if and only if $\mathsf{girth}(S) \geq 4$. Recall that the *girth* of a graph is the infimum of the lengths of its cycles.

The *link* of a 0-cube v in a cube complex X is the complex built from simplices that corresponds to the ϵ-sphere about v. Specifically, $link(v)$ has an $(n-1)$-simplex for each corner of an n-cube at v. A cube complex X is *nonpositively curved* if $\mathrm{link}(v)$ is a flag complex for each $v \in X^0$. A *CAT(0) cube complex* is a simply-connected nonpositively curved cube complex.

Nonpositively curved cube complexes were introduced by Gromov in [19] as a convenient source of examples of metric spaces with nonpositive curvature. When X is nonpositively curved in the above combinatorial sense, its universal cover $\widetilde{X}$ has a CAT(0) metric such that each n-cube is isometric to the standard Euclidean n-cube. This metric has been constructed in increasing levels of generality by Moussong, Bridson, and Leary [10, 39, 45].

One consequence of a complete CAT(0) metric is that any group acting freely on $\widetilde{X}$ is torsion-free. Some examples of other properties of groups acting on CAT(0) cube complexes are as follows: Let G act cellularly by isometries on the CAT(0) cube complex $\widetilde{X}$. Then G is biautomatic if the action is proper and cocompact [48], G is aTmenable if the action is metrically proper [46, 49], and G satisfies the Tits alternative if $\widetilde{X}$ is finite dimensional and there is an upper bound on the size of stabilizers [56].

3. Raags

Let Γ denote a simplicial graph. The *right-angled Artin group* (*raag*) $A(\Gamma)$ has the following presentation:

$$\langle\ v\ :\ v \in \text{Vertices}(\Gamma)\ \mid\ uv = vu\ :\ (u,v) \in \text{Edges}(\Gamma)\ \rangle$$

Note that the standard 2-complex of a raag is a cube complex with a single 0-cube, a 1-cube for each generator and a 2-cube for each relator. When $\mathsf{girth}(\Gamma) \geq 4$, this 2-complex is a nonpositively curved cube complex. In general, $A(\Gamma)$ is the fundamental group of a nonpositively curved cube complex $R(\Gamma)$ called the *Salvetti Complex* that is obtained by adding an n-cube for each collection of pairwise commutating generators - i.e. each $K(n)$ in Γ. Note that the 2-cubes are already in the standard 2-complex of the above presentation. Some easy examples of raags are: a rank n free group F_n which corresponds to a graph with n vertices and no edges, a rank n free abelian group $\mathbb{Z}^n$ which correspond to a complete graph $K(n)$, and a product $F_n \times F_m$ which corresponds to a complete bipartite graph $K(m,n)$. Every raag is linear, and in fact a subgroup of $SL_n(\mathbb{Z})$ since it is a subgroup of a right-angled Coxeter group [13, 32, 35]. We refer to [12] for more about raags.

4. Special cube complexes

A *midcube* in $[-1,1]^n$ is a connected subspace obtained by restricting exactly one coordinate to 0. Note that an n-cube has n distinct midcubes. A *hyperplane* $\widetilde{Y}$ in a CAT(0) cube complex $\widetilde{X}$ is a connected subspace that intersects each cube in a midcube or in $\emptyset$. As noted by Sageev [53], each midcube lies in a unique hyperplane, and each hyperplane separates $\widetilde{X}$ into two complementary components.

Let $\widetilde{Y}$ be a hyperplane of the universal cover $\widetilde{X}$ of a nonpositively curved cube complex X. Let $H = \mathrm{Stabilizer}(Y)$. Let $Y = H\backslash\widetilde{Y}$, and note that there is a map $Y \to X$. We refer to each such Y as an *immersed hyperplane* of X, and note that each midcube of X extends to a unique immersed hyperplane. When an immersed hyperplane embeds (i.e. its image does not contain distinct midcubes of the same cube of X) then we simply refer to it as a *hyperplane*. For a hyperplane Y that embeds, it is natural to consider the subspace $N^o(Y)$ consisting of the open cubes that it intersects. The open 1-cubes that Y intersects are *dual* to Y. The hyperplane Y is *2-sided* if the space $N^o(Y)$ is isomorphic to $Y \times (-1, 1)$ with $Y \times \{0\}$ corresponding to the subspace Y in the obvious way. When Y is 2-sided we can direct all 1-cubes dual to Y from $Y \times \{-1\}$ to $Y \times \{+1\}$.

We studied the following in [25]:

Definition 4.1. A *special cube complex* is a nonpositively curved cube complex with the following properties:

1. There is no self-crossing hyperplane. That is, each immersed hyperplane of $Y \to X$ is embedded
2. There is no 1-sided hyperplane. That is, each hyperplane of X is 2-sided.
3. There is no hyperplane of X that *self-osculates* in the sense that it is dual to distinct directed 1-cubes with the same initial or terminal 0-cube.
4. There do not exist distinct hyperplanes Y_1, Y_2 of X that *inter-osculate* in the sense that: Y_1, Y_2 intersect, and Y_1, Y_2 are dual to closed 1-cubes that share a 0-cube but do not lie on a common 2-cube.

For instance, any graph is special, any Salvetti complex $R(\Gamma)$ is special, and any CAT(0) cube complex is special. A beautiful source of special cube complexes are the *state complexes* of Abrams and Ghrist [1, 17].

Generalizing separability for a subgroup, we say a double coset HK is *separable* in G if it is closed in the profinite topology of G (i.e. the topology whose basis consist of left cosets of finite-index subgroups). The following criterion for virtual specialness was given in [25]:

Theorem 4.2. *Let X be a compact nonpositively curved cube complex. Suppose that for each immersed hyperplane $A \to X$ we have that $\pi_1 A$ is separable in $\pi_1 X$. Suppose that for each pair of crossing immersed hyperplanes $A \to X$ and $B \to X$, we have $\pi_1 A \pi_1 B$ is separable in $\pi_1 X$. Then X has a finite cover that is special.*

A noncocompact variant of Theorem 4.2 was used in [26] to see that every Coxeter group is virtually special using the cube complex of Theorem 6.1, and it was also used to see that simple-type arithmetic hyperbolic lattices are virtually special in [6]. It is interesting to note that Bergeron had independently engaged with the double hyperplane separability in his studies of totally geodesic submanifolds [5].

Theorem 4.2 has the following consequence:

Corollary 4.3. *Let X be a compact nonpositively curved cube complex. Suppose that $\pi_1 X$ is hyperbolic. If each quasiconvex subgroup of $\pi_1 X$ is separable then X is virtually special.*

A map $\phi : A \to B$ between nonpositively curved cube complexes is a *local isometry* if ϕ is *combinatorial* in the sense that ϕ maps open n-cubes homeomorphically to n-cubes, and ϕ is an *immersion* in the sense that ϕ is locally injective, and finally for each $a \in A^0$ the

induced map $\phi : \mathrm{link}(a) \to \mathrm{link}(\phi(a))$ has the property that if u, v are vertices of $\mathrm{link}(a)$ such that $\phi(u), \phi(v)$ are joined by an edge in $\mathrm{link}(\phi(a))$ then u, v are joined by an edge in $\mathrm{link}(a)$. As observed in [44], if $\phi : A \to B$ is a local isometry then the map $\widetilde{\phi} : \widetilde{A} \to \widetilde{B}$ is an isometric embedding, and moreover $\widetilde{A}$ embeds as a convex subcomplex of $\widetilde{B}$.

The definition of special cube complex was designed to enable the following, and the reader can refer to [25] or [27] for the details:

Lemma 4.4 (Canonical Completion and Retraction). *Let $\phi : A \to B$ be a local isometry of nonpositively curved cube complexes where B is special and A is compact. Then there exists a finite cover $\widehat{B} \to B$ such that $A \to B$ lifts to an embedding $A \hookrightarrow \widehat{B}$. Moreover, there is a retraction $\widehat{B} \to A$.*

Let D be a hyperplane of $\widetilde{X}$. Its *halfspace carriers* are the subcomplexes containing the two components of $\widetilde{X} - D$. Each halfspace carrier is a convex subcomplex since it maps to $\widetilde{X}$ by a local isometry. For a subspace $S \subset \widetilde{X}$ we let $\mathsf{hull}(S)$ denote the intersection of all halfspace carriers of $\widetilde{X}$ containing S. Note that $\mathsf{hull}(S)$ is a convex subcomplex of $\widetilde{X}$ since each halfspace carrier is convex. The following was observed in [23] and [55]. It also has a relatively hyperbolic generalization.

Lemma 4.5. *Let G be a hyperbolic group that acts properly and cocompactly on a CAT(0) cube complex $\widetilde{X}$. Let H be a quasiconvex subgroup of G. Let K be a compact subspace of $\widetilde{X}$. Then $\mathsf{hull}(HK) \subset \mathcal{N}_r(HK)$ for some $r \geq 0$.*

In particular, if X is a compact nonpositively curved cube complex with $\pi_1 X$ hyperbolic, then for each quasiconvex subgroup $H \subset \pi_1 X$, there exists a based local isometry $Y \to X$ such that Y is compact and $\pi_1 Y = H$.

A group G is *residually finite* if the trivial subgroup is the intersection of finite index subgroups of G. A subgroup $H \subset G$ is *separable* if H is the intersection of finite index subgroups of G. Thus G is residually finite precisely if $\{1_G\}$ is separable. Equivalently, H is separable if and only if for each $g \notin H$, there exists a finite quotient $G \to \bar{G}$ such that $\bar{g} \notin \bar{H}$. One can deduce the residual finiteness of $\pi_1 X$ from the specialness of X by applying Lemma 4.5 to a compact convex subcomplex of $\widetilde{X}$ containing $\widetilde{x}, g\widetilde{x}$. Moreover, since G' is residually finite whenever $G' \subset G$, and since $H \subset G$ is separable whenever $[G : G'] < \infty$ and $H \subset G'$ is separable, and since retracts of residually finite groups are separable (they correspond to closed subspaces in the profinite topology) we see from Lemma 4.4 and Lemma 4.5 that quasiconvex subgroups of a special hyperbolic group are separable.

The following theorem [25], connects special cube complexes to raags: Accordingly, we say that a group G is *special* if G is isomorphic to a subgroup of a raag.

Theorem 4.6. *X is special if and only if there is a local isometry $X \to R$ to the Salvetti complex $R = R(\Gamma)$ of a raag.*

Proof. If there is a local isometry $X \to R$, then X is special since an excluded hyperplane pathology would project to a hyperplane pathology in R, which is impossible since R is itself special.

Let Γ be the graph with a vertex for each hyperplane of X and such that two vertices are adjacent if and only if the corresponding hyperplanes cross. Let $R = R(\Gamma)$. As each hyperplane is 2-sided, we can label each 1-cube by the hyperplane it is dual to, and direct all

the dual 1-cubes consistently as above. This provides a map $X^1 \to R^1$ and it is readily seen that this extends to an immersion $X \to R$ because there is no self-osculation, and moreover $X \to R$ is a local isometry because there is no inter-osculation. □

5. Cubical small-cancellation theory

5.a. Classical small-cancellation. Let X denote a graph, and let $\{Y_i \to X\}$ be immersed circles. We summarize this data by $\langle X \mid Y_1, \dots, Y_r\rangle$ and refer to this as a *presentation*. When X is a bouquet of circles, we can regard each Y_i as a word in the generators, and the term presentation nearly corresponds to the usual notion. We let X^* denote the complex associated to the presentation, so X^* is the quotient $X \cup \bigcup_i \mathsf{Cone}(Y_i)$ obtained by attaching a cone with base Y_i to X for each relator Y_i.

A *piece* $P \to X$ is a combinatorial path that factors through lifts to Y_i and Y_j as on the left below, but such that these two lifts are *distinct* in the sense that there is no map $Y_i \to Y_j$ so that the diagram on the right below commutes:

$$\begin{array}{ccc} P & \to & Y_j \\ \downarrow & & \downarrow \\ Y_i & \to & X \end{array} \qquad \begin{array}{ccc} P & \to & Y_j \\ \downarrow & \nearrow & \downarrow \\ Y_i & \to & X \end{array} \tag{5.1}$$

The systole $\|Y_i\|$ is the girth of Y_i. A presentation satisfies the $C'(\frac{1}{n})$ *small-cancellation condition* if $|P| < \frac{1}{n}\|Y_i\|$ whenever P is a piece that lifts to Y_i. Here $|P|$ denotes the length of the immersed path, or equivalently, the distance between the endpoints of the lift of P in $\widetilde{Y}_i \subset \widetilde{X}$.

When $\langle X \mid Y_1, \dots, Y_r\rangle$ satisfies the $C'(\frac{1}{6})$ condition the group $\pi_1 X^* = \pi_1 X / \langle\langle \pi_1 Y_i \rangle\rangle$ is a hyperbolic group many of whose properties are particulary easy to understand. We refer to [41] for a historical account of this theory, and to [43] for a geometric account more consistent with the language below. The main result here is Greendlinger's lemma which can be summarized as follows:

Theorem 5.1. *Any minimal area disk diagram $D \to X^*$ is either*

(1) trivial *in the sense that it consists of a single 0-cell or single closed 2-cell*

(2) *a* ladder *in the sense that it is the union of a sequence of closed 1-cells or 2-cells $R_1 \cup R_2 \cup \cdots \cup R_m$ with $R_i \cap R_j = \emptyset$ for $|i - j| > 1$ and $R_i \cap R_{i+1}$ equal to a (possibly trivial) arc otherwise.*

(3) *D has three or more shells and/or spurs.*

A *shell* is a 2-cell R whose boundary path $\partial_p R = QS$ is the concatenation of two paths, where the *outer path* Q is a subpath of the boundary path $\partial_p D$ and the *inner path* S has the property that $|S| < |Q|$. A *spur* is a 1-cell terminating at a valence 1 vertex in D where $\partial_p D$ backtracks.

5.b. Cubical small-cancellation. A *cubical presentation* $\langle X \mid Y_1, \dots, Y_r\rangle$ consists of a nonpositively curved cube complex X, and a collection of local isometries $Y_i \to X$ of nonpositively curved cube complexes. The group of this presentation is $\pi_1 X / \langle\langle \pi_1 Y_1, \dots, \pi_1 Y_r \rangle\rangle \cong \pi_1 X^*$ where X^* is the complex obtained by attaching cones on the Y_i as above.

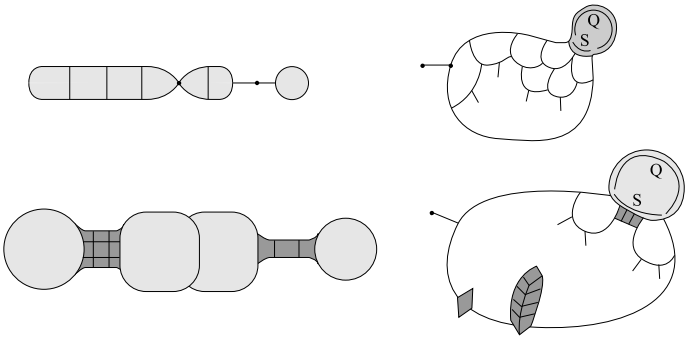

Figure 5.1. Ladders and disk diagrams with spurs, shells, and cornsquares for the classical and cubical cases

In contrast to the classical case, there are now two types of pieces: A *wall-piece* is a path $P \to Y_i$ such that the lift $\widetilde{P} \to \widetilde{Y}_i \subset \widetilde{X}$ has the property that $\widetilde{P}$ is a subpath of $N(V)$ where V is a hyperplane of $\widetilde{X}$ and $N(V)$ is the convex subcomplex consisting of all cubes intersecting V (so $N(V)$ is the closure of $N^o(V)$ discussed earlier). A *cone-piece* is a path $P \to Y_i$ such that $P \to X$ factors as $P \to Y_j$ as on the left of Equation (5.1) and these two paths are distinct in the sense that there is no map $Y_i \to Y_j$ such that the diagram on the right of Equation (5.1). Within $\widetilde{X}$, this means that the lift of P to $\widetilde{Y}_i$ and $\widetilde{Y}_j$ are distinct in the sense that $\widetilde{Y}_i$ and $\widetilde{Y}_j$ look different from the viewpoint of $\widetilde{P}$.

The cubical presentation is $C'(\frac{1}{n})$ if $|P| < \frac{1}{n}\|Y_i\|$ whenever $P \to Y_i$ is a piece. Now $\|Y_i\|$ denotes the infimum of the lengths of the closed essential paths in Y_i, and $|P|$ denotes the distance between the endpoints of the lift of P in $\widetilde{Y}_i \subset \widetilde{X}$. (Here we use the distance in the graph metric on the 1-skeleton.)

Let $P \to X$ be a closed combinatorial path such that $P \to X^*$ is null-homotopic. Note that the 2-cells of X^* are triangles and squares, and the triangles in a disc diagram can be assembled cyclically around 0-cells mapping to conepoints to form *cone-cells* whose interiors are open disks. The boundary path of each cone-cell maps to some Y_i. We are interested in disk diagrams of *minimal area* in the sense that $\big(\#(\text{cone-cells}), \#(\text{squares})\big)$ is minimized in the lexicographical order. Among other things, minimality guarantees that the boundary path of each cone-cell R is essential for otherwise we could replace that cone-cell by a square diagram. A *spur* is as before and a *shell* in D is also as before: it is a cone-cell R such that $\partial_p(R) = QS$ where $|S| < |Q|$ and where Q is a subpath of $P = \partial_p D$. There is now an additional object: A *cornsquare* is a square in D such that (parts of) the two hyperplanes emanating from D end on adjacent 1-cells of $\partial_p D$, and such that they bound a square subdiagram. A *ladder* in X^* is a disk diagram formed from a sequence of cone-cells joined by $n \times m$ square grids with $n, m \geq 0$. See Figure 5.1. The main theorem of cubical small-cancellation theory is very similar to the classical case:

Theorem 5.2. *Suppose that the cubical presentation $\langle X \mid Y_1, \dots, Y_r\rangle$ satisfies the $C'(\frac{1}{12})$ condition. Let $D \to X^*$ be a minimal area diagram. Then either*

(1) *D is a single 0-cell or cone-cell*

(2) *D is a ladder*

(3) *D contains three or more spurs, cornsquares, or shells.*

6. Groups acting on cube complexes

We now turn to the notion of a wallspace introduced by Haglund and Paulin in [24], and the dual cube complex of Sageev [53].

6.a. Wallspaces. A *wall* in a topological space X is a decomposition $X = \overleftarrow{W} \cup \overrightarrow{W}$. It is often simplest to work under the assumption that $\overleftarrow{W} \cap \overrightarrow{W} = \emptyset$. A convenient way to obtain a wall is when a subspace $W \subset X$ has more than one complementary component, in which case we let $\overrightarrow{W}$ be the union of W and some of these components, and we let $\overleftarrow{W} = X - \overrightarrow{W}$. The spaces $\overleftarrow{W}, \overrightarrow{W}$ are the *halfspaces* of the wall. We say p, q are *separated* by the wall $\{\overleftarrow{W}, \overrightarrow{W}\}$ if p, q do not both lie in the same halfspace. A *wallspace* is the space X together with a collection $\mathcal{W}$ of walls such that $\#(p, q) < \infty$ whenever $p, q \in X$. Here $\#(p, q)$ denotes the number of walls separating p, q.

6.b. Codimension-one subgroups. Let G be a f.g. group, and let $\Upsilon = \Upsilon(G, S)$ denote its Cayley graph with respect to a finite generating set S and give Υ the graph metric. A subgroup H of G is *codimension-one* if for some $r > 0$ the complement $\Upsilon - \mathcal{N}_r(H)$ contains more than one H-orbit of component that is *deep* in the sense that it does not lie in $\mathcal{N}_s(H)$ for any $s > 0$. Note that being codimension-one does not depend on the choice of generators although the constant r might be affected. An equivalent formulation is that H is codimension-one if the coset graph $H\backslash\Upsilon$ has more than one end. For instance, any embedding of $\mathbb{Z}^m \subset \mathbb{Z}^n$ is codimension-one precisely when $m = n-1$. Another visual example is any infinite cyclic subgroup of a closed surface group, or indeed, any subgroup $\pi_1 M \subset \pi_1 N$ where M and N are closed aspherical manifolds with $\dim(N) = \dim(M) + 1$.

Given a codimension-one subgroup H of a group G, Sageev produced a wall in the Cayley graph Υ from a codimension-one subgroup H by letting $\overrightarrow{W}$ be HK where K is a deep component, and letting $\overleftarrow{W} = \Upsilon - \overrightarrow{W}$. Note that if $\{\overleftarrow{W}, \overrightarrow{W}\}$ is a wall then $\{g\overleftarrow{W}, g\overrightarrow{W}\}$ is a wall for $g \in G$. By varying $g \in G$, we obtain an infinite set of walls that G will then permute. Performing this procedure for one or more codimension-one subgroups H_i and chosen decompositions of $\Upsilon - \mathcal{N}_{r_i}(H_i)$ we obtain a wallspace that has a *G-action* in the sense that G also acts on the collection of walls. If our collection $\{H_1, \ldots, H_k\}$ is finite then we can be assured that the finiteness condition $\#(p, q) < \infty$ holds so we obtain a genuine wallspace.

6.c. The dual cube complex. Let $(X, \mathcal{W})$ be a wallspace. Sageev defined its *dual CAT(0) cube complex* as follows: Each 0-cube v is a choice of one halfspace from each wall that satisfies the following two conditions:

1. Any two chosen halfspaces of v have nonempty intersection.
2. For some (and hence any) point $x \in X$, all but finitely many of the chosen halfspaces of v contain x.

The 0-cubes u, v are joined by a 1-cube precisely when the u, v choices differ on exactly one wall. For each $n \geq 2$ we add an n-cube whenever its $(n-1)$-skeleton is present. Sageev proved that the dual is CAT(0): the nonpositive curvature condition is immediate, and simple connectivity holds by an argument that uses that every closed path has to pass through 1-cubes corresponding to each wall an even number of times [53].

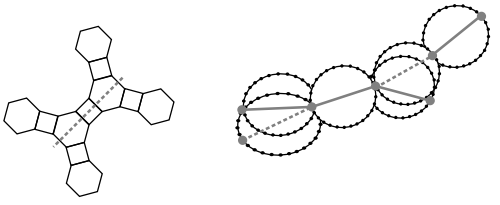

Figure 6.1. A wall for the Coxeter group $\langle a, b, c \mid a^2, b^2, c^2, (ab)^2, (bc)^3 \rangle$, and a wall in an anonymous small-cancellation complex.

We now describe to noteworthy applications of the dual cube complex:

Niblo-Reeves proved the following result in [47]. The walls they used are precisely the reflection walls of the Coxeter group. (See the left of Figure 6.1.)

Theorem 6.1 (Cubulating Coxeter Groups). *Every f.g. Coxeter group acts properly on a finite dimensional CAT(0) cube complex.*

Each $C'(\frac{1}{6})$ 2-complex $\widetilde{X}$ has walls that are trees whose vertices are midpoints of 1-cells of $\widetilde{X}$ and whose edges are arcs in 2-cells joining opposite 1-cells. (See the right of Figure 6.1.)

Theorem 6.2 (Cubulating $C'(\frac{1}{6})$ Groups). *Every f.g. $C'(\frac{1}{6})$ small-cancellation group acts properly and cocompactly on a CAT(0) cube complex [63].*

6.d. Finiteness Properties. The finiteness properties of the dual are related to properties of the walls and their stabilizers. The maximal cubes in the dual (if they exist) correspond to maximal collections of pairwise crossing walls. We obtain cocompactness of the dual when there are finitely many orbits of collections of pairwise crossing walls, as shown by Sageev when the wall stabilizers are quasiconvex and the space X is δ-hyperbolic [54]. We assume now that X is a metric space, as would be the case when X is the Cayley graph of a group or when $X = \mathbb{H}^n$. The group G acts metrically properly on the dual cube complex when there are sufficiently many walls in the sense that $\#(p, q) \to \infty$ when $\mathsf{d}_X(p, q) \to \infty$. A comprehensive examination of the finiteness properties is given in [29]. Producing codimension-one subgroups can be very challenging, and even when they exist, it is often tricky to verify that the group G acts properly on the dual cube complex.

6.e. Cubulating from the boundary. In [7] we gave a criterion to verify that a group G acts properly and cocompactly on a CAT(0) cube complex when there is a rich collection of walls with relatively quasiconvex stabilizers. This result was also obtained by Dufour who applied it to cubulate fibered hyperbolic 3-manifolds in his PhD thesis.

Theorem 6.3. *Let G be a relatively hyperbolic group, and let ∂G denote the Bowditch boundary of G. Suppose that for each pair of points $p, q \in \partial G$ there exists a relatively quasiconvex codimension-one subgroup H such that p, q lie in distinct H-orbits of components of $\partial G - \partial H$. Then G acts properly and relatively cocompactly on a CAT(0) cube complex.*

If the term "relatively" is omitted from Theorem 6.3, the statement applies in the more standard setting where ∂G is the Gromov boundary of a hyperbolic group G, and the meaning of cocompactness in the conclusion is as usual.

In the relatively hyperbolic case, acting *relatively cocompactly* on the dual $\widetilde{C}$ means that there is a collection of convex *parabolic* subcomplexes $\widetilde{C}_i$ that are stabilized by the P_i, and a compact subcomplex K such that $\widetilde{C} = GK \cup \widetilde{G}\widetilde{C}_i$, and these parabolic subcomplexes $\widetilde{C}_i$ are *isolated* in the sense that $g_i\widetilde{C}_i \cap \widetilde{g}_j\widetilde{C}_j \subset GK$ unless $g_i\widetilde{C}_i = g_j\widetilde{C}_j$.

Corollary 6.4. *Let G act freely and cocompactly on $\mathbb{H}^3$. Suppose that for each pair of points $p, q \in \partial\mathbb{H}^3$ there is a quasifuchsian subgroup H such that ∂H is an embedded circle that separates p, q. Then there exists a finite subcollection of quasifuchsian subgroups $\{H_1, \dots, H_k\}$ such that G acts properly and cocompactly on the resulting dual cube complex.*

Kahn and Markovic proved the following in [37]:

Theorem 6.5. *Let M be a closed hyperbolic 3-manifold. For each circle $O \subset \partial\mathbb{H}^3$ there is a sequence of quasifuchsian surfaces $S_i \to M$, such that $\partial\widetilde{S}_i \hookrightarrow \partial\widetilde{M} = \partial\mathbb{H}^3$ converges pointwise to O.*

Kahn and Markovic built these surfaces by amalgamating a family of immersed geodesic pairs of pants, using ergodicity of the geodesic flow to ensure choices so that the surface closes and such that consecutive pants in the gluing nearly followed a fixed $\mathbb{H}^2$ trajectory. In view of Corollary 6.4, we obtain the following consequence of the Kahn-Markovic surfaces:

Corollary 6.6. *Let M be a closed hyperbolic 3-manifold. Then $\pi_1 M$ acts properly and cocompactly on a CAT(0) cube complex.*

Bergeron and I worked this out in 2006 (in the word-hyperbolic case) but the only applications available then were already handled by a direct geometric computation - namely the simple-type arithmetic hyperbolic lattices that were cubulated with Haglund in [6]. Upon hearing of the breakthrough of Kahn-Markovic, we connected it to our work. It appears that there will be further cubulation results following this method, since it avoids certain messy computations. There have not yet been applications using the relatively hyperbolic case, although it is likely that the argument for free-by-cyclic groups in [22] can be generalized in this direction. The case where M is a hyperbolic manifold with nonempty boundary was treated using hierarchies, and is discussed in Section 11.

7. Cubulating Malnormal Amalgams

Definition 7.1. A collection $\{H_1, \dots, H_r\}$ of subgroups of G is *almost malnormal* if $g^{-1}H_i g \cap H_j$ is finite unless $i = j$ and $g \in H_i$. Similarly, the term *malnormal* means that each such intersection of distinct conjugates is trivial.

The following is proven in [31]:

Theorem 7.2. *Let G be a hyperbolic group that splits as a finite graph of groups such that each vertex group is virtually compact special, each edge group is quasiconvex, and the collection of edge groups is almost malnormal. Then G acts properly and cocompactly on a CAT(0) cube complex.*

The idea of the proof of Theorem 7.2 is best motivated by considering the case where all edge groups are infinite cyclic. Let X be a graph of spaces where the vertex spaces are

nonpositively curved cube complexes and the edge spaces are cylinders. Its universal cover, $\widetilde{X}$, is a tree of spaces where the vertex spaces are CAT(0) cube complexes and where the edge spaces are strips attached along geodesics. We make $\widetilde{X}$ into a wallspace as follows: There is a wall for each edge space but the other walls are more complicated. If the attaching geodesics of an edge space have the same combinatorial length on each side, then we choose an equivariant bijection between corresponding hyperplanes in the two vertex spaces and connect corresponding hyperplanes with arcs cutting through the edge space. Otherwise there are more hyperplanes on one side than the other, in which case we choose an injection from the smaller side to the larger side and attach arcs as before. We then equivariantly glue the excess hyperplanes together in pairs using arcs that start and end on excess hyperplanes on the longer side. When these arcs are sufficiently long, and the cyclic subgroup is malnormal, and the vertex space is hyperbolic, then the resulting glued hyperplane-arc-hyperplane objects are genuine walls. Moreover, with careful choices they are quasiconvex and there are sufficiently many so that $\pi_1 X$ acts freely on the resulting dual cube complex.

Remark 7.3. Virtual compact specialness of the vertex groups provide the actual enabling properties of the proof of Theorem 7.2: That the vertex groups act properly and cocompactly on CAT(0) cube complexes, that their edge groups have separable quasiconvex subgroups, and that every quasiconvex wall in an edge group extends to a quasiconvex wall in its vertex group. This last "extension property" is provided by an argument using Lemma 4.5.

Remark 7.4. A relatively hyperbolic variation of Theorem 7.2 is as follows: We assume that G is hyperbolic relative to virtually abelian subgroups $\{P_1, \dots, P_r\}$, but we require that each edge group is relatively quasiconvex and genuinely hyperbolic. We reach the weaker conclusion that G acts *cosparsely* on the dual cube complex $\widetilde{C}$. This means that for each i there is a cube complex $\widetilde{C}_i$ stabilized by P_i and quasi-isometric to some $\mathbb{E}^n$, and there is a compact subcomplex K such that $\widetilde{C} = GK \cup G\widetilde{C}_1 \cup \cdots \cup G\widetilde{C}_r$ and finally $g_i\widetilde{C}_i \cap g_j\widetilde{C}_j \subset GK$ unless $g_i\widetilde{C}_i = g_j\widetilde{C}_j$.

There is more work to be done here: One expects a generalization of Theorem 7.2 to apply to an arbitrary relatively hyperbolic group that splits as a finite graph of virtually compact special vertex groups with edge groups that are relatively quasiconvex and also relatively malnormal in the sense that they intersect their conjugates in finite or parabolic subgroups. (See Problem 13.31.) However, there are groups G that split as a graph of abelian vertex groups with maximal cyclic edge groups, such that G cannot act freely on a CAT(0) cube complex [59].

8. Virtually special cubical Malnormal Amalgams

The following is the main result in [27] which substantially generalizes [62]:

Theorem 8.1 (Virtual Specialness of Malnormal Cubical Amalgams). *Let G be a hyperbolic group that acts properly and cocompactly on a CAT(0) cube complex $\widetilde{X}$. Suppose there is a hyperplane $\widetilde{Y}$ such that $g\widetilde{Y} \cap \widetilde{Y} = \emptyset$ unless $g\overleftarrow{\widetilde{Y}} = \overleftarrow{\widetilde{Y}}$ where $\overleftarrow{\widetilde{Y}}$ denotes the left halfspace of $\widetilde{Y}$ in $\widetilde{X}$. Suppose that* $\mathrm{Stabilizer}(\widetilde{Y})$ *is almost malnormal in G. Let $N^o(\widetilde{Y})$ denote the open cubical neighborhood of $\widetilde{Y}$ in $\widetilde{X}$. Suppose that for each component $\widetilde{X}_*$ of $\widetilde{X} - GN^o(\widetilde{Y})$ the group* $\mathrm{Stabilizer}(\widetilde{X}_*)$ *has a finite index subgroup that acts freely on $\widetilde{X}_*$ with a special quotient. Then G has a finite index subgroup G' that acts freely with a special quotient.*

Corollary 8.2 (Geometric Special Case). *Let X be a compact nonpositively curved cube complex with $\pi_1 X$ hyperbolic. Let $Y \subset X$ be a hyperplane. Suppose that Y is embedded and 2-sided so that $N^o(Y) \cong Y \times (-1, 1)$. Suppose that $\pi_1 Y$ is malnormal in $\pi_1 X$. Suppose that each component of $X - N^o(Y)$ is virtually special. Then X is virtually special.*

To prove virtual specialness, we show that every quasiconvex subgroup is separable and thus apply Corollary 4.3. Let us focus on the statement of Corollary 8.2 in the case where $X - N^o(Y)$ is a disjoint union $L \sqcup R$. The heart of the matter is to be able to show that for any finite covers $\widehat{L}' \to L$ and $\widehat{R}' \to R$, there are finite regular covers $\widehat{L} \to L$ and $\widehat{R} \to R$ that factor through them, so that they induce the same cover $\widehat{Y}$ of Y. We are thus able to build a cover of X from the disjoint union of a collection of covers of copies of $\widehat{L}$ and $\widehat{R}$, by attaching copies of $N(\widehat{Y}) = \widehat{Y} \times [-1, 1]$. The key to producing $\widehat{L}$ and $\widehat{R}$ is to use functorial properties of the canonical completion and retraction of Lemma 4.4. These properties allow one to treat a malnormal quasiconvex subgroup A of a hyperbolic special group B almost as if A were a retract of B.

9. Malnormal quasiconvex hierarchy

Definition 9.1. The group G has a [*malnormal*] *quasiconvex hierarchy terminating in groups of type $\mathcal{T}$* if G can be built from groups of type $\mathcal{T}$ by a finite sequence of finite graphs of groups, such that the edge groups are f.g. and quasi-isometrically embedded [and form an almost malnormal collection] at each stage.

When $\mathcal{T}$ is the class of finite groups, we simply say that G has a *quasiconvex hierarchy*. Our main case of interest is when G is hyperbolic in which case being quasi-isometrically embedded is equivalent to being quasiconvex. When G has a specified relatively hyperbolic structure it is natural to instead require that the edge groups are relatively quasiconvex.

Example 9.2. The fundamental groups of surfaces have hierarchies, and these hierarchies are always quasiconvex, and also often malnormal (except for the torus and klein bottle and when an edge group is generated by a glide reflection). Any Haken 3-manifold M has a (topological) hierarchy which provides a hierarchy for $\pi_1 M$. When M is a fibered hyperbolic 3-manifold this gives a very short hierarchy, but the hierarchy will not be quasiconvex since the fundamental group of the fiber is not quasiconvex. A similar situation occurs for one-relator groups, whose Magnus-Moldavanskii hierarchies (providing the foundation for the theory of one-relator groups), but these hierarchies are typically not quasiconvex.

Combining Theorem 7.2 and Theorem 8.1 we have the following result which functions as a target criterion for virtual specialness.

Theorem 9.3. *Let $\mathcal{S}$ denote the class of hyperbolic virtually compact special groups. Let G be a hyperbolic group with a malnormal quasiconvex hierarchy terminating in groups of type $\mathcal{S}$. Then G is in $\mathcal{S}$.*

10. Special quotient theorem

Theorem 10.1 (Malnormal Special Quotient Theorem). *Let G be hyperbolic and virtually compact special. Let $\{H_1, \ldots, H_r\}$ be an almost malnormal collection of quasiconvex sub-*

groups. There exist finite index subgroups $\{H_i^\circ \subset H_i\}$, such that for any normal finite index subgroups $H_i' \subset H_i$ with $H_i' \subset H_i^\circ$ the quotient $\bar{G} = G/\langle\langle H_1', \dots, H_r' \rangle\rangle$ is hyperbolic and virtually compact special.

Theorem 10.1 is already interesting when G is a rank 2 free group and $\{H_1, \dots, H_r\}$ is a malnormal collection of f.g. subgroups. Among other things we find that $\bar{G}$ is residually finite. In particular, we obtain the following corollary:

Corollary 10.2. *Let $\{W_1, \dots, W_r\}$ be a collection of elements of a free group F with basis $\{a, b\}$, and suppose that W_i, W_j do not have conjugate nontrivial powers for $i \neq j$. Then there exists $k_i \geq 1$ for each i so that the following group is virtually compact special for all $n_i \geq 1$.*

$$\langle a, b \mid W_1^{n_1 k_1}, \dots, W_r^{n_r k_r} \rangle$$

In particular, we can control the relative orders of $\{\bar{W}_1, \dots, \bar{W}_r\}$ in finite quotients $F \to \bar{F}$.

As a finite collection of quasiconvex subgroups has finite *height* which is the maximal number of infinitely intersecting distinct conjugates [18], variations of the following consequence can be obtained by inductively repeatedly applying Theorem 10.1 to an almost malnormal collection of subgroups arising from intersections of conjugates of the $\{H_1, \dots H_r\}$:

Corollary 10.3 (Special Quotient Theorem). *Let G be hyperbolic and virtually compact special. Let $\{H_1, \dots, H_r\}$ be a collection of quasiconvex subgroups. There exist finite index subgroups $H_i' \subset H_i$ such that the quotient $G/\langle\langle H_1', \dots, H_r' \rangle\rangle$ is hyperbolic and virtually compact special.*

We prove Theorem 10.1 by choosing the H_i° so that $\bar{G} = G/\langle\langle H_i' \rangle\rangle$ is arranged to have a finite index subgroup with an almost malnormal quasiconvex hierarchy, and so Theorem 9.3 implies that $\bar{G}$ is virtually compact special. The proof is organized via cubical small-cancellation theory. My original conception for the proof was based on my (thus far unrealized) expectation that $\bar{G}$ would be cubulated (using a generalization of Theorem 6.2), in which case the proof would be completed by using only Theorem 8.1 since the hyperplanes are malnormal. When I was ultimately unable to realize this expectation, I instead applied Theorem 9.3. The required properties of the malnormal quasiconvex hierarchy were verified using cubical small-cancellation theory. In retrospect, much of this could have been done using the theory of Osin or Groves-Manning [20, 50], keeping track of the walls where the virtual splittings would take place. Nevertheless, the cubical small-cancellation theory helped navigate towards the desired virtual hierarchy, and it is another matter to reposition an exposition upon a recognized target.

A relatively hyperbolic version of Theorem 10.1 can also be proven that follows the same argument, although we only implemented this in a limited fashion in [60]. In particular, we showed the following:

Theorem 10.4. *Let G be hyperbolic relative to virtually abelian subgroups $P_1, \dots, P_r$. Suppose that G is virtually compact special. Then there exist finite index subgroups $P_i^\circ \subset P_i$ such that for any normal finite index subgroups $P_i' \subset P_i$ with $P_i' \subset P_i^\circ$, the quotient $\bar{G} = G/\langle\langle P_1', \dots, P_r' \rangle\rangle$ is virtually compact special and hyperbolic.*

One consequence of Theorem 10.4 is that for a closed hyperbolic 3-manifold M with $\partial M = T_1 \sqcup \cdots \sqcup T_r$, there are covers $\widehat{T}_r^\circ \to T_r$ so that for any further covers $\widehat{T}_r' \to \widehat{T}_r^\circ$,

there exists a regular cover $\widehat{M} \to M$ such that each component of the preimage of T_r is isomorphic as a covering space to $\widehat{T}'_r$.

11. Quasiconvex hierarchy

Theorem 11.1. *Let G be a hyperbolic group with a quasiconvex hierarchy. Then G is virtually compact special.*

The proof is staged by applying Theorem 10.1 to the vertex group of an HNN extension $A*_{C^t=D}$ (relative to subgroups related to intersections of various conjugates of C, D) and obtaining a quotient group $\bar{A}*_{\bar{C}^{\bar{t}}=\bar{D}}$ that is closer to being an almost malnormal HNN extension in the sense that $\{\bar{C}, \bar{D}\}$ has lower height in $\bar{G}$ than $\{C, D\}$ in G. The result then follows by induction.

Theorem 11.1 applies to one-relator groups with torsion, since their Magnus-Moldavanskii hierarchy is quasiconvex, and thus resolves Baumslag's conjecture on the residual finiteness of one-relator groups with torsion. It applies to closed hyperbolic 3-manifolds with a geometrically finite incompressible surface since by a result of Thurston's, the Haken hierarchy is quasiconvex provided the first cut is geometrically finite [11].

There are relatively hyperbolic versions of this in [60] which are not powerful enough to handle an arbitrary relatively hyperbolic group with a quasiconvex hierarchy, but they are sufficient to handle fundamental groups of cusped hyperbolic 3-manifolds, and can also handle limit groups which have a hierarchy whose edge groups are cyclic at each stage. A useful step in the relatively hyperbolic direction is the following:

Theorem 11.2. *Let G be hyperbolic relative to $\mathbb{Z}^2$ subgroups. Suppose that G splits as a graph of groups where the vertex groups are virtually compact special and hyperbolic, and the edge groups are relatively quasiconvex. Then G is virtually compact special.*

A hyperbolic 3-manifold M with $\partial M \neq \emptyset$ has a finite cover $\widehat{M}$ with an incompressible geometrically finite surface that cuts all the tori. We thus obtain:

Corollary 11.3. *Let M be a hyperbolic 3-manifold with nonempty boundary. Then $\pi_1 M$ has a finite index subgroup that is isomorphic to π_1 of a compact special cube complex.*

12. Virtually Haken conclusion

A final goal for understanding cubulated groups in the hyperbolic setting was achieved by Agol who proved the following result [3]. I first openly conjectured this and its associated 3-manifold consequence at the 2005 Spring Topology and Dynamics conference and have been working towards it since then.

Theorem 12.1. *Let G be a hyperbolic group that acts properly and cocompactly on a CAT(0) cube complex $\widetilde{X}$. Then G contains a finite index torsion-free subgroup G' such that $G'\backslash\widetilde{X}$ is special.*

In view of Corollary 6.6, this resolved the virtual Haken problem for closed hyperbolic manifolds, and it conclusively impacts geometric group theory, perhaps most obviously since

all f.p. $C'(\frac{1}{6})$ groups are virtually special in view of Theorem 6.2. In a reasonable sense, most groups with comparatively few relators are given by a $C'(\frac{1}{6})$ presentations, so it seems that most groups arising in combinatorial group theory are virtually special.

A quick sketch of the proof of Theorem 12.1 proceeds as follows: A *block* is a compact space that is the quotient $J\backslash\widetilde{Y}$ by a torsion-free subgroup $J \subset G$ where $\widetilde{Y}$ is the intersection of a collection of closed halfspaces of $\widetilde{X}$, and where the hyperplanes of Y embed. The *faces* of $\widetilde{Y}$ are the intersections with hyperplanes that don't separate it, and the images of these faces are *faces* of the block Y. Color all the faces so that intersecting faces have different colors. Repeatedly glue covers of blocks together along faces of the same color to form larger blocks (with fewer types of faces). Here the special quotient theorem is ingeniously applied to produce the covers that ensure that we are gluing along isomorphic faces. With each gluing, there are fewer colors of exposed faces, and one eventually obtains a space corresponding to a quotient of $\widetilde{X}$ by a finite index torsion-free subgroup. With some additional coloring care one can directly arrange that this space already be special. Alternatively, since the hyperplanes embed one can apply Theorem 11.1 and pass to a finite special cover.

We have described that cusped hyperbolic 3-manifolds and closed hyperbolic 3-manifolds have virtually compact special π_1. Liu showed that a graph manifold is virtually special exactly when it admits a metric of nonpositive curvature [40]. To complete the picture, we mention the following obtained with P.Przytycki [52]:

Theorem 12.2. *Let M be a compact irreducible 3-manifold that is neither hyperbolic nor a closed graph manifold. Then M has a finite cover $\widehat{M}$ such that $\pi_1\widehat{M} \cong \pi_1 X$ where X is a special cube complex.*

13. A collection of problems

G is *locally indicable* if every nontrivial finite generated subgroup $H \subset G$ has in infinite cyclic quotient. A hyperbolic group G is *locally quasiconvex* if each f.g. subgroup of G is quasiconvex. Examples of locally indicable groups that are also locally quasiconvex are given in [58]. There are no known torsion-free locally quasiconvex groups that are not also locally indicable. However there are locally indicable hyperbolic groups that are not locally quasiconvex (for instance, hyperbolic free-by-cyclic groups). It is conceivable that the following conjecture holds with only one of the assumptions of locally quasiconvex or locally indicable. There are not yet enough examples understood here.

Conjecture 13.1. Let G be a hyperbolic group that is locally quasiconvex and locally indicable. Then G acts freely and cocompactly on a CAT(0) cube complex.

As described in Lemma 4.5, cyclic subgroups of hyperbolic special groups are virtual retracts. The following proposes that this is essentially a characterization of specialness. It is conceivable that one could find examples of hyperbolic groups where every infinite cyclic subgroup survives in the abelianization of some finite index subgroup.

Conjecture 13.2. A f.g. (hyperbolic) group G is virtually special iff every cyclic subgroup is a virtual retract.

Problem 13.3. Let G be [relatively] hyperbolic. Show that G acts properly on a CAT(0)

cube complex iff every cyclic subgroup is cut by a [relatively] quasiconvex codimension-1 subgroup. (The "if" direction is straightforward).

Problem 13.4. Does every braid group act freely (and cocompactly) on a CAT(0) cube complex? Is every braid group virtually special?

I suspect the answer to the above problems might be no for B_4, although the second problem will be easier to negate. We note that B_4 was shown to be the fundamental group of a compact nonpositively curved space in [9], and other researchers have pushed this to higher B_n, but asking for a nonpositively curved cube complex is considerably more demanding.

Problem 13.5. Characterize when a group that is F_n-by-F_m acts freely on a CAT(0) cube complex. (In particular, find examples that do not act freely.)

Problem 13.6. Let G be the fundamental group of a compact nonpositively curved cube complex. Is G hopfian?

Problem 13.7. Show that the isomorphism problem for fundamental groups of compact nonpositively curved cube complexes is undecidable.

Problem 13.8. Show that not being virtually special is undecidable for compact nonpositively curved cube complexes (even for npc $\mathcal{VH}$-complexes).

The following problem is phrased in the direction that I think it will be resolved:

Problem 13.9. (Gromov) Find a compact nonpositively curved square complex X such that $\pi_1 X$ is not hyperbolic, but $\pi_1 X$ does not contain $\mathbb{Z}^2$ subgroup.

I hope the following variant of a well-known problem in geometric group theory will be approachable for special cube complexes:

Problem 13.10. Let X be a compact special cube complex. Suppose that $\pi_1 X$ is hyperbolic relative to abelian subgroups. Show that $H \subset \pi_1 X$ is quasi-isometrically embedded if H is malnormal. More generally, show that H is quasi-isometrically embedded unless there are infinitely many left cosets $\{Hg_i\}$ such that $g_i^{-1} H g_i \cap H$ is neither parabolic nor finite.

Problem 13.11. Let H be a f.g. quasiisometrically embedded subgroup of a raag. Is H separable? Same question under the stricter hypothesis that H is quasiconvex with respect to the CAT(0) metric.

Problem 13.12. Suppose G is special, so G is a subgroup of a raag. Suppose $G = \pi_1 X$ with X a compact nonpositively curved cube complex. Is X virtually special? Similarly, suppose X, Y are compact nonpositively curved cube complexes with $\pi_1 X \cong \pi_1 Y$. Is X virtually special if and only if Y is virtually special?

Problem 13.13. Find conditions on a 2-complex X that ensure that there are no codimension-one subgroups (á la the Garland spectral gap condition of [4, 68]). Find conditions that control the "direction" of the codimension-one subgroups.

Problem 13.14. Does every infinite f.p. $C(6)$ group have a codimension-1 subgroup? Does every infinite f.p. $C(4) - T(4)$ group have a codimension-1 subgroup?

Problem 13.15. Let G be a hyperbolic group with a hierarchy. Does G act properly and cocompactly on a CAT(0) cube complex? In particular, this should be true for a hyperbolic one-relator group. The case of free-by-cyclic groups is treated in [21, 22]. Another test case to consider are f.g. free-by-free groups.

Problem 13.16. Let H be a malnormal quasiconvex subgroup of a hyperbolic group G that acts properly and cocompactly on a CAT(0) cube complex. Is $G/\langle\langle H'\rangle\rangle$ cubulated when $H' \subset H$ and the systole of H' is sufficient. Does $G/\langle\langle H'\rangle\rangle$ always contain a codimension-1 subgroup? (I guess these have negative answers in general, but they hold when H is cyclic [60]).

Problem 13.17. Give conditions on a cubical presentation $\langle X \mid Y_1, \dots, Y_r\rangle$ that guarantee that the corresponding quotient group $\pi_1 X^*$ acts properly on a CAT(0) cube complex. Some conditions are given when X is 1-dimensional in [60].

Problem 13.18. Generalize the cubical small-cancellation theory in [60] to deal with quotients of groups acting (not freely) on a CAT(0) cube complex $\widetilde{X}$.

Conjecture 13.19. Let X be a compact special cube complex with $\chi(X) \geq 0$. Then either $\pi_1 X$ is abelian, or $\pi_1 X$ contains a f.g. non-abelian subgroup H containing a f.g. normal subgroup N with $H/N \cong \mathbb{Z}$.

Show that if X is 2-dimensional and special and $\chi(X) > 0$, then either $\pi_1 X = 1$ or $\pi_1 X$ contains a f.g. subgroup that is not f.p.

The plan is to apply Bestvina-Brady Morse theory [8] to a suitable immersed subspace. This was my intended route towards virtual fibering before Agol produced his criterion - which is a sophisticated 3-manifold topology argument enabled by a basic property enjoyed by raags [2]. Conjecture 13.19 is examined when G acts properly and cocompactly on a Bourdon building in [66].

A *complete square complex* (CSC) is a nonpositively curved square complex X such that the link of each 0-cube of X is a complete bipartite graph. Equivalently, X is a CSC if $\widetilde{X}$ is isomorphic to the product of two trees.

Problem 13.20. Let X be a compact CSC with $\chi(X) > 0$. Does $\pi_1 X$ contain a f.g. subgroup that is not f.p.?

Problem 13.21. Give novel examples of compact nonpositively curved cube complexes that are not virtually special. Currently, all known nonexamples can be traced to an irreducibe CSC.

Conjecture 13.22. Let X be a compact nonpositively curved cube complex. Then X is virtually special iff for each immersed hyperplane $D \to X$, there are finitely many distinct subgroups of $\pi_1 D$ that are of the form $\pi_1 D \cap g\pi_1 D g^{-1}$.

Motivation for the above conjecture can be found in the realm of CSC's (see [65] and the problems listed there): A CSC is virtually special (equivalently, it is a virtually product) iff one (and hence all) of its hyperplanes satisfy the finiteness condition listed above.

Conjecture 13.23. Let H be a quasiconvex codimension-one subgroup of a hyperbolic group G. Then G has a finite index subgroup that splits along H. This should follow the proof in [3].

The following is a variation on the Algebraic Torus Theorem [16]:

Problem 13.24. Suppose G has a codimension-1 amenable subgroup. Does G virtually splits over an amenable subgroup?

Problem 13.25. (Kropholler-Roller Conjecture [38]) Let H be a f.g. subgroup of a f.g. group G. Suppose there is an H almost-invariant proper subset $A \subset G$ with $A = HAH$. Does G split over a subgroup (presumably related to H)?

Problem 13.26. Let M be a hyperbolic 3-manifold. Does M have a finite cover that is homeomorphic to a nonpositively curved cube complex?

Problem 13.27. Let M be a cusped hyperbolic 3-manifold. Does M have a finite index subgroup that is the fundamental group of a 2-dimensional nonpositively curved cube complex. A $\mathcal{VH}$-complex? Equivalently, does there exist $\widehat{M}$ such that $\pi_1\widehat{M}$ acts freely on the product of two trees?

Problem 13.28. Let M be a closed hyperbolic 3-manifold. Does $\pi_1 M$ have a finite cover that is the fundamental group of a compact 3-dimensional nonpositively curved cube complex. Does $\pi_1 M$ have a finite index subgroup that acts freely on the product of three trees?

Problem 13.29. Let X be a nonpositively curved cube complex that is homeomorphic to a closed manifold. Is X virtually special? (I guess there is an example with an irreducible CSC mapped inside by a local isometry).

Problem 13.30 ("Special" Charney-Davis-Hopf conjecture). Let M be a closed $2n$-manifold homeomorphic to a special cube complex. Show that $(-1)^k\chi(M) \geq 0$.

Problem 13.31. Let G be hyperbolic relative to abelian subgroups. Suppose G splits as a graph of groups where all the vertex (or equivalently all the edge groups) are relatively quasiconvex. Suppose the edge groups are relatively malnormal, and vertex groups are virtually compact special. Show that G acts properly and [relatively cocompactly] on a CAT(0) cube complex. Generalize this further to handle the case where the parabolic subgroups are virtually special (instead of just virtually abelian).

Motivation for the following problem is that it was done in the special case of certain cusped hyperbolic manifolds in [42].

Problem 13.32. Let G be hyperbolic relative to proper subgroups $\{P_i\}$. Suppose G acts properly and cocompactly on a CAT(0) cube complex. Find a codimension-one subgroup that does not contain any infinite order parabolic elements.

Problem 13.33. Let G act properly and cocompactly on a nonpositively curved cube complex. Suppose G is hyperbolic relative to subgroups $\{P_1, \ldots, P_r\}$. Let $P_i' \subset P_i$ be subgroups such that each $P_i/\langle\langle P_i' \rangle\rangle$ acts properly [and cocompactly] on a CAT(0) cube complex. Does $G/\langle\langle P_1', \ldots, P_r' \rangle\rangle$ act properly [and cocompactly] on a CAT(0) cube complex?

One approach to the above problem follows the proof of Theorem 10.1.

Problem 13.34. Let G act properly and cocompactly on a CAT(0) space $\widetilde{X}$. Let H be a quasiconvex subgroup of G (i.e. an orbit Hx is *quasiconvex* in the sense that there exists r such that any geodesic with endpoints in Hx lies in $\mathcal{N}_r(Hx)$). Suppose that W is a wall in

$\widetilde{X}$ whose stabilizer is H. Is the dual cube complex finite dimensional? Equivalently, does H have the bounded packing property (see [30])? The same problem for quasi-isometrically embedded subgroups. Some examples of CAT(0) groups with such walls are the rhombus groups in [36].

Problem 13.35. Suppose a hyperbolic group G acts freely on a CAT(0) cube complex. Does G act freely and cocompactly on a CAT(0) cube complex? I guess there are counterexamples. The work of [14] might be relevant here.

Here are two variants to the above problem: Let G be an aTmenable hyperbolic group. Does G act metrically properly on a CAT(0) cube complex? Let G be a hyperbolic group that is a subgroup of a raag. Is G the fundamental group of a compact nonpositively curved cube complex?

Problem 13.36. Virtual Specialness of hierarchies without relative hyperbolicity. This is very open ended. It should require a finiteness property on the height as in Conjecture 13.22.

Problem 13.37. Suppose that G acts properly and cocompactly on a CAT(0) space. Suppose G splits as a graph of groups where each vertex group acts freely on a CAT(0) cube complex. Does G act freely on a CAT(0) cube complex? (Perhaps B_4 will provide a counterexample.)

Problem 13.38. Let X be a compact nonpositively curved cube complex. Suppose that $\pi_1 D$ is separable in $\pi_1 X$ for each immersed hyperplane $D \to X$. Does it follow that X is virtually special?

Harder: Suppose that all hyperplanes are embedded, 2-sided, and do not self-osculate. Does it follow that X is virtually special?

Problem 13.39. Let G be hyperbolic relative to subgroups $\{P_1, \dots, P_r\}$. Suppose that each P_i is quasi-isometric to a CAT(0) cube complex. Prove that G is quasi-isometric to a CAT(0) cube complex. (This holds when G is hyperbolic [27].)

Problem 13.40. Is every CAT(0) space (with a proper cocompact group action) quasi-isometric to a CAT(0) cube complex?

Problem 13.41. Challenge: Give an example of two groups G_1, G_2 that are quasi-isometric, but where G_1 is the fundamental group of a compact nonpositively curved cube complex, and G_2 has property (T).

Problem 13.42. Characterize the groups acting metrically properly [or freely] on CAT(0) cube complexes that have a quadratic isoperimetric function. (One expects a characterization in terms of properties of a wallspace structure on G.)

Problem 13.43. Let G be hyperbolic relative to abelian groups, and suppose G has a cyclic hierarchy terminating in free-abelian groups (that is, at each step the amalgamated subgroup is is either trivial or cyclic). Is G virtually a limit group? (This is related to special cube complexes through Sela's retractive towers.)

Problem 13.44. Let G act on a CAT(0) cube complex $\widetilde{X}$ with amenable [or even aTmenable] vertex stabilizers, trivial edge stabilizers, and finitely many orbits of hyperplanes. Is G aTmenable? (See [46, 49] for the finite stabilizer case).

Problem 13.45. Let G be a hyperbolic group that splits as a graph of hyperbolic groups with aTmenable vertex groups. Show that G is aTmenable.

Problem 13.46. Let G be an aTmenable hyperbolic group. Let h be an infinite order element. Show that $G/\langle\langle h^n \rangle\rangle$ is aTmenable for sufficiently large n.

Problem 13.47. Does every f.g. raag G admit a faithful discrete affine representation? If not all raags, then which special G admit such representations? See [15] for the case when G is free.

Problem 13.48. Does G satisfy Kaplansky's zero divisor conjecture hold when G acts freely on a CAT(0) cube complex? That is, does the group ring $R[G]$ have no zero-divisors when R is an integral domain? (G need not satisfy the unique product property as Promislow's example [51] acts freely on CAT(0) cube complex.)

Problem 13.49. Let $P(\Gamma)$ be the ring of formal power series with variables equal to the vertices of Γ, and where two such variables commute if the corresponding vertices are adjacent. Let U be the group of units of $P(\Gamma)$. Suppose $G \subset U$ is a f.g. subgroup. Is G (virtually) a subgroup of a raag?

Problem 13.50. Let G be the fundamental group of a special cube complex. Suppose that G is not a surface group nor free. Does G contain an infinite index subgroup that is not free? Does G contain a surface subgroup? (It suffices to prove this when G is not free and G splits as an amalgam of a free group along a malnormal subgroup.)

Problem 13.51. Let G be the fundamental group of a nonpositively curved complex complex X. Let $\mathsf{cd}(G)$ denote the cohomological dimension of G. Prove that for $0 \leq k \leq \mathsf{cd}(G)$ there is a subgroup $H_k \subset G$ with $\mathsf{cd}(H_k) = k$. Arguing by induction on the dimension, this is equivalent to showing that for some hyperplane Y of X, $\mathsf{cd}(\pi_1 Y) \geq \mathsf{cd}(G) - 1$.

Conjecture 13.52. Every lattice in hyperbolic space acts properly and cocompactly on a CAT(0) cube complex. This is still open for uniform arithmetic lattices [6]. (In the nonuniform case one should conclude: either relatively cocompactly or virtually cocompactly.) The same for geometrically finite subgroups.

Problem 13.53. Suppose G is a word-hyperbolic group that acts properly and cocompactly on a CAT(0) cube complex. Prove that G is a discrete subgroup of $\mathrm{Isom}(\mathbb{H}^n)$ for some n.

Problem 13.54. Let M be a hyperbolic m-manifold. Let J be a geometrically finite subgroup of $\pi_1 M$. Prove that for some $n \geq m$ there is (virtually?) a discrete representation $\pi_1 M \to \mathrm{Isom}(\mathbb{H}^n)$ and a hyperplane $\mathbb{H}^p \subset \mathbb{H}^n$ such that J is the preimage of $\mathrm{Stabilizer}(\mathbb{H}^p)$.

6. Topology

A guide to (étale) motivic sheaves

Joseph Ayoub

Abstract. We recall the construction, following the method of Morel and Voevodsky, of the triangulated category of étale motivic sheaves over a base scheme. We go through the formalism of Grothendieck's six operations for these categories. We mention the relative rigidity theorem. We discuss some of the tools developed by Voevodsky to analyze motives over a base field. Finally, we discuss some long-standing conjectures.

Mathematics Subject Classification (2010). Primary 14C25, 14F05, 14F20, 14F42; Secondary 18F20.

Keywords. Motives, motivic sheaves, motivic cohomology, Grothendieck's six operations, conservativity conjecture, motivic t-structures.

1. Introduction

The (co)homological invariants associated to an algebraic variety fall into two classes:

(a) the *algebro-geometric invariants* such as higher Chow groups (measuring the complexity of algebraic cycles inside the variety) and Quillen K-theory groups (measuring the complexity of vector bundles over the variety);

(b) the class of *transcendental invariants* such as Betti cohomology (with its mixed Hodge structure) and ℓ-adic cohomology (with its Galois representation).

The distinction between these two classes is extreme.

- The algebro-geometric invariants are abstract Abelian groups, often of infinite rank, carrying no extra structure.[1]They vary chaotically in families and are not computable in any reasonable sense.
- On the other hand, transcendental invariants are concrete groups of finite rank (over some coefficient ring) carrying a rich extra structure. Together with their extra structure, they vary "continuously" in families.

Nevertheless, all these invariants are expected to be shadows of some master invariants, called the *motives* of the algebraic variety. The algebro-geometric invariants are expected to be groups of morphisms, extensions and higher extensions between these motives and other basic ones (such as Tate motives), while each of these motives *realizes* (i.e., gives rise) to a multitude of transcendental invariants of different types that, a priori, look poorly related.

Proceedings of the International Congress of Mathematicians, Seoul, 2014

One of the ultimate goals of the theory of motives is to serve as a bridge *between the above two classes of cohomological invariants.*

Until now, establishing a fully satisfactory theory of motives has defied all attempts. Thinking about it as a bridge between (a) and (b), one can describe the present status of the theory as a broken bridge or, better, as a union of two half-bridges that, for the moment, fail to meet.

- The first half bridge, the one starting from (a), is a theory of motives that gives a satisfactory framework for understanding the algebro-geometric invariants.
- The second half-bridge, the one starting form (b), is a theory of motives that encapsulates the transcendental invariants and endows them with universal extra structures.

Concerning the second half-bridge, we just mention few highlights. In the *pure* case, i.e., for smooth and proper varieties, an approach was pioneered by Grothendieck [20]. Roughly speaking, Grothendieck's idea was to "decompose" smooth and proper varieties into "cohomological atoms" called *pure numerical motives* using certain *algebraic cycles* whose existence would be guaranteed by his (yet unproven) *Standard Conjectures* [12]. Later on, Deligne [11] and then André [2] made Grothendieck's approach unconditional by replacing algebraic cycles with *absolute Hodge cycles* and *motivated cycles* respectively. In the *mixed* case, i.e., for possibly open and singular varieties, an approach was invented by Nori (unpublished, but see [23, §5.3.3] for an account) based on his weak Tannakian reconstruction theorem which is an abstract devise yielding an Abelian category out of a representation of a diagram (aka., quiver). The main geometric ingredient behind most results about Nori's motives is the so-called *Basic Lemma* which can be considered as an enhanced form of the Lefschetz hyperplane theorem. In all these approaches (in the pure and mixed cases), the outcome is a *Tannakian* (and hence *Abelian*) category of motives whose fundamental group is the so-called *motivic Galois group*. It is also important to note here a crucial drawback: except the original construction of Grothendieck which is conditional on the Standard Conjectures, all available unconditional constructions of Abelian categories of motives depend on transcendental data (namely, a Weil cohomology theory such as Betti cohomology or ℓ-adic cohomology). For this reason, the existence of the "true" Abelian category of motives is still considered to be an open question.[2]

The present article is mainly concerned with the first half-bridge, i.e., the one starting from (a). Here the outcome of the theory is a *triangulated* category of motives whose groups of morphisms are blends of the algebro-geometric invariants of algebraic varieties (and more precisely, their higher Chow groups). If the existence of such categories was part of the Grothendieck motivic picture, it was probably Beilinson and Deligne who first expressed the hope that such categories might be easier to construct than their Abelian counterparts. And indeed, three different constructions of triangulated categories of motives appeared in the nineties by Hanamura [13–15], Levine [22] and Voevodsky [29] (see also its precursor [28]).

[1]To avoid confusion, we mention that the kind of extra structures we have in mind are those that can be given by the action of some group of symmetries such as the Galois group of the base field or, more generally, the fundamental group of a Tannakian category such as the category of mixed Hodge structures. It should be mentioned here that higher Chow groups are expected to carry a filtration, the conjectural Bloch–Beilinson filtration, with quite remarkable properties.

[2]Over a field of characteristic zero, it can be shown that if the "true" Abelian category of mixed motives exists, then it must be equivalent to Nori's category, and its subcategory of semi-simple objects must be equivalent to André's category. (The equivalence between André's and Deligne's categories is another story as it would require a weak form of the *Hodge Conjecture*.)

Although, the three categories were found to be equivalent, Voevodsky's construction [29] attracted most attention due to its beauty, simplicity and potential.

Nearly a decade later, it was realized (based on work of Morel and Cisinski–Déglise) that a mild modification of Voevodsky's construction, yields an even simpler (and certainly as beautiful) construction of the same (up to equivalence) triangulated category of motives at least if torsion is neglected or, more precisely, if descent for the étale topology is imposed (which is the right thing to do for many questions concerning integral motives such as the Hodge and Tate conjectures, existence of a motivic t-structure, etc; see §5.2). This simplified construction is more in the spirit of the construction of the Morel–Voevodsky $\mathbb{A}^1$-homotopy category [25] (and more precisely its stabilization that was worked out by Jardine [19]) and has the advantage of giving the correct triangulated categories over any base scheme.[3] These triangulated categories are denoted by $\mathbf{DA}^{\text{ét}}(S;\Lambda)$, where S is the base scheme and Λ is the ring of coefficients, and their objects are called *motivic sheaves* over S or simply *S-motives*;[4] they are the subject of this paper.

The organization is as follows. In §2 we give the details of the construction of $\mathbf{DA}^{\text{ét}}(S;\Lambda)$. We hope to convince the reader that this construction is simple and natural. In §3 we explain the basic operations that one can do on motivic sheaves; the story here is parallel to what one has in the context of étale and ℓ-adic sheaves although the construction of the operations follows a different route. One should consider the formalism of the six operations as a tool to reduce questions about motivic sheaves over general bases to questions about motives over a point (i.e., the spectrum of a field). In order for this formalism to be of any use, one needs information about motives over fields. In §4 we start discussing results about the internal structure of the category of motives over a field. More precisely, we give a concrete description of the group of morphisms between certain motives; such groups are usually called *motivic cohomology*. Here all the results are due to Voevodsky and this is the place where the extra complexity in his original construction pays off. In particular, we recall the original construction of Voevodsky in §4.1 and explain in §4.2 how it permits the computation of motivic cohomology. In §5 we list some of the big open questions concerning motives. It is these conjectures that need to be solved for having a satisfactory theory of motivic sheaves and filling the gap between the two half-bridges discussed above.

2. Construction

In this section, we go through the construction of the categories $\mathbf{DA}^{\text{ét}}(S;\Lambda)$ of *étale motivic sheaves* (or *motivic sheaves* for short) over a base scheme S and with coefficients in a commutative ring Λ. This construction is a slight variation of Voevodsky's original construction of his $\mathbf{DM}^{\text{ét}}(S;\Lambda)$ [24, 29] (see Remark 4.3 for more precisions). In fact, it is really a *simplification* of the latter as sheaves with transfers get replaced by ordinary sheaves. The category $\mathbf{DA}^{\text{ét}}(S;\Lambda)$ should be also considered as the linearized counterpart of the Morel–Voevodsky stable $\mathbb{A}^1$-homotopy category in the étale topology $\mathbf{SH}^{\text{ét}}(S)$ [19, 25]. In fact, both categories $\mathbf{DA}^{\text{ét}}(S;\Lambda)$ and $\mathbf{SH}^{\text{ét}}(S)$ are constructed in a uniform way in [6, Chapitre 4] as special cases of categories $\mathbf{SH}^{T}_{\mathfrak{M}}(S)$ by choosing $\mathfrak{M}$ to be the category of Λ-modules

[3] The original construction of Voevodsky is also known to give the correct triangulated categories when the base scheme is normal. However, the question remains open for more general base schemes (but see Remark 4.6).

[4] It is common to use the terminology "étale motivic sheaves". However, as the main article concerns motives in the étale topology, we use the shorthand "motivic sheaves".

or the category of simplicial symmetric spectra.

In order to keep the technicalities as low as possible, we will be using Verdier localization of triangulated categories [27] instead of the more natural/satisfactory Bousfield localization of model categories [16] which is usually employed in this context. We start by recalling Verdier localization.

2.1. A technical tool: Verdier localization. Recall that a *triangulated category* $\mathcal{T}$ is an additive category endowed with an autoequivalence $A \mapsto A[1]$ and a class of *distinguished triangles* which are diagrams of the form

$$A \xrightarrow{\alpha} B \xrightarrow{\beta} C \xrightarrow{\gamma} A[1] \tag{2.1}$$

satisfying a list of axioms. In particular, given a distinguished triangle as above, one has $\beta \circ \alpha = 0$ and $\gamma \circ \alpha = 0$. Moreover, the distinguished triangle (2.1) is determined by the map $\alpha : A \to B$ up to an isomorphism, which is in general not unique. Nevertheless, it will be sometimes convenient to abuse notation by writing $C = \mathrm{Cone}(\alpha)$ (and thus pretending that C depends canonically on α). Of course, this notation is inspired from topology: one thinks about a distinguished triangle (2.1) as an abstract version of a cofibre sequence. An important fact to keep in mind is the following: *α is an isomorphism if and only if* $\mathrm{Cone}(\alpha)$ *is zero*.

Now, let $\mathcal{T}$ be a triangulated category and $\mathcal{E} \subset \mathcal{T}$ a full subcategory closed under suspensions and desuspensions (i.e., under application of the powers $[n]$, positive and negative, of the autoequivalence $[1]$) and under cones. (Such an $\mathcal{E}$ is called a *triangulated subcategory* of $\mathcal{T}$.) In this situation, we have (see [27, Théorème 2.2.6]):

Proposition 2.1. *There exists a triangulated category $\mathcal{T}/\mathcal{E}$, called the* Verdier quotient *of $\mathcal{T}$ by $\mathcal{E}$, which is universal for the following two properties.*

i) *There is a canonical triangulated functor $\mathcal{T} \to \mathcal{T}/\mathcal{E}$ which is the identity on objects (in particular $\mathcal{T}$ and $\mathcal{T}/\mathcal{E}$ have the same class of objects).*

ii) *For every $A \in \mathcal{E}$, one has $A \simeq 0$ in $\mathcal{T}/\mathcal{E}$.*

Remark 2.2. The construction of $\mathcal{T}/\mathcal{E}$ goes as follows. Consider the class of arrows $S_{\mathcal{E}}$ in $\mathcal{T}$ given by

$$S_{\mathcal{E}} = \{\alpha : A \to B \mid \mathrm{Cone}(\alpha) \in \mathcal{E}\}.$$

The axioms satisfied by the class of distinguished triangles imply that $S_{\mathcal{E}}$ admits a "calculus of fractions". The Verdier quotient is then defined by

$$\mathcal{T}/\mathcal{E} := \mathcal{T}[(S_{\mathcal{E}})^{-1}].$$

In words, $\mathcal{T}/\mathcal{E}$ is the category obtained by formally inverting the arrows in $S_{\mathcal{E}}$.[5] This explains why the Verdier quotient is also called a *localization*.

2.2. An almost correct construction in two steps. The category $\mathbf{DA}^{\text{ét}}(S;\Lambda)$ is obtained from the derived category of étale sheaves on smooth S-schemes by formally forcing two simple properties. In this subsection, we discuss these properties and explain how to force them successively. This yields a slightly naive notion of motivic sheaves. The correct notion will be given in §2.3.

[5] Needless to say that we are ignoring some set-theoretical issues here.

2.2.1. Some notation. From now on, Λ will always denote a commutative ring that we call the *ring of coefficients*. (In practice, Λ is $\mathbb{Z}$, $\mathbb{Q}$, a subring of $\mathbb{Q}$ or a quotient of $\mathbb{Z}$. However, it is sometimes useful to take for Λ a number ring, a number field, a local field, etc.) Given a set E, we denote by $\Lambda \otimes E = \bigoplus_{e\in E} \Lambda \cdot e$ the free Λ-module generated by E.

For simplicity, all schemes will be separated and the reader will not loose much by assuming that all schemes are also Noetherian of finite Krull dimension.

Let S be a base scheme. We denote by Sm/S the category of smooth S-schemes.[6] We endow Sm/S with the étale topology ([3, Exposé VII]) and we denote by $\mathrm{Shv}_{\text{ét}}(\mathrm{Sm}/S;\Lambda)$ the category of étale sheaves with values in Λ-modules. If no confusion can arise, objects of $\mathrm{Shv}_{\text{ét}}(\mathrm{Sm}/S;\Lambda)$ will be simply called *étale sheaves* on Sm/S. Given a smooth S-scheme X, we denote by $\Lambda_{\text{ét}}(X) := \mathrm{a}_{\text{ét}}(\Lambda \otimes X)$ the étale sheaf associated to the presheaf $U \in \mathrm{Sm}/S \mapsto \Lambda \otimes \mathrm{Hom}_S(U, X)$. This gives a Yoneda functor

$$\Lambda_{\text{ét}} : \mathrm{Sm}/S \to \mathrm{Shv}_{\text{ét}}(\mathrm{Sm}/S;\Lambda) \tag{2.2}$$

which one should consider as the first/obvious linearization of the category of smooth S-schemes, a necessary step for passing from S-schemes to S-motives.

The following lemma is left as an exercise and will not be used elsewhere. It shows that étale sheaves on Sm/S have transfers along finite étale covers.

Lemma 2.3. *Let X and U be smooth S-schemes and assume that S is normal. Then $\Lambda_{\text{ét}}(X)(U)$ is the free Λ-module generated by closed integral subschemes $Z \subset U \times_S X$ such that the normalization of Z is étale and finite over U.*

The category $\mathrm{Shv}_{\text{ét}}(\mathrm{Sm}/S;\Lambda)$ possesses a monoidal structure. If $\mathcal{M}$ and $\mathcal{N}$ are étale sheaves on Sm/S, then $\mathcal{M} \otimes_\Lambda \mathcal{N}$ is simply the étale sheaf associated to the presheaf $U \in \mathrm{Sm}/S \mapsto \mathcal{M}(U) \otimes_\Lambda \mathcal{N}(U)$. If there is no risk of confusion, we will write $- \otimes -$ instead of $- \otimes_\Lambda -$ for the tensor product of Λ-modules and sheaves of Λ-modules. Given two smooth S-schemes X and Y, it follows readily from the definitions that

$$\Lambda_{\text{ét}}(X) \otimes \Lambda_{\text{ét}}(Y) \simeq \Lambda_{\text{ét}}(X \times_S Y).$$

Said differently, the functor $\Lambda_{\text{ét}}$ is monoidal (when Sm/S is endowed with its Cartesian monoidal structure).

2.2.2. First step: $\mathbb{A}^1$-localization. To motivate what follows, we note that, for a scheme U, the projection $\mathbb{A}^1 \times U \to U$ (where $\mathbb{A}^1 = \mathrm{Spec}(\mathbb{Z}[t])$ is the affine line) induces isomorphisms in most cohomology theories (for instance, in Betti cohomology if $U \in \mathrm{Sm}/\mathbb{C}$, in ℓ-adic cohomology if ℓ is invertible on U, in algebraic K-theory if U is regular, etc). Thus, it is natural to expect the motives of U and $\mathbb{A}^1 \times U$ to be isomorphic.

To impose this in a "homologically correct" manner, we consider the derived category $\mathbf{D}(\mathrm{Shv}_{\text{ét}}(\mathrm{Sm}/S;\Lambda))$ of the Abelian category $\mathrm{Shv}_{\text{ét}}(\mathrm{Sm}/S;\Lambda)$. Let $\mathcal{T}_{\mathbb{A}^1}$ be the smallest triangulated subcategory of $\mathbf{D}(\mathrm{Shv}_{\text{ét}}(\mathrm{Sm}/S;\Lambda))$ which is closed under arbitrary direct sums and containing the 2-terms complexes

$$[\ldots \to 0 \to \Lambda_{\text{ét}}(\mathbb{A}^1 \times U) \to \Lambda_{\text{ét}}(U) \to 0 \to \ldots] \tag{2.3}$$

[6] Recall that *smooth* implies in particular *locally of finite presentation*. One may also restrict to smooth quasi-projective S-schemes and even to smooth quasi-affine S-schemes as these will define equivalent sites for the étale topology.

for all smooth S-schemes U. (In the above complex, the nonzero map is induced by the obvious projection $\mathbb{A}^1 \times U \to U$.) Then define $\mathbf{DA}^{\mathrm{eff},\text{ét}}(S;\Lambda)$ to be the Verdier quotient of $\mathbf{D}(\mathrm{Shv}_{\text{ét}}(\mathrm{Sm}/S))$ by $\mathcal{T}_{\mathbb{A}^1}$:

$$\mathbf{DA}^{\mathrm{eff},\text{ét}}(S;\Lambda) := \mathbf{D}(\mathrm{Shv}_{\text{ét}}(\mathrm{Sm}/S;\Lambda))/\mathcal{T}_{\mathbb{A}^1}.$$

The categories $\mathbf{DA}^{\mathrm{eff},\text{ét}}(S;\Lambda)$ and $\mathbf{D}(\mathrm{Shv}_{\text{ét}}(\mathrm{Sm}/S;\Lambda))$ have the same objects, that is complexes of étale sheaves on Sm/S; however, a morphism in $\mathbf{D}(\mathrm{Shv}_{\text{ét}}(\mathrm{Sm}/S;\Lambda))$ whose cone belongs to $\mathcal{T}_{\mathbb{A}^1}$ gets inverted in $\mathbf{DA}^{\mathrm{eff},\text{ét}}(S;\Lambda)$. As a matter of fact, the map $\Lambda_{\text{ét}}(\mathbb{A}^1 \times U) \to \Lambda_{\text{ét}}(U)$, whose cone is the complex (2.3), is an isomorphism in $\mathbf{DA}^{\mathrm{eff},\text{ét}}(S;\Lambda)$.

Definition 2.4. An object of $\mathbf{DA}^{\mathrm{eff},\text{ét}}(S;\Lambda)$ is called an *effective motivic sheaf* over S (or simply an *effective S-motive*). Given a smooth S-scheme X, then $\Lambda_{\text{ét}}(X)$, viewed as an object of $\mathbf{DA}^{\mathrm{eff},\text{ét}}(S;\Lambda)$, is called the *effective homological motive* of X and will be denoted by $\mathrm{M}^{\mathrm{eff}}(X)$.

Definition 2.5. Let us denote by $\mathbf{DA}^{\mathrm{eff},\text{ét}}_{\mathrm{ct}}(S;\Lambda)$ the smallest triangulated subcategory of $\mathbf{DA}^{\mathrm{eff},\text{ét}}(S;\Lambda)$ closed under direct summands and containing the motives $\mathrm{M}^{\mathrm{eff}}(X)$ for $X \in \mathrm{Sm}/S$ of finite presentation. Effective motivic sheaves in $\mathbf{DA}^{\mathrm{eff},\text{ét}}_{\mathrm{ct}}(S;\Lambda)$ are called *constructible*.

Remark 2.6. The category $\mathbf{DA}^{\mathrm{eff},\text{ét}}(S;\Lambda)$ (as well as $\mathbf{D}(\mathrm{Shv}_{\text{ét}}(\mathrm{Sm}/S;\Lambda))$) inherits the monoidal structure of $\mathrm{Shv}_{\text{ét}}(\mathrm{Sm}/S;\Lambda)$. If $\mathcal{M}_\bullet$ and $\mathcal{N}_\bullet$ are complexes of étale sheaves on Sm/S (i.e., objets of $\mathbf{DA}^{\mathrm{eff},\text{ét}}(S;\Lambda)$), then their tensor product $(\mathcal{M}\otimes\mathcal{N})_\bullet$ is the total complex associated to the bi-complex $\mathcal{M}_\bullet \otimes \mathcal{N}_\bullet$.

2.2.3. Second step: naive stabilization. In this subsection, we give a low-tech (and slightly naive) construction yielding the category $\mathbf{DA}^{\text{ét},\,\mathrm{naive}}(S;\Lambda)$ which, nevertheless, captures the essence of the category $\mathbf{DA}^{\text{ét}}(S;\Lambda)$ (see Remark 2.7).

The stabilization here refers to the process of rendering the Tate motive invertible for the tensor product.

To motivate this process, we need to explain another simple fact about the cohomology of algebraic varieties. To fix ideas, we consider ℓ-adic cohomology H^*_ℓ for schemes over an algebraically closed field k in which ℓ is invertible. The reduced cohomology of the pointed (by infinity) projective line $(\mathbb{P}^1_k,\infty)$ is given by

$$H^*_\ell(\mathbb{P}^1_k,\infty) \simeq \mathbb{Z}_\ell(-1)[-2]$$

where, as usual, $\mathbb{Z}_\ell(-1)$ is the dual of the Tate module $\mathbb{Z}_\ell(1) = \mathrm{Lim}_{n\in\mathbb{N}}\ \mu_{\ell^n}(k)$. Hence, seen as an object of the derived category $\mathbf{D}(\mathbb{Z}_\ell)$, the complex $H^*_\ell(\mathbb{P}^1_k,\infty)$ has total rank one and, equivalently, is invertible for the tensor product. It is the latter property that we want to impose on the motivic level.

To this effect, let $L := \Lambda_{\text{ét}}(\mathbb{P}^1_S,\infty_S)$ be the étale sheaf on Sm/S given by the cokernel of the inclusion $\Lambda(\infty_S) \hookrightarrow \Lambda_{\text{ét}}(\mathbb{P}^1_S)$. Seen as an object of $\mathbf{DA}^{\mathrm{eff},\text{ét}}(S;\Lambda)$, L is the reduced effective homological S-motive of the pointed S-scheme $(\mathbb{P}^1_S,\infty_S)$. We will refer to L as the *Lefschetz motive*; it is the motive that corresponds to the constant complex of ℓ-adic sheaves $\mathbb{Z}_\ell(1)[2]$ over S (for ℓ invertible in $\mathcal{O}_S$).[7] However, it is easy to see that L is not an invertible

[7]This is consistent with what we said before: the ℓ-adic cohomology of $(\mathbb{P}^1_k,\infty)$ is $\mathbb{Z}_\ell(-1)[-2]$ and hence its ℓ-adic homology is $\mathbb{Z}_\ell(1)[2]$; it is the latter that should corresponds to the homological motive of $(\mathbb{P}^1_k,\infty)$.

object of $\mathbf{DA}^{\mathrm{eff},\text{ét}}(S;\Lambda)$. Therefore, one is lead to invert it formally by considering

$$\mathbf{DA}^{\text{ét},\,\mathrm{naive}}(S;\Lambda) := \mathbf{DA}^{\mathrm{eff},\text{ét}}(S;\Lambda)[L^{-1}].$$

An objet of $\mathbf{DA}^{\text{ét},\,\mathrm{naive}}(S;\Lambda)$ consists of a pair (M,m) where $M \in \mathbf{DA}^{\mathrm{eff},\text{ét}}(S;\Lambda)$ and $m \in \mathbb{Z}$. The group $\hom_{\mathbf{DA}^{\text{ét},\,\mathrm{naive}}(S;\Lambda)}((M,m),(N,n))$ of morphisms between two such objets is given by

$$\varinjlim_{r\geq -\min(m,n)} \hom_{\mathbf{DA}^{\mathrm{eff},\text{ét}}(S;\Lambda)}(M\otimes L^{r+m}, N\otimes L^{r+n}). \tag{2.4}$$

With this definition, it is easy to see that the endofunctor $-\otimes L$ on $\mathbf{DA}^{\mathrm{eff},\text{ét}}(S;\Lambda)$ corresponds to the functor $(M,m)\mapsto(M,m+1)$ on $\mathbf{DA}^{\text{ét},\,\mathrm{naive}}(S;\Lambda)$ which is an equivalence of categories with inverse $(M,m)\mapsto(M,m-1)$.

The formula (2.4) is reminiscent to the formula computing stable homotopy groups ot a topological space. This analogy suggests already that, as in topology, it is technically more convenient to use the formalism of spectra for inverting L. This is indeed the right method and will be explained in §2.3.

Remark 2.7. The category $\mathbf{DA}^{\text{ét},\,\mathrm{naive}}(S;\Lambda)$ suffers many technical defects. For instance, it is not a triangulated category and it doesn't have arbitrary direct sums. However, modulo these technical defects, $\mathbf{DA}^{\text{ét},\,\mathrm{naive}}(S;\Lambda)$ is essentially the right category of S-motives. More precisely, under some technical assumptions,[8] its full subcategory $\mathbf{DA}^{\text{ét},\,\mathrm{naive}}_{\mathrm{ct}}(S;\Lambda)$ consisting of pairs (M,m) with $M \in \mathbf{DA}^{\mathrm{eff},\text{ét}}_{\mathrm{ct}}(S;\Lambda)$, is equivalent to the category $\mathbf{DA}^{\text{ét}}_{\mathrm{ct}}(S;\Lambda)$ of constructible motives (see Definition 2.11 below), which is certainly the most interesting part of $\mathbf{DA}^{\text{ét}}(S;\Lambda)$.

2.3. The definitive construction. This subsection can be skipped by the reader who is satisfied by the almost correct construction explained in §2.2. The goal here is to invert in a "homologically correct" manner the Lefschetz motive $L = \Lambda_{\text{ét}}(\mathbb{P}^1_S,\infty_S)$ for the tensor product. In fact, we will treat the localization (§2.2.2) and the stabilization (§2.2.3) in one single step!

We will borrow the machinery developed by topologists in the context of stable homotopy theory [1, 30] for inverting the (pointed) 1-dimensional sphere S^1 for the smash product. The only difference is that, instead of considering S^1-spectra (for the smash product), we will consider L-spectra (for the tensor product).

Definition 2.8. An *L-spectrum* (of étale sheaves on Sm/S) is a pair

$$\mathcal{E} = ((\mathcal{E}_n)_{n\in\mathbb{N}}, (\gamma_n)_{n\in\mathbb{N}})$$

where $\mathcal{E}_n$ is an étale sheaf on Sm/S and $\gamma_n : L\otimes\mathcal{E}_n \to \mathcal{E}_{n+1}$ is a morphism of sheaves called the n-th *assembly map*. We refer to the sheaf $\mathcal{E}_n$ as the n-th *level* of the L-spectrum $\mathcal{E}$.

A morphism of L-spectra $f : \mathcal{E}\to\mathcal{E}'$ is a collection of morphisms of sheaves $f_n : \mathcal{E}_n \to \mathcal{E}'_n$ that commute with the assembly maps, i.e., such that $f_{n+1}\circ\gamma_n = \gamma'_n\circ(\mathrm{id}_L\otimes f_n)$ for all $n\in\mathbb{N}$. We denote by $\mathrm{Spt}_L(\mathrm{Shv}_{\text{ét}}(\mathrm{Sm}/S;\Lambda))$ the category of L-spectra. This is an Abelian category.

[8] Such as S being Noetherian, of finite Krull dimension and of pointwise finite ℓ-cohomological dimension for very prime ℓ which is not invertible in Λ.

Remark 2.9. The functor $\mathrm{Ev}_p : \mathcal{E} \mapsto \mathcal{E}_p$, sending an L-spectrum to its p-th level admits a left adjoint

$$\mathrm{Sus}^p_L : \mathrm{Shv}_{\text{ét}}(\mathrm{Sm}/S;\Lambda) \to \mathrm{Spt}_L(\mathrm{Shv}_{\text{ét}}(\mathrm{Sm}/S;\Lambda)).$$

If $\mathcal{F}$ is a complex of sheaves on Sm/S, then $\mathrm{Sus}^p_L\mathcal{F}$ is given by

$$(\mathrm{Sus}^p_L\mathcal{F})_n = \begin{cases} 0 & \text{if} \quad n \leq p-1, \\ L^{\otimes n-p} \otimes \mathcal{F} & \text{if} \quad n \geq p, \end{cases}$$

with the obvious assembly maps. Usually, Sus^0_L is called the *infinite suspension* functor and is denoted by Σ^∞_L.

We will construct $\mathbf{DA}^{\text{ét}}(S;\Lambda)$ as a Verdier localization of the derived category

$$\mathbf{D}(\mathrm{Spt}_L(\mathrm{Shv}_{\text{ét}}(\mathrm{Sm}/S;\Lambda)))$$

of L-spectra over Sm/S. For this, we consider the smallest triangulated subcategory $\mathcal{T}_{\mathbb{A}^1-\mathrm{st}}$ ("st" stands for "stable") of the latter closed under arbitrary direct sums and containing the complexes

$$[\ldots \to 0 \to \mathrm{Sus}^p_L\Lambda_{\text{ét}}(\mathbb{A}^1 \times U) \to \mathrm{Sus}^p_L\Lambda_{\text{ét}}(U) \to 0 \to \ldots] \tag{2.5}$$

$$[\ldots \to 0 \to \mathrm{Sus}^{p+1}_L(L \otimes \Lambda_{\text{ét}}(U)) \to \mathrm{Sus}^p_L\Lambda_{\text{ét}}(U) \to 0 \to \ldots] \tag{2.6}$$

for all smooth S-schemes U and all $p \in \mathbb{N}$. (In the first complex above, the nonzero map is induced by the projection to the second factor; in the second complex above, the nonzero map is the map of L-spectra given by the identity starting from level $p+1$.) We now define a new triangulated category as a Verdier quotient

$$\mathbf{DA}^{\text{ét}}(S;\Lambda) := \mathbf{D}(\mathrm{Spt}_L(\mathrm{Shv}_{\text{ét}}(\mathrm{Sm}/S;\Lambda)))/\mathcal{T}_{\mathbb{A}^1-\mathrm{st}}.$$

Definition 2.10. An object of $\mathbf{DA}^{\text{ét}}(S;\Lambda)$ is called a *motivic sheaf* over S (or simply an S-*motive*). Given a smooth S-scheme X, then $\Sigma^\infty_L\Lambda_{\text{ét}}(X)$, viewed as an object of $\mathbf{DA}^{\text{ét}}(S;\Lambda)$, is called the *homological motive* of X and will be denoted by $\mathrm{M}(X)$.

Definition 2.11. Let us denote by $\mathbf{DA}^{\text{ét}}_{\text{ct}}(S;\Lambda)$ the smallest triangulated subcategory of $\mathbf{DA}^{\text{ét}}(S;\Lambda)$ closed under direct summands and containing the motives $\mathrm{M}(X)(-p)[-2p] := \mathrm{Sus}^p_L\Lambda_{\text{ét}}(X)$ for $p \in \mathbb{N}$ and $X \in \mathrm{Sm}/S$ of finite presentation. Motivic sheaves in $\mathbf{DA}^{\text{ét}}_{\text{ct}}(S;\Lambda)$ are called *constructible*.

Remark 2.12. It can be shown that $\mathbf{DA}^{\text{ét}}(S;\Lambda)$ is a triangulated category admitting arbitrary direct sums. Therefore, the construction via L-spectra resolves the technical defects of the category $\mathbf{DA}^{\text{ét, naive}}(S;\Lambda)$ constructed in §2.2.3.

Definition 2.13. For $p \in \mathbb{N}$, denote by $\Lambda_S(p)$ (or simply $\Lambda(p)$) the S-motive $\mathrm{Sus}^0_L(L^{\otimes p})[-2p]$ and $\Lambda_S(-p)$ (or simply $\Lambda(-p)$) the S-motive $\mathrm{Sus}^p(\Lambda)[2p]$. These are the Tate motives over S. We also define

$$H^p_{\mathcal{L}}(S;\Lambda(q)) := \hom_{\mathbf{DA}^{\text{ét}}(S;\Lambda)}(\Lambda_S(0), \Lambda_S(q)[p])$$

for p, $q \in \mathbb{Z}$. These groups are called the *étale* (or *Lichtenbaum*) *motivic cohomology* of S (with coefficients in Λ).

2.4. Complements. From Definition 2.10, a motivic sheaf over S is simply a complex of L-spectra on Sm/S, i.e., essentially a sequence of complexes of étale sheaves on Sm/S. This is of course deceiving and slightly misleading. The point is that every complex of L-spectra is *isomorphic* in $\mathbf{DA}^{\text{ét}}(S;\Lambda)$ to a *stably* $\mathbb{A}^1$*-local* complex of L-spectra and it is the latter that deserves better to be called a motivic sheaf. Our goal in this paragraph is to explain this in some detail. We start with the effective case. (Below, $H^i_{\text{ét}}(-;A)$ stands for the étale hyper-cohomology with coefficients in a complex of étale sheaves A.)

Definition 2.14. Let $\mathcal{F}$ be a complex of étale sheaves on Sm/S. We say that $\mathcal{F}$ is $\mathbb{A}^1$*-local* if for all $U \in \mathrm{Sm}/S$ and $i \in \mathbb{Z}$, the map

$$H^i_{\text{ét}}(U;\mathcal{F}) \to H^i_{\text{ét}}(\mathbb{A}^1 \times U;\mathcal{F}),$$

induced by the projection to the second factor, is an isomorphism.

Remark 2.15. $\mathbb{A}^1$-locality is important for the following reason. Let $\mathcal{E}$ and $\mathcal{F}$ be two complexes of étale sheaves on Sm/S. Then, if $\mathcal{F}$ is $\mathbb{A}^1$-local, the natural homomorphism

$$\hom_{\mathbf{D}(\mathrm{Shv}_{\text{ét}}(\mathrm{Sm}/S;\Lambda))}(\mathcal{E},\mathcal{F}) \to \hom_{\mathbf{DA}^{\text{eff},\,\text{ét}}(S;\Lambda)}(\mathcal{E},\mathcal{F})$$

is an isomorphism. In words, computing morphisms between effective motivic sheaves can be performed in the more familiar derived category of étale sheaves when the target is $\mathbb{A}^1$-local. The next result gives, in theory, a way to reduce to this favorable case.

Lemma 2.16. *There is, up to a unique isomorphism, a triangulated endofunctor* $\mathrm{Loc}_{\mathbb{A}^1}$ *of* $\mathbf{D}(\mathrm{Shv}_{\text{ét}}(\mathrm{Sm}/S;\Lambda))$ *endowed with a natural transformation* $\mathrm{id} \to \mathrm{Loc}_{\mathbb{A}^1}$ *such that the following two properties are satisfied for every complex* $\mathcal{F}$ *of étale sheaves on* Sm/S*:*

- $\mathrm{Loc}_{\mathbb{A}^1}(\mathcal{F})$ *is* $\mathbb{A}^1$*-local, and*
- $\mathcal{F} \to \mathrm{Loc}_{\mathbb{A}^1}(\mathcal{F})$ *is an* $\mathbb{A}^1$-weak equivalence (*i.e., becomes an isomorphism in the category* $\mathbf{DA}^{\text{eff},\,\text{ét}}(S;\Lambda)$).

$\mathrm{Loc}_{\mathbb{A}^1}$ *is called the* $\mathbb{A}^1$*-localization functor.*

Remark 2.17. If one adopts the convention that an "effective S-motive" is an $\mathbb{A}^1$-local complex of sheaves on Sm/S, then the effective motive of a smooth S-scheme X would be given by $\mathrm{Loc}_{\mathbb{A}^1}(\Lambda_{\text{ét}}(X))$. Therefore, understanding the $\mathbb{A}^1$-localization functor is of utmost importance in the theory of motives!

Remark 2.18. One of the drawback of the abstract construction is that it gives no information about the $\mathbb{A}^1$-localization functor. We will explain in §4.2 how Voevodsky is able to overcome this crucial difficulty (sadly, only when S is the spectrum of a field) using his theory of *homotopy invariant presheaves with transfers*.

We now turn to the stable setting.

Definition 2.19. Let $\mathcal{K} = ((\mathcal{K}_n)_{n\in\mathbb{N}}, (\gamma_n)_{n\in\mathbb{N}})$ be a complex of L-spectra of étale sheaves on Sm/S. We say that $\mathcal{K}$ is *stably* $\mathbb{A}^1$*-local* if the following two properties are satisfied for all $U \in \mathrm{Sm}/S$, $i \in \mathbb{Z}$ and $n \in \mathbb{N}$:

i) the map

$$H^i_{\text{ét}}(U;\mathcal{K}_n) \to H^i_{\text{ét}}(\mathbb{A}^1 \times U;\mathcal{K}_n),$$

induced by the projection to the second factor, is an isomorphism;

ii) the map

$$H^i_{\text{ét}}(U;\mathcal{K}_n) \to H^{i+2}_{\text{ét}}((\mathbb{P}^1,\infty)\times U;\mathcal{K}_{n+1}),$$

induced by the n-th assembly map, is an isomorphism.

Remark 2.20. Stably $\mathbb{A}^1$-local complexes of L-spectra are important for the same reason as the one explained in Remark 2.15.

Remark 2.21. Let $\mathcal{K}$ be a stably $\mathbb{A}^1$-local complex of L-spectra. Writing $\mathcal{K}(n)$ for the complex $\mathcal{K}_n[-2n]$, the two properties in Definition 2.19 gives the familiar isomorphisms:

i) $H^*_{\text{ét}}(\mathbb{A}^1\times U;\mathcal{K}(n)) = H^*_{\text{ét}}(U;\mathcal{K}(n))$;

ii) $H^*_{\text{ét}}((\mathbb{A}^1\smallsetminus 0)\times U;\mathcal{K}(n)) \simeq H^*_{\text{ét}}(U;\mathcal{K}(n)) \oplus H^{*-1}_{\text{ét}}(U;\mathcal{K}(n-1))$.

Lemma 2.22. *There is, up to a unique isomorphism, a triangulated endofunctor* $\mathrm{Loc}_{\mathbb{A}^1\text{-st}}$ *of* $\mathbf{D}(\mathrm{Spt}_L(\mathrm{Shv}_{\text{ét}}(\mathrm{Sm}/S;\Lambda)))$ *endowed with a natural transformation* $\mathrm{id}\to\mathrm{Loc}_{\mathbb{A}^1\text{-st}}$ *such that the following two properties are satisfied for every complex of L-spectra $\mathcal{K}$:*

- $\mathrm{Loc}_{\mathbb{A}^1\text{-st}}(\mathcal{K})$ *is stably $\mathbb{A}^1$-local, and*
- $\mathcal{K}\to\mathrm{Loc}_{\mathbb{A}^1\text{-st}}(\mathcal{K})$ *is a* stable $\mathbb{A}^1$-weak equivalence *(i.e., becomes an isomorphism in* $\mathbf{DA}^{\text{ét}}(S;\Lambda)$*).*

Remark 2.23. As in the effective case, if one adopts the convention that an "S-motive" is a stably $\mathbb{A}^1$-local complex of L-spectra, then the motive of a smooth S-scheme X would be given by $\mathrm{Loc}_{\mathbb{A}^1\text{-st}}(\Sigma^\infty_T\Lambda_{\text{ét}}(X))$.

2.5. Relative rigidity theorem. When the characteristic of Λ is non-zero, the category $\mathbf{DA}^{\text{ét}}(S;\Lambda)$ has a very simple description. Indeed, one has the following (see [9, Théorème 4.1]):

Theorem 2.24. *Let $n\in\mathbb{N}\smallsetminus\{0\}$ be an integer invertible in $\mathcal{O}(S)$. If Λ is a $\mathbb{Z}/n\mathbb{Z}$-algebra (and S satisfies some mild technical hypothesis*[9]*), then there is an equivalence of categories*

$$\mathbf{DA}^{\text{ét}}(S;\Lambda)\simeq\mathbf{D}(S_{\text{ét}};\Lambda)$$

where $\mathbf{D}(S_{\text{ét}};\Lambda)$ is the derived category of étale sheaves on $S_{\text{ét}}$ (the small étale site of S).

Remark 2.25. Theorem 2.24 is a relative version of a well-known result of Suslin–Voevodsky [29, Proposition 3.3.3 of Chapter 5] stating the same conclusion for the category $\mathbf{DM}^{\text{ét}}(S;\Lambda)$ when S is a field.

Remark 2.26. From a certain perspective, Theorem 2.24 is disappointing. Indeed, its shows that the categories $\mathbf{DA}^{\text{ét}}(S;\Lambda)$ are too simple to capture the complexity of the torsion in Chow groups. This is not so surprising as it is well-known that higher Chow groups do not satisfy étale descent. A way around this is to replace in the construction "étale" by "Nisnevich" which yields the categories $\mathbf{DA}(S;\Lambda)$. The latter "see" the higher Chow groups integrally (but also other things like oriented Chow groups).

[9] These hypothesis are satisfied when S is excellent.

Remark 2.27. From another perspective, Theorem 2.24 is encouraging. Indeed, it is also well-known that integrality in Chow groups is chaotic in general. For instance, there are famous counterexamples (the first ones by Atiyah–Hirzebruch [4, Theorem 6.5] and Kollár [21, page 134–135]) to the integral Hodge and Tate conjectures. Imposing étale descent forces a better organization in the integral structure of higher Chow groups. As a matter of fact, it has been shown recently by Rosenschon–Srinivas [26] that the Hodge and Tate conjectures can be "corrected" integrally by replacing the Chow groups by their étale version.[10] See also Remark 5.7 below for another (but related) reason to be happy about Theorem 2.24.

3. Operations on motivic sheaves

In this section, we review the functorialities of the categories of motivic sheaves. As for the classical "cohomological coefficients" (in the sense of Grothendieck), one has for motivic sheaves the Grothendieck six operations formalism and Verdier's duality. One also has the nearby cycles formalism, but this will not be discussed here (see [6, Chapitre 4] and [9]).

3.1. Operations associated to morphisms of schemes. In this subsection, we will recall the construction of the formalism of the four operations f^*, f_*, $f_!$ and $f^!$, associated to a morphism of schemes f, in the context of motivic sheaves.

3.1.1. Ordinary inverse and direct images. Let $f : T \to S$ be a morphism of schemes. Then f induces a pair of adjoint functors:

$$f^* : \mathrm{Shv}_{\text{ét}}(\mathrm{Sm}/S;\Lambda) \rightleftarrows \mathrm{Shv}_{\text{ét}}(\mathrm{Sm}/T;\Lambda) : f_*. \tag{3.1}$$

The functor f_* is easy to understand; given an étale sheaf $\mathcal{G}$ over Sm/T, one has $f_*\mathcal{G}(U) := \mathcal{G}(T \times_S U)$ for all $U \in \mathrm{Sm}/S$. The functor f^* is characterized by its property of commuting with arbitrary colimits and by the formula

$$f^*\Lambda_{\text{ét}}(U) \simeq \Lambda_{\text{ét}}(T \times_S U) \tag{3.2}$$

for all $U \in \mathrm{Sm}/S$.

The adjunction (3.1) can be derived yielding an adjunction on the level of effective motivic sheaves

$$\mathrm{L}f^* : \mathbf{DA}^{\mathrm{eff},\,\text{ét}}(S;\Lambda) \rightleftarrows \mathbf{DA}^{\mathrm{eff},\,\text{ét}}(T;\Lambda) : \mathrm{R}f_*. \tag{3.3}$$

It can also be extended to L-spectra and then derived yielding an adjunction on the level of motivic sheaves

$$\mathrm{L}f^* : \mathbf{DA}^{\text{ét}}(S;\Lambda) \rightleftarrows \mathbf{DA}^{\text{ét}}(T;\Lambda) : \mathrm{R}f_*. \tag{3.4}$$

These functors are triangulated.

[10] For a smooth algebraic variety X over a field k, the étale Chow groups of X can be defined by the formula (see Definition 2.13)

$$\mathrm{CH}^n_{\text{ét}}(X) := H^{2n}_{\mathcal{L}}(X;\mathbb{Z}(n)) = \hom_{\mathbf{DA}^{\text{ét}}(k;\mathbb{Z})}(\mathrm{M}(X),\mathbb{Z}(n)[2n])$$

(or, equivalently, using $\mathbf{DM}^{\text{ét}}(k;\mathbb{Z})$ instead of $\mathbf{DA}^{\text{ét}}(k;\mathbb{Z})$). When $k = \mathbb{C}$, Rosenschon and Srinivas construct in [26] a cycle map $\mathrm{CH}^n_{\text{ét}}(X) \to H^{2n}(X(\mathbb{C}),\mathbb{Z})$ and show that if the Hodge conjecture holds for the rational Chow groups (i.e., for $\mathrm{CH}^n_{\mathbb{Q}}(X) := \mathrm{CH}^n(X) \otimes \mathbb{Q}$) then it also holds integrally for the étale Chow groups. They also show a similar statement for the Tate conjecture.

Remark 3.1. The formula (3.2) still holds for the left derived functors $\mathrm{L}f^*$ in (3.3) and (3.4). In words, $\mathrm{L}f^*$ takes the homological motive of an S-scheme U to the homological motive of the T-scheme $T \times_S U$ (in the effective and non-effective settings).

Lemma 3.2. *Assume that f is smooth. Then, the functor f^* admits a left adjoint*

$$f_\sharp : \mathrm{Shv}_{\text{ét}}(\mathrm{Sm}/T; \Lambda) \to \mathrm{Shv}_{\text{ét}}(\mathrm{Sm}/S; \Lambda).$$

If $V \in \mathrm{Sm}/T$, then $f_\sharp \Lambda_{\text{ét}}(V/T) = \Lambda_{\text{ét}}(V/S)$. Moreover, $f_\sharp$ can be left derived yielding left adjoints to $\mathrm{L}f^*$ on the level of motivic sheaves:

$$\mathrm{L}f_\sharp : \mathbf{DA}^{\mathrm{eff},\text{ét}}(T; \Lambda) \to \mathbf{DA}^{\mathrm{eff},\text{ét}}(S; \Lambda) \text{ and } \mathrm{L}f_\sharp : \mathbf{DA}^{\text{ét}}(T; \Lambda) \to \mathbf{DA}^{\text{ét}}(S; \Lambda).$$

Remark 3.3. The existence of a left adjoint to f^*, when f is smooth, is part of the formalism of the six operations of Grothendieck. However, in the classical setting, this property is one of the deepest, whereas for motivic sheaves one has it for free!

3.1.2. A list of axioms. From now on, we will drop the "L" and "R" when dealing with the operations $\mathrm{L}f^*$, $\mathrm{L}f_\sharp$ and $\mathrm{R}f_*$.

Let SCH be the category of all schemes and $\mathfrak{TR}$ the 2-category of triangulated categories. Then, the 2-functor

$$\begin{array}{rccc} \mathbf{DA}^{\text{ét}}(-;\Lambda) \ : & \mathrm{SCH} & \to & \mathfrak{TR} \\ & f & \mapsto & f^* \end{array}$$

satisfies the following list of axioms. (Only one of these axioms fails to hold for $\mathbf{DA}^{\mathrm{eff},\text{ét}}(-,\Lambda)$, namely the sixth!)

1. $\mathbf{DA}^{\text{ét}}(\emptyset;\Lambda)$ is equivalent to the zero triangulated category.
2. For every morphism of schemes $f : T \to S$, the functor $f^* : \mathbf{DA}^{\text{ét}}(S;\Lambda) \to \mathbf{DA}^{\text{ét}}(T;\Lambda)$ admits a right adjoint f_*.
3. For every *smooth* morphism $f : T \to S$, the functor $f^* : \mathbf{DA}^{\text{ét}}(S;\Lambda) \to \mathbf{DA}^{\text{ét}}(T;\Lambda)$ admits a left adjoint $f_\sharp$. Moreover, given a cartesian square

$$\begin{array}{ccc} T' & \xrightarrow{g'} & T \\ \downarrow{\scriptstyle f'} & & \downarrow{\scriptstyle f} \\ S' & \xrightarrow{g} & S, \end{array}$$

   the natural exchange morphism $f'_\sharp \circ g'^* \to g^* \circ f_\sharp$ is an isomorphism.
4. For every closed immersion i with complementary open immersion j, the pair (i^*, j^*) is conservative (i.e., if a motive M satisfies $i^*M \simeq 0$ and $j^*M \simeq 0$, then $M \simeq 0$). Moreover, the counit of the adjunction $i^* \circ i_* \to \mathrm{id}$ is an isomorphism.
5. If $p : V \to S$ is the projection of a vector bundle, then the unit of the adjunction $\mathrm{id} \to p_* p^*$ is an isomorphism.
6. If $f : T \to S$ is smooth and $s : S \to T$ is a section of f (i.e., $f \circ s = \mathrm{id}_S$), then the functor $f_\sharp \circ s_*$ is an autoequivalence of $\mathbf{DA}^{\text{ét}}(S;\Lambda)$.

We will call such a 2-functor an *extended stable homotopical* 2*-functor*.

Remark 3.4. Except the fourth axiom, all these axioms follow readily from the construction. For instance, the fifth axiom is a consequence of the $\mathbb{A}^1$-localization and the sixth axiom follows from inverting the Lefschetz motive (for the tensor product).

The fourth axiom (aka., the locality axiom) is due to Morel–Voevodsky [25, Theorem 2.21 of §3.2]. (In loc. cit., only the non-Abelian setting is considered but their proof can be adapted to the additive setting without much difficulties; see [6, §4.5.3].) It is the proof of this axiom that dictates some of the choices that were made by Morel–Voevodsky (and repeated in §2) such as considering sheaves on *smooth* S-schemes instead of sheaves on larger categories of S-schemes.

Remark 3.5. That these axioms suffices to derive the full formalism of the four operations is due to Voevodsky (unpublished). The details of the verifications were carried on in [5, Chapitre 1].

For later use, we make the following definition.

Definition 3.6. Given an $\mathcal{O}_S$-module $\mathcal{M}$ on a scheme S, we set $\mathrm{Th}(\mathcal{M}) = p_\sharp \circ s_*$ where $p : \mathrm{V}(\mathcal{M}) \to S$ is the projection of the associated vector bundle and s is its zero section. By the sixth axiom, $\mathrm{Th}(\mathcal{M})$ is an autoequivalence of $\mathbf{DA}^{\text{ét}}(S;\Lambda)$, called the *Thom equivalence*. Its inverse is denoted by $\mathrm{Th}^{-1}(\mathcal{M})$.

Remark 3.7. It is customary to denote $\mathrm{Th}(\mathcal{O}_S^{\oplus r})(-)[-2r]$ by $(-)(r)$ and to call it the r-th *Tate twist* (extended to negative integers in the usual way).

If $\mathcal{M}$ has constant rank r, it can be shown that $\mathrm{Th}(\mathcal{M})[-2r]$ is canonically equivalent to $(-)(r)$ (see [9, Remarque 11.3]). This is a special property of $\mathbf{DA}^{\text{ét}}(-;\Lambda)$ called *orientation*.

3.1.3. The proper base change theorem. One of the most surprising fact here is that the axioms of §3.1.2 imply quite formally the so-called *proper base change theorem*. (All the axioms are used in the proof of this theorem; as a matter of fact, this theorem fails for the categories $\mathbf{DA}^{\text{eff},\text{ét}}(-;\Lambda)$.)

Theorem 3.8. *Given a cartesian square*

$$\begin{array}{ccc} Y' & \xrightarrow{g'} & Y \\ \downarrow{\scriptstyle f'} & & \downarrow{\scriptstyle f} \\ X' & \xrightarrow{g} & X \end{array}$$

with f proper, the exchange morphism $g^* \circ f_*(\mathcal{M}) \to f'_* \circ g'^*(\mathcal{M})$ is an isomorphism for every motivic sheaf $\mathcal{M} \in \mathbf{DA}^{\text{ét}}(Y;\Lambda)$.

To prove Theorem 3.8, it is enough to treat the case where f is the projection $p_n : \mathbb{P}^n_X \to X$. (This reduction is easy and classical; it appears for example in [3, Exposé XII].) To treat the case of p_n, one needs a completely different approach than the one used in [3, Exposés XII et XIII]. Here is a sketch of the proof following [5, Chapitre 1]:

Proof. In contrast with the étale formalism, here we define the extraordinary push-forward functors $f_!$ before knowing the validity of the proper base change theorem. That this can be done relies on the (easy) existence of a left adjoint $h_\sharp$ to h^* when h is smooth. Indeed,

assuming that f is smoothable, i.e., can be written as $f = h \circ i$ with h smooth and i a closed immersion, one sets

$$f_! := h_\sharp \circ \mathrm{Th}^{-1}(\Omega_h) \circ i_* \qquad \text{(and dually} \quad f^! := i^! \circ \mathrm{Th}(\Omega_h) \circ h^*).$$

A big deal of effort in [5, Chapitre 1] is devoted to showing that these definitions are independent (up to natural isomorphisms) of the choice of the factorization $f = h \circ i$ and that there are coherent choices of isomorphisms $(f \circ f')_! \simeq f_! \circ f'_!$, for composable smoothable morphisms, etc. Assuming this is granted, it is then easy to explain the strategy of the proof of Theorem 3.8.

From the third axiom in §3.1.2 and the definition of the extraordinary direct image, it is quite easy to see that one has an exchange isomorphism $g^* \circ f_! \simeq f'_! \circ g'^*$ (without any condition on f beside being smoothable).

On the other hand, one can construct a natural transformation $\alpha_f : f_! \to f_*$ (which is reminiscent to the obvious morphism from cohomology with support to ordinary cohomology). It is defined as follows. Consider the commutative diagram

$$\begin{array}{ccc} Y & & \\ & \searrow^{\Delta} & \\ & Y \times_X Y & \xrightarrow[pr_1]{} Y \\ & \downarrow{\scriptstyle pr_2} & \downarrow{\scriptstyle f} \\ Y & \xrightarrow[f]{} & X. \end{array}$$

From the square, one gets a natural exchange morphism $f_! \circ pr_{1*} \to f_* \circ pr_{2!}$ (deduced by adjunction from the exchange isomorphism given by the third axiom of §3.1.2). Applying this to $\Delta_* = \Delta_!$ and using the identifications $pr_{1*} \circ \Delta_* = \mathrm{id}$ and $pr_{2!} \circ \Delta_! = \mathrm{id}$, one gets the promised natural transformation.

This is said, we are left to showing that $p_{n!} \to p_{n*}$ is an isomorphism for $p_n : \mathbb{P}^n \times X \to X$. This is done by induction on n using a rather tricky argument. The point is to realize that it suffices to show that

$$p_{n!} \circ p_n^* \to p_{n*} \circ p_n^* \qquad \text{and} \qquad p_{n!} \circ p_n^! \to p_{n*} \circ p_n^!$$

are both isomorphisms. Indeed, assuming this, one can then define two maps $p_n^* \to p_n^!$ by the compositions of

$$p_{n*} \xrightarrow{\eta} p_{n*} \circ p_n^* \circ p_{n*} \simeq p_{n!} \circ p_n^* \circ p_{n*} \xrightarrow{\delta} p_{n!}$$

$$p_{n*} \xrightarrow{\eta} p_{n*} \circ p_n^! \circ p_{n!} \simeq p_{n!} \circ p_n^! \circ p_{n!} \xrightarrow{\delta} p_{n!}$$

A direct computation shows that these morphisms give respectively left and right inverses to the canonical morphism $p_{n!} \to p_{n*}$. See [5, §1.7.2] for the complete proof. □

3.1.4. Extraordinary direct and inverse images. As said in the sketch of the proof of Theorem 3.8, one has, for f smoothable (and, in particular, for f quasi-projective), two extraordinary operations $f^!$ and $f_!$.

Once the proper base change theorem is established, it is possible to extend the extraordinary operations to the case where f is of finite presentation (but not necessarily smoothable)

following the receipt of [3, Exposé XVII]. Indeed, by Nagata's compactification, we may factor $f = \overline{f} \circ j$ where $\overline{f}$ is proper and j is an open immersion. Then, one sets $f_! := \overline{f}_* \circ j_\sharp$. The proper base change theorem implies that this is independent of the choice of the compactification.[11]

In any case, one has an adjunction $(f_!, f^!)$ for every finite type separated morphism. (The existence of $f^!$ is local over the source of f and hence, one may reduce to the case where f is quasi-projective.)

Theorem 3.9. *For every cartesian square*

$$\begin{array}{ccc} Y' & \xrightarrow{g'} & Y \\ \downarrow{\scriptstyle f'} & & \downarrow{\scriptstyle f} \\ X' & \xrightarrow{g} & X \end{array}$$

with f of finite type and g arbitrary, one has exchange isomorphisms

$$g^* f_! \simeq f'_! g'^* \qquad \text{and} \qquad f^! g_* \simeq g'_* f'^!.$$

3.2. Closed monoidal structures and Verdier duality. As constructed in §2.3, the category $\mathbf{DA}^{\text{ét}}(S;\Lambda)$, possesses a monoidal structure. However, as it is the case for the smash product of spectra in topology, it is not possible to define the tensor product directly on the category $\mathrm{Spt}_L(\mathrm{Shv}_{\text{ét}}(\mathrm{Sm}/S;\Lambda))$ of L-spectra. Different ways around this difficulty have been developed in topology. One of these ways is via the notion of *symmetric spectra* [18] that had been greatly generalized in [17].

More specifically, one considers the Abelian category $\mathrm{Spt}^\Sigma_L(\mathrm{Shv}_{\text{ét}}(S;\Lambda))$ of symmetric L-spectra of étale sheaves on Sm/S. A symmetric L-spectrum is an L-spectrum $\mathcal{E}$ endowed with an action of the n-th symmetric group Σ_n on its n-th level $\mathcal{E}_n$ and such that the assembly maps are equivariant in an appropriate sense.

The point is that the extra symmetry that symmetric L-spectra possess permits to define a symmetric and associative tensor product on $\mathrm{Spt}^\Sigma_L(\mathrm{Shv}_{\text{ét}}(\mathrm{Sm}/S;\Lambda))$. The latter induces a tensor product on $\mathbf{D}(\mathrm{Spt}^\Sigma_L(\mathrm{Shv}_{\text{ét}}(\mathrm{Sm}/S;\Lambda)))$ and its localization with respect to its triangulated subcategory $\mathcal{T}^\Sigma_{\mathbb{A}^1-\mathrm{st}}$ defined similarly as in §2.3. Finally, one can show that this localization yields an equivalent category to $\mathbf{DA}^{\text{ét}}(S;\Lambda)$ inducing a monoidal structure on the latter.

Unfortunately, the details of this story are quite technical and boring. We refer the interested reader to [6, Chapitre 4] for a complete (and self-contained) account (using however the language of model categories).

Theorem 3.10. *The categories $\mathbf{DA}^{\text{ét}}(S;\Lambda)$ are symmetric monoidal and closed (i.e., $A \otimes -$ admits a right adjoint $\underline{Hom}(A,-)$ for every S-motive A). The operations f^* are monoidal functors. One also has the usual formulas*

$$f_!(-) \otimes - \simeq f_!(- \otimes f^*(-)), \quad f^! \underline{Hom}(-,-) \simeq \underline{Hom}(f^*(-), f^!(-)),$$

$$f_* \underline{Hom}(f^*(-),-) \simeq \underline{Hom}(-, f_*(-)), \quad \underline{Hom}(f_!(-),-) \simeq f_* \underline{Hom}(-, f^!(-)), \text{ etc.}$$

[11] It is worth noting here that checking that $\overline{f}_* \circ j_\sharp$ is independent of the factorization $f = \overline{f} \circ j$ is easier than checking that $h_\sharp \circ \mathrm{Th}(\Omega_h) \circ i_*$ is independent of the factorization $f = h \circ i$. The reason for this is that "the category of compactifications" is filtered whereas the "category of smoothifications" is not.

Finally, assuming that S is of finite type over a characteristic zero field k and denoting π_S to projection to the point, there is a dualizable objet in $\mathbf{DA}^{\text{ét}}_{\text{ct}}(S;\Lambda)$ given by $\pi_S^!\Lambda(0)$.

Another important result to mention here is:

Theorem 3.11. *If X is a proper and smooth S-scheme of pure relative dimension d, then $\mathrm{M}(X)$ admits a strong dual given by $\mathrm{M}(X)(-d)[-2d]$.*

Proof. This follows from Theorem 3.10 using that

$$\mathrm{M}(X)\simeq(\pi_X)_!(\pi_X)^!\Lambda_S(0)\qquad\text{and}\qquad \mathrm{M}(X)(-d)[-2d]\simeq(\pi_X)_*(\pi_X)^*\Lambda_S(0)$$

where $\pi_X : X\to S$ is the structural morphism. □

4. Motives over a base field

The formalism of Grothendieck's six operations is a powerful tool for reducing questions about general sheaves to questions about lisse sheaves and, ultimately, to questions about (germs of) sheaves on generic points of varieties. For this formalism to be of any use in the context of motivic sheaves, one needs informations about motives over fields.

In this section we list some of what is known concerning motives over a field; everything here is essentially due to Voevodsky. When dealing with Voevodsky's motives, we mostly work over a base field k except for the construction §4.1.1 and the comparison theorem §4.1.2 where this restriction is irrelevant. The use of the étale topology results in inverting automatically the exponent-characteristic of k.[12] Therefore, there is no need in assuming k perfect in quoting [24, 29].

4.1. Voevodsky's motives. Many theorems about motives over a field and morphisms between them are obtained by using a slightly more complicated construction than the one explained in §2. The extra complication is the requirement of having transfers and is the key for many concrete computations.

4.1.1. The construction. The construction of Voevodsky's category $\mathbf{DM}^{\text{ét}}(k;\Lambda)$ follows exactly the same pattern as the construction given in §2 with only one difference: one uses the Abelian category of étale *sheaves with transfers* instead of the Abelian category of ordinary étale sheaves. To expand on this, we need some notation.

Let S be a base scheme that we assume to be Noetherian. In [29, Chapter 2], a category of finite correspondences SmCor/S was constructed. This is an additive category whose objects are smooth S-schemes. Given two smooth S-schemes U and V, the group of morphisms from U to V in SmCor/S is denoted by $\mathrm{Cor}_S(U,V)$. When S is regular, this group is freely generated by integral and closed subschemes $Z\subset U\times_S V$ such that the projection

[12] This is well-known and easy. Indeed, if $k=\mathbb{F}_p$, then the Artin–Schreier exact sequence of étale sheaves on $\mathrm{Sm}/\mathbb{F}_p$:

$$0\to\mathbb{Z}/p\mathbb{Z}\to\mathcal{O}\overset{(-)^p}{\to}\mathcal{O}\to 0,$$

and the fact that $\mathcal{O}$ is $\mathbb{A}^1$-contractible, show that the constant étale sheaf $\mathbb{Z}/p\mathbb{Z}$ is also $\mathbb{A}^1$-contractible. From this, it is easy to deduce that multiplication by p is invertible in $\mathbf{DA}^{\text{ét}}(\mathbb{F}_p;\Lambda)$ and more generally in $\mathbf{DA}^{\text{ét}}(S;\Lambda)$ for every $\mathbb{F}_p$-scheme S. The same holds true for $\mathbf{DM}^{\text{ét}}(\mathbb{F}_p;\Lambda)$ and $\mathbf{DM}^{\text{ét}}(S;\Lambda)$.

$Z \to U$ is finite and surjective over a connected component of U. Moreover, the composition of finite correspondences is then given by the usual formula involving Serre's multiplicities.

Definition 4.1. A *presheaf with transfers* on Sm/S is a contravariant additive functor from SmCor/S to the category of Λ-modules. An *étale sheaf with transfers* is a presheaf with transfers Sm/S which is, after forgetting transfers, a sheaf for the étale topology. Étale sheaves with transfers form an Abelian category that we denote by $\mathrm{Str}_{\text{ét}}(\mathrm{Sm}/S;\Lambda)$.

Example 4.2. For a smooth S-scheme X, we denote by $\Lambda_{\mathrm{tr}}(X)$ the presheaf with transfers on Sm/S represented by X, i.e., given by $\Lambda_{\mathrm{tr}}(X)(U) = \mathrm{Cor}_S(U,X)\otimes_{\mathbb{Z}}\Lambda$ for all $U \in \mathrm{Sm}/S$. In fact, $\Lambda_{\mathrm{tr}}(X)$ is an étale sheaf with transfers on Sm/S. After forgetting transfers, one has an inclusion of étale sheaves $\Lambda_{\text{ét}}(X) \subset \Lambda_{\mathrm{tr}}(X)$.

As said before, replacing everywhere "$\mathrm{Shv}_{\text{ét}}(\mathrm{Sm}/S;\Lambda)$" by "$\mathrm{Str}_{\text{ét}}(\mathrm{Sm}/S;\Lambda)$" in §2 yields Voevodsky's triangulated categories of S-motives. More precisely, one obtains two versions.

- The category of *effective Voevodsky S-motives* given by
$$\mathbf{DM}^{\mathrm{eff},\,\text{ét}}(S;\Lambda) := \mathbf{D}(\mathrm{Str}_{\text{ét}}(\mathrm{Sm}/S;\Lambda))/\mathcal{T}^{\mathrm{tr}}_{\mathbb{A}^1}$$
where $\mathcal{T}^{\mathrm{tr}}_{\mathbb{A}^1}$ is defined similarly as $\mathcal{T}_{\mathbb{A}^1}$ in §2.2.2 (writing "Λ_{tr}" instead of "$\Lambda_{\text{ét}}$" in (2.3)).
- The category of (non-effective) *Voevodsky S-motives* given by
$$\mathbf{DM}^{\text{ét}}(S;\Lambda) := \mathbf{D}(\mathrm{Spt}_{L_{\mathrm{tr}}}(\mathrm{Str}_{\text{ét}}(\mathrm{Sm}/S;\Lambda)))/\mathcal{T}^{\mathrm{tr}}_{\mathbb{A}^1-\mathrm{st}}$$
where $L_{\mathrm{tr}} = \Lambda_{\mathrm{tr}}(\mathbb{P}^1_S,\infty_S)$ and $\mathcal{T}^{\mathrm{tr}}_{\mathbb{A}^1-\mathrm{st}}$ is defined similarly as $\mathcal{T}_{\mathbb{A}^1-\mathrm{st}}$ in §2.3 (writing "Λ_{tr}" and "L_{tr}" instead of "$\Lambda_{\text{ét}}$" and "L" in (2.5) and (2.6)).

Remark 4.3. Strictly speaking, Voevodsky [24] considered categories
$$\mathbf{DM}^{\mathrm{eff},\,\text{ét}}_{-}(S;\Lambda) \qquad \text{and} \qquad \mathbf{DM}^{\text{ét}}_{\mathrm{gm}}(S;\Lambda)$$
for S the spectrum of a perfect field (with finite cohomological dimension). The category $\mathbf{DM}^{\mathrm{eff},\,\text{ét}}_{-}(S;\Lambda)$ is the triangulated subcategory of $\mathbf{DM}^{\mathrm{eff},\,\text{ét}}(S;\Lambda)$ consisting of complexes that are bounded on the right. The category $\mathbf{DM}^{\mathrm{eff},\,\text{ét}}_{\mathrm{gm}}(S;\Lambda)$ is the triangulated subcategory of $\mathbf{DM}^{\mathrm{eff},\,\text{ét}}(S;\Lambda)$ generated by $\Lambda_{\mathrm{tr}}(X)$ for $X \in \mathrm{Sm}/S$ of finite type. Finally, $\mathbf{DM}^{\text{ét}}_{\mathrm{gm}}(S;\Lambda)$ is obtained from $\mathbf{DM}^{\mathrm{eff},\,\text{ét}}_{\mathrm{gm}}(S;\Lambda)$ by formally inverting tensoring by the Lefschetz motive L_{tr} (i.e., using the naive construction as in §2.2.3); it is also the triangulated subcategory of $\mathbf{DM}^{\text{ét}}(S;\Lambda)$ generated by S-motives of finite type smooth S-schemes and their negative Tate twists.

4.1.2. The comparison theorem. There is a pair of adjoint functors:
$$\mathrm{a}_{\mathrm{tr}} : \mathrm{Shv}_{\text{ét}}(\mathrm{Sm}/S;\Lambda) \rightleftarrows \mathrm{Str}_{\text{ét}}(\mathrm{Sm}/S;\Lambda) : \mathrm{o}_{\mathrm{tr}}. \tag{4.1}$$
The functor o_{tr} is a forgetful functor: it takes an étale sheaf with transfers to its underlying étale sheaf. The functor a_{tr} is characterized by its property of commuting with arbitrary colimits and by the formula
$$\mathrm{a}_{\mathrm{tr}}(\Lambda_{\text{ét}}(U)) \simeq \Lambda_{\mathrm{tr}}(U)$$

for all $U \in \mathrm{Sm}/S$. The adjunction (4.1) can be derived yielding an adjunction on the level of effective S-motives:

$$\mathrm{La}_{\mathrm{tr}} : \mathbf{DA}^{\mathrm{eff},\text{ét}}(S;\Lambda) \rightleftarrows \mathbf{DM}^{\mathrm{eff},\text{ét}}(S;\Lambda) : \mathrm{Ro}_{\mathrm{tr}}. \tag{4.2}$$

It can also be extended to spectra and then derived yielding an adjunction on the level of (non-effective) S-motives:

$$\mathrm{La}_{\mathrm{tr}} : \mathbf{DA}^{\text{ét}}(S;\Lambda) \rightleftarrows \mathbf{DM}^{\text{ét}}(S;\Lambda) : \mathrm{Ro}_{\mathrm{tr}}. \tag{4.3}$$

Theorem 4.4. *If S is normal (and some technical assumptions are satisfied), the functors in* (4.3) *are equivalences of categories.*

Proof. When Λ is a $\mathbb{Q}$-algebra, Theorem 4.4 was proved by Morel, for S the spectrum of a field, and was generalized later by Cisinski–Déglise.[13] In [9, Annexe B], we simplified the proof of Cisinski–Déglise and extended their result to more general coefficient rings using Theorem 2.24. □

Remark 4.5. If the normal scheme S has characteristic zero and if Λ is a $\mathbb{Q}$-algebra, then the functors in (4.2) are also known to be equivalences of categories by [8, Théorème B.1]. (This is indeed a stronger statement!)

Remark 4.6. It is unknown if Theorem 4.4 holds for general base schemes (e.g., reducible). This is because the theory of finite correspondences over non-normal schemes is quite complicated. A related (and probably equivalent) open question is to know if the 2-functor $\mathbf{DM}^{\text{ét}}(-;\Lambda)$ satisfies the localization axiom (i.e., the fourth axiom in §3.1.2). In fact, this is the only missing property that prevents one to promote $\mathbf{DM}^{\text{ét}}(-;\Lambda)$ into an extended stable homotopical 2-functor. But, in our opinion, these questions have minor impact for the following reasons:

1. A stable homotopical 2-functor H, say over quasi-projective S-schemes with S regular, is essentially determined by its values on smooth S-schemes. Indeed, if X is a quasi-projective S-scheme, one can choose an embedding $i : X \hookrightarrow Y$ with Y a smooth S-scheme. Then, thanks to the locality axiom, $\mathsf{H}(X)$ can be described as the subcategory of $\mathsf{H}(Y)$ consisting of those objects supported on X, i.e., those objects that vanish when pulled back along the complement of i. Therefore, Theorem 4.4 tells that $\mathbf{DA}^{\text{ét}}(-;\Lambda)$ is, up to an equivalence, the unique stable homotopical 2-functor that extends Voevodsky's category of motives over regular bases.
2. A stressed before, the construction of $\mathbf{DA}^{\text{ét}}(S;\Lambda)$ is really simpler than $\mathbf{DM}^{\text{ét}}(S;\Lambda)$. Moreover, the advantage of using transfers in defining motivic sheaves disappears when the base scheme S has dimension ≥ 1. Indeed, all the results that will be explained in §4.2 require the base to be a field.

Remark 4.7. The reader might wonder which construction of categories of motives is better. The answer is that both $\mathbf{DA}^{\text{ét}}(S;\Lambda)$ and $\mathbf{DM}^{\text{ét}}(S;\Lambda)$ have their advantages and disadvantages.

[13] In fact, Morel and Cisinski–Déglise prove a stronger result where the étale topology is replaced by the Nisnevich topology. Indeed, they prove that $\mathbf{DM}(k;\mathbb{Q})$ is equivalent to a direct summand $\mathbf{DA}(S;\mathbb{Q})_+$ of $\mathbf{DA}(S;\mathbb{Q})$ whose complement vanishes when étale descent is imposed.

- $\mathbf{DA}^{\text{ét}}(S;\Lambda)$ is simpler[14] and is the correct category of motivic sheaves for any S. On the other hand, one does not have a concrete model for the $\mathbb{A}^1$-localization functor when S is the spectrum of a field.
- Over a field, one has the theory of homotopy invariant presheaves with transfers which is a powerful tool to study the category $\mathbf{DM}^{\text{ét}}(k;\Lambda)$. However, over a curve and higher dimensional bases, this advantage disappears as the theory of homotopy invariant presheaves with transfers breaks down completely. Moreover, it is unclear if $\mathbf{DM}^{\text{ét}}(S;\Lambda)$ is the correct category when S is not normal.

4.2. Homotopy invariant presheaves with transfers. Let $\mathcal{F}$ be a presheaf on Sm/k. We say that $\mathcal{F}$ is homotopy invariant if $\mathcal{F}(U) \to \mathcal{F}(\mathbb{A}^1 \times U)$ is an isomorphism for all $U \in \mathrm{Sm}/k$. For simplicity, we assume that the exponent characteristic of k is invertible in Λ. A basic theorem of Voevodsky [29, Chapter 3] states the following.[15]

Theorem 4.8. *Let $\mathcal{F}$ be a homotopy invariant presheaf with transfers on Sm/k (with values in Λ-modules). Then $\mathrm{a}_{\text{ét}}(\mathcal{F})$, the étale sheaf associated to $\mathcal{F}$, is an $\mathbb{A}^1$-local object of $\mathbf{D}(\mathrm{Str}_{\text{ét}}(\mathrm{Sm}/k;\Lambda))$. More concretely,*

$$H^i_{\text{ét}}(U;\mathrm{a}_{\text{ét}}(\mathcal{F})) \to H^i_{\text{ét}}(\mathbb{A}^1 \times U;\mathrm{a}_{\text{ét}}(\mathcal{F}))$$

is an isomorphism for all $i \in \mathbb{N}$ and $U \in \mathrm{Sm}/k$.

Remark 4.9. All the hypothesis in this theorem are necessary. For instance, the theorem is wrong for presheaves without transfers. It is also wrong if k is replaced by a curve or a higher dimensional base.

One reason why this theorem is important is that it enables one to construct very easily the $\mathbb{A}^1$-localization of any complex of étale sheaves with transfers. To explain this, we need some notation.

Definition 4.10. For $n \in \mathbb{N}$, set

$$\Delta^n = \mathrm{Spec}(\mathbb{Z}[t_0,\dots,t_n]/(t_0+\dots+t_n-1)).$$

These schemes form a cosimplicial scheme $\Delta^\bullet$. Given a complex of presheaves with transfers $\mathcal{K}_\bullet$, we define $\mathrm{Sing}^{\mathbb{A}^1}(\mathcal{K})$ to be the total complex of the double complex $\underline{\hom}(\Delta^\bullet;\mathcal{K}_\bullet)$. (Recall that $\underline{\hom}(\Delta^n,\mathcal{F})(U) = \mathcal{F}(\Delta^n \times U)$ for any presheaf $\mathcal{F}$ and any $U \in \mathrm{Sm}/k$.) The functor $\mathrm{Sing}^{\mathbb{A}^1}$ is called the *Suslin–Voevodsky construction*.

Corollary 4.11. *Let $\mathcal{K}$ be a complex of étale sheaves with transfers. Then $\mathrm{Loc}_{\mathbb{A}^1}(\mathcal{K})$ is given by the Suslin–Voevodsky construction $\mathrm{Sing}^{\mathbb{A}^1}(\mathcal{K})$.*

Proof. It follows formally from the construction that the canonical map $\mathcal{K} \to \mathrm{Sing}^{\mathbb{A}^1}(\mathcal{K})$ is an isomorphism in $\mathbf{DM}^{\text{eff},\text{ét}}(k;\Lambda)$. It remains to show that $\mathrm{Sing}^{\mathbb{A}^1}(\mathcal{K})$ is $\mathbb{A}^1$-local. But again, it follows formally form the construction that the homology presheaves of the complex

[14] For instance, it is very convenient not to have to worry about transfers when discussing realizations!

[15] In loc. cit., the result is established for the Nisnevich topology. However, it is an exercise to deduce the result for the étale topology using Suslin's rigidity theorem [24, Theorem 7.20] and the homotopy invariance of étale cohomology with values in $\Lambda/n\Lambda$ for n prime to the exponent-characteristic of k.

$\mathrm{Sing}^{\mathbb{A}^1}(\mathcal{K})$ are homotopy invariant (and admits transfers). Applying Theorem 4.8 to these and using a spectral sequence, one deduces that the maps

$$H^i_{\text{ét}}(U, \mathrm{Sing}^{\mathbb{A}^1}(\mathcal{K})) \to H^i_{\text{ét}}(\mathbb{A}^1 \times U; \mathrm{Sing}^{\mathbb{A}^1}(\mathcal{K}))$$

are isomorphisms. □

4.3. Application: morphisms between motivic sheaves. A basic question about motivic sheaves is the following.

Question. *Given two motivic sheaves $\mathcal{M}$ and $\mathcal{N}$ over a base scheme S, how to compute the group* $\hom_{\mathbf{DA}^{\text{ét}}(S;\Lambda)}(\mathcal{M}, \mathcal{N})$*?*

As said before, in theory, the formalism of the six operations reduces the above question to computing some groups of morphisms (usually many) in $\mathbf{DA}^{\text{ét}}(k;\Lambda) \simeq \mathbf{DM}^{\text{ét}}(k;\Lambda)$ (for various fields k). Therefore, it is important to have a solution of this question when the base is a field.

Let k be a field and assume that the exponent-characteristic of k is invertible in Λ. We will explain the solution of the above question in the case where $\mathcal{M}$ and $\mathcal{N}$ are the motives of smooth k-varieties X and Y respectively. Hence, we concentrate on the groups

$$\hom_{\mathbf{DM}^{\text{ét}}(k;\Lambda)}(\mathrm{M}(X); \mathrm{M}(Y)[n]).$$

For simplicity, we assume that Y is proper of pure dimension d_Y. By Theorem 3.11, we know that $\mathrm{M}(Y)$ has a strong dual given by $\mathrm{M}(Y)^\vee = \mathrm{M}(Y)(-d_Y)[-2d_Y]$. Hence, we are left to compute the étale motivic cohomology groups

$$H^p_{\mathcal{L}}(Z; \Lambda(q)) := \hom_{\mathbf{DM}^{\text{ét}}(k;\Lambda)}(\mathrm{M}(Z); \Lambda(q)[p])$$

(for $Z = X \times_k Y$ and $q = d_Y$ and $p = n + 2d_Y$). The answer is as follows.

Theorem 4.12. *Let X be a smooth k-variety. Then there is a canonical isomorphism*

$$\hom_{\mathbf{DM}^{\text{ét}}(k;\Lambda)}(\mathrm{M}(X); \Lambda(q)[p]) \simeq H^{p-2q}_{\text{ét}}(X; \mathrm{Sing}^{\mathbb{A}^1}\Lambda_{\mathrm{tr}}(\mathbb{P}^1_k, \infty_k)^{\wedge q}) \tag{4.4}$$

where the right-hand side is the étale hypercohomology of X with values in the complex of étale sheaves $\mathrm{Sing}^{\mathbb{A}^1}\Lambda_{\mathrm{tr}}(\mathbb{P}^1_k, \infty_k)^{\wedge q}$.

Remark 4.13. Theorem 4.12 is an immediate consequence of Theorem 4.8. Another theorem of Voevodsky asserts that the complex $\mathrm{Sing}^{\mathbb{A}^1}\Lambda_{\mathrm{tr}}(\mathbb{P}^1_k, \infty_k)^{\wedge q}$ satisfies Nisnevich descent. Therefore, if Λ is a $\mathbb{Q}$-algebra (or when "étale" is replaced by "Nisnevich"), the right hand side in (4.4) is simply the cohomology of a concrete complex of cycles, namely $\mathrm{Cor}_k(\Delta^\bullet \times X, (\mathbb{P}^1_k, \infty_k)^{\wedge q}) \otimes \Lambda$.

5. Conjectures

There are many outstanding conjectures concerning motives and algebraic cycles. Some of these seem desperately out of reach such as the Hodge and Tate conjectures (that already made an appearance in Remark 2.27) or the Grothendieck and Kontsevich–Zagier conjectures on periods.

In this section we will discuss two other conjectures that, in comparison with the previous ones, seem more approachable. These two conjectures (as well as the previous ones) predict relations between algebro-geometric objects and transcendental objects, and each one of these conjectures fills some part of the gap between the two half-bridges discussed in the Introduction.

5.1. The conservativity conjecture. Let k be a field of characteristic zero and let $\sigma : k \hookrightarrow \mathbb{C}$ be a complex embedding. Given a finite type k-scheme X, denote by X_{an} the set $X(\mathbb{C})$ endowed with its analytic topology. One has a Betti realization functor [7]

$$\mathrm{B}^*_X : \mathbf{DA}^{\text{ét}}(X;\Lambda) \to \mathbf{D}(X_{\mathrm{an}};\Lambda) \tag{5.1}$$

where $\mathbf{D}(X_{\mathrm{an}};\Lambda)$ is the derived category of sheaves of Λ-modules on X_{an}. A central conjecture concerning motives states the following.

Conjecture 5.1 (Conservativity Conjecture). *The functor B^*_X, restricted to the subcategory $\mathbf{DA}^{\text{ét}}_{\mathrm{ct}}(X;\Lambda)$, is conservative. Said differently, if $\mathcal{M}$ is a constructible motivic sheaf on X such that $\mathrm{B}^*_X(\mathcal{M}) \simeq 0$, then necessarily $\mathcal{M} \simeq 0$.*

Lemma 5.2. *It suffices to prove Conjecture 5.1 for $X = \mathrm{Spec}(k)$ and $\Lambda = \mathbb{Q}$.*

Proof. The reduction to the case $\Lambda = \mathbb{Q}$ follows from Theorem 2.24. The reduction to the case $X = \mathrm{Spec}(k)$ is a consequence of the compatibility of the Betti realization with inverse images. □

Conjectures such as the Hodge and Tate Conjectures concern existence of algebraic cycles (and hence elements in motivic cohomology). On the contrary, Conjecture 5.1 concerns motives which makes it look more approachable. However, the next remark suggests that this hope might be too naive.

Remark 5.3. It is well-known that the category of Chow motives with rational coefficients embeds fully faithfully inside $\mathbf{DM}^{\text{ét}}(k;\mathbb{Q})$. Applying Conjecture 5.1 to Chow motives one obtains the following particular case. *Let X and Y be smooth and projective varieties over k of pure dimension d. Let $\gamma \in \mathrm{CH}^d_{\mathbb{Q}}(X \times_k Y)$ be an algebraic cycle inducing an isomorphism in cohomology $\gamma : H^*(Y(\mathbb{C});\mathbb{Q}) \xrightarrow{\sim} H^*(X(\mathbb{C});\mathbb{Q})$. Then, there exists an algebraic cycle $\delta \in \mathrm{CH}^d_{\mathbb{Q}}(Y \times_k X)$ such that $\delta \circ \gamma = [\Delta_X]$ and $\gamma \circ \delta = [\Delta_Y]$.* This reveals a strong analogy/connexion between the Conservativity Conjecture and the Standard Conjecture of Lefschetz type [12].

Remark 5.4. On a more optimistic note, we mention that we formulated in [8, Conjecture B of §2.4] a concrete (although very complicated) conjecture that would implies Conjecture 5.1. We like to think that this is a non trivial step (although, probably, a very small one) towards a potential solution of the Conservativity Conjecture.

5.2. Existence of a motivic *t*-structure. Keep the notation as in §5.1.

Conjecture 5.5 (t-Structure Conjecture). *The category $\mathbf{DA}^{\text{ét}}_{\mathrm{ct}}(X;\Lambda)$ carries a t-structure, called the* motivic t-structure*, making B^*_X exact. (Said differently, if $\mathcal{M}$ is a constructible X-motive which belongs to the heart of the motivic t-structure, then $\mathrm{B}^*_X(\mathcal{M})$ is concentrated in degree zero, i.e., is isomorphic to a constructible sheaf on X_{an}.) Moreover, this t-structure is independent of the choice of the complex embedding σ.*

Remark 5.6. Conjecture 5.5 can be reduced to the case where $X = \mathrm{Spec}(k)$ using gluing techniques. Moreover, these gluing techniques can also be used to define perverse motivic t-structures assuming the existence of the usual motivic t-structure.

Remark 5.7. It is important to note that we do not assume Λ to be a $\mathbb{Q}$-algebra in Conjecture 5.5. Indeed, the t-Structure Conjecture is expected to hold *integrally* for $\mathbf{DA}^{\text{ét}}_{\text{ct}}(X;\Lambda)$; in fact, assuming that $\mathbf{DA}^{\text{ét}}_{\text{ct}}(S;\mathbb{Q})$ admits a motivic t-structure, it is easy to construct a motivic t-structure on $\mathbf{DA}^{\text{ét}}_{\text{ct}}(X;\mathbb{Z})$ using Theorem 2.24.

This is particularly significant as it is well-known that $\mathbf{DM}_{\text{gm}}(k;\Lambda)$ (The "Nisnevich" variant of $\mathbf{DM}^{\text{ét}}_{\text{gm}}(k;\Lambda)$) cannot admit a motivic t-structure unless Λ is a $\mathbb{Q}$-algebra. (A simple explanation for this was given by Voevodsky [29, Remark on page 217].) This indicates that, in view of a future theory of *Abelian motivic sheaves*, it is more natural to impose étale descent.

Remark 5.8. In [8, Conjecture A of §2.4] we formulated a very concrete conjecture that, together with Conjecture B of loc. cit., should imply Conjecture 5.5 and more. (By "more", we have in mind the property that $\mathbf{DA}^{\text{ét}}_{\text{ct}}(S;\Lambda)$ is equivalent to the derived category of the heart of its motivic t-structure.)

Remark 5.9. As a measure of the deepness of Conjectures 5.1 and 5.5, we mention that they imply the Standard Conjectures in characteristic zero (as explained by Beilinson [10]). They imply many other well-established conjectures such as the Bloch Conjecture for surfaces and its generalizations, Kimura finiteness for Chow motives, the existence of the Bloch–Beilinson filtration on Chow groups, etc.

Isogenies, power operations, and homotopy theory

Charles Rezk

Abstract. The modern understanding of the homotopy theory of spaces and spectra is organized by the chromatic philosophy, which relates phenomena in homotopy theory with the moduli of one-dimensional formal groups. In this paper, we describe how certain phenomena $K(n)$-local homotopy can be computed from knowledge of isogenies of deformations of formal groups of height n.

Mathematics Subject Classification (2010). Primary 55S25; Secondary 55N34, 55P43.

Keywords. Homotopy theory, formal groups, power operations.

1. Introduction

A sweeping theme in the study of homotopy theory over the past several decades is the *chromatic viewpoint*. In this philosophy, phenomena in homotopy theory are associated to phenomena in the theory of one-dimensional formal groups. This program was instigated by Quillen's observation of the connection between complex bordism and formal group laws [32].

The chromatic picture is best described in terms of localization at a chosen prime p. After one localizes at a prime p, the moduli of formal groups admits a descending filtration, called the *height* filtration. According the chromatic philosophy, this filtration is mirrored by a sequence of successive approximations to homotopy theory. The difference between adjacent approximation is the *nth chromatic layer*, which is associated by the chromatic picture to formal groups of height n. Phenomena in the nth chromatic layer may be detected using cohomology theories called *Morava K-theories* and *Morava E-theories*, which are typically (and unimaginatively) denoted $K(n)$ and E_n. A good recent introduction to this point of view is is [17].

In this paper I will describe a particular manifestation of the chromatic picture, which relates "$K(n)$-local homotopy theory" (i.e., one manifestation of the nth chromatic layer in homotopy theory), to *isogenies* of formal groups.

Some of the results describe here are joint work with others, including some not-yet-published work with Matt Ando, Mark Behrens, and Mike Hopkins.

2. Formal groups and localized homotopy theory

We briefly recall the role and significance of formal groups in homotopy theory.

Proceedings of the International Congress of Mathematicians, Seoul, 2014

2.1. Complex orientation and formal groups. Recall that a generalized cohomology theory E^* is said to be **complex orientable** if (i) it takes values in graded rings, and (ii) if there exists an element $x \in \widetilde{E}^*\mathbb{CP}^\infty$ which restricts to the fundamental class in $\widetilde{E}^*\mathbb{CP}^1$. To such a theory is associated a (one-dimensional, commutative) **formal group** $\mathbb{G}_E$, which is the formal scheme over the ring E^* with coefficient ring $\mathcal{O}_{\mathbb{G}_E} = E^*\mathbb{CP}^\infty$.

Remark 2.1. For a complex orientable theory, a choice of element x as in (ii) gives rise to an "Euler class" on complex line bundles, defined by $e_x(L \to X) := f^*(x) \in E^*(X)$ where $f\colon X \to \mathbb{CP}^\infty$ classifies L, together with a power series $F_x(t_1, t_2) \in E^*[\![t_1, t_2]\!]$ expressing the Euler class of a tensor product of lines:

$$e_x(L_1 \otimes L_2) = F_x(e_x(L_1), e_x(L_2)),$$

which is an example of a **formal group law** on E^*. Both e_x and F_x depend on the choice of "coordinate" $x \in \mathcal{O}_{\mathbb{G}_E} = E^*\mathbb{CP}^\infty$. The formal group $\mathbb{G}_E$ is a coordinate-free expression of the collection of formal group laws associated to E, and depends only on the cohomology theory E itself.

Example 2.1. For a ring R, let HR^* denote ordinary cohomology with coefficients in R. For any R, the theory HR^* is complex orientable, and the resulting formal group $\mathbb{G}_R$ is the *additive* formal group. In fact, if we take $x \in HR^2(\mathbb{CP}^\infty)$ to be any generator, we have that $F_x(t_1, t_2) = t_1 + t_2$, and recover the classical addition formula for first Chern classes of complex line bundles.

Example 2.2. Complex bordism MU^* is a complex oriented theory, which comes with a tautological choice of coordinate $x \in MU^2\mathbb{CP}^\infty$. Quillen [32] identified the resulting formal group F_x as the *universal* formal group law. In coordinate-free language, we may say that the formal group $\mathbb{G}_{MU}$ of complex bordism is the universal example of a formal group equipped with the data of a choice of coordinate.

All formal groups over a given field of characteristic 0 are isomorphic to the additive formal group. For a formal groups $\mathbb{G}$ over fields k of characteristic p, there is an isomorphism invariant called the **height** of $\mathbb{G}$, which is an element $n \in \mathbb{Z}_{\geq 1} \cup \{\infty\}$. For separably closed k, the height is a complete invariant.

Example 2.3. Fix a prime p. For any height $n \in \mathbb{Z}_{\geq 1}$, there exist complex cohomology theories whose formal group is one of height n. The standard examples are the **Morava K-theories** $K(n)$, whose coefficient ring is $K(n)^* = \mathbb{F}_p[v_n^{\pm}]$ with $v_n \in K(n)^{-2(p^n-1)}$, and whose formal group is the **Honda formal group** of height n.

Example 2.4. For any formal group G_0 of height $1 \leq n < \infty$ over a perfect field k, Lubin and Tate constructed its *universal deformation*, which is a formal group G defined over the complete local ring $\mathbb{W}_p[\![u_1, \dots, u_{n-1}]\!]$, whose restriction at the special fiber is G_0. There is a corresponding cohomology theory called **Morava E-theory**, which will play an important role in our story; see §4.2 below.

Formal groups of infinite height over fields of characteristic p are isomorphic to the additive formal group. Ordinary homology $H\mathbb{F}_p$ with mod p coefficients is an example of a complex oriented theory whose formal group has infinite height.

It is conventional to say that any formal group over a field of characteristic zero has height 0. Ordinary homology $H\mathbb{Q}$ with rational coefficients is an example of a theory with such a formal group.

2.2. Localized homotopy theory. Associated to any homology theory E is a corresponding **localization functor**, first constructed in full generality by Bousfield [10]. Say that a based space Y is E**-local** if for any based CW-complex K such that $\widetilde{E}_*(K) \approx 0$, the space $\mathrm{Map}_*(K, Y)$ of based maps is weakly contractible. Bousfield showed that for any space X, there exists a space X_E and a map $\eta_E\colon X \to X_E$, called the E**-localization** of X, such that (i) the map η_E induces an isomorphism in E-homology, and (ii) X_E is E-local. Furthermore, the operation $X \mapsto X_E$ can be realized functorially.

Example 2.5. For ordinary homology theories $E = HR$, localization of spaces is well-behaved in the absence of fundamental groups. For instance, $\pi_*(X_{H\mathbb{Q}}) \approx \pi_* X \otimes \mathbb{Q}$ if X is simply connected, and $\pi_*(X_{H\mathbb{F}_p}) \approx (\pi_* X)^\wedge_p$ if X is simply connected and finite type.

There is an analogous localization construction for spectra. In what follows we will be most interested in localization with respect to Morava K-theory spectra. In particular, for every prime p and $n \geq 1$, there is a localization functor

$$X \mapsto X_{K(n)}\colon h\mathrm{Spectra} \to h\mathrm{Spectra}_{K(n)} \subset h\mathrm{Spectra}$$

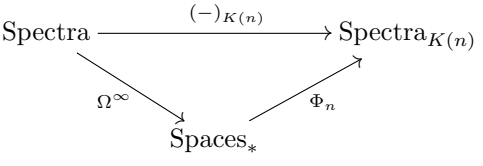
from the homotopy category of spectra to the full subcategory of $K(n)$-local spectra.

2.3. The functor of Bousfield and Kuhn. It is a remarkable observation of Bousfield[11] and Kuhn[22] that localization functors on spectra with respect to certain homology theories (such as Morava K-theories) actually factor through the underlying space.

Fix a prime p and an integer $n \geq 1$. There exists a functor

$$\Phi_n\colon \mathrm{Spaces}_* \to \mathrm{Spectra}_{K(n)} \subset \mathrm{Spectra}$$

from pointed spaces to $K(n)$-local spectra which makes the following diagram commute up to natural weak equivalence.



The functor Φ_n is constructed using the existence of periodic phenomena in stable homotopy theory [20]. Observe that given any space Y and map $g\colon Y \to \Omega^d Y$ with $d \geq 1$, we can obtain a spectrum E by setting $\underline{E}_{kd} = Y$ using the g as the structure map $\underline{E}_{kd} \to \Omega^d \underline{E}_{kd+d}$ (much as periodic K-theory is obtained from the Bott periodicity map $U \to \Omega^2 U$, though in our case g need not be an equivalence). Given a based finite CW-complex K and a map $f\colon \Sigma^d K \to K$ for some $d \geq 1$, define a functor $\Phi_{K,f}\colon \mathrm{Spaces}_* \to \mathrm{Spectra}$ by associating to a based space X the map

$$f^*\colon \mathrm{Map}_*(K, X) \xrightarrow{f} \mathrm{Map}_*(\Sigma^d K, X) \approx \Omega^d \mathrm{Map}_*(K, X),$$

from which we obtain a spectrum $\Phi_{K,f}(X)$ as above. The functor $\Phi_{K,f}(X)$ has the properties:

- $\Phi_{K,f}(\Omega X) \approx \Omega \Phi_{K,f}(X)$,

- If $X = \Omega^\infty Y$ is the 0-space of a spectrum Y, then

$$\Phi_{K,f}(\Omega^\infty Y) \approx \operatorname{hocolim}_k \Sigma^{-kd}\underline{\mathrm{Hom}}(\Sigma^\infty K, Y) \approx (\Sigma^\infty f)^{-1}\underline{\mathrm{Hom}}(\Sigma^\infty K, Y),$$

  the "telescope" of the function spectrum $\underline{\mathrm{Hom}}(\Sigma^\infty K, Y)$ induced by the map $\Sigma^\infty f$.

Non-trivial examples are provided by a v_n-self map, i.e., a pair (K, f) such that K is a finite CW complex with $K(n)_*K \neq 0$ and $f\colon \Sigma^d K \to K$ with $d \geq 1$ such that $K(n)_*f$ is an isomorphism. (This implies that for any spectrum Y, the map $\underline{\mathrm{Hom}}(K, Y) \to f^{-1}\underline{\mathrm{Hom}}(K, Y)$ induces an isomorphism on $K(n)_*$-homology, and thus $\Phi_{K,f}$ is seen to be non-trivial.)

Such v_n-self maps are plentiful by the *periodicity theorem* of Hopkins-Smith [20]. Using this theory, [22] constructs Φ_n^f as a homotopy inverse limit of a suitably chosen family of functors $\Sigma^{-q_i}\Phi_{K_i,f_i}$; then $\Phi_n(X) := \Phi_n^f(X)_{K(n)}$.

Remark 2.2. Given a v_n-self map f of K, the homotopy groups

$$\pi_*\Phi_{K,f}(X) \approx f^{-1}\pi_* \operatorname{Map}(K, X)$$

are the v_n**-periodic homotopy groups** of the space X, usually denoted $v_n^{-1}\pi_*(X; K)$ (they depend on K, but not on the choice of v_n-self map f). As a result, the spectrum $\Phi_n(X)$ contains information about the v_n-periodic homotopy groups of the space X. The extent to which this information is captured depends in part on the status of the *telescope conjecture*, which if true would imply that $\Phi_n = \Phi_n^f$; see the discussion in [23].

Bousfield has developed a theory to effectively compute invariants of $\Phi_1(X)$ for certain spaces X, such as spheres and finite H-spaces [13, 14]. In §5, we will outline an approach to generalize Bousfield's results to the case of $n \geq 2$.

2.4. The Bousfield-Kuhn idempotent. Given a basepoint preserving unstable map $f\colon \Omega^\infty F \to \Omega^\infty E$ where E is a $K(n)$-local spectrum, the $K(n)$-local Bousfield-Kuhn functor gives rise to a map of spectra

$$F \xrightarrow{\iota} F_{K(n)} \approx \Phi_n\Omega^\infty F \xrightarrow{\Phi_n(f)} \Omega^\infty E \approx E,$$

and hence an infinite loop space map

$$\phi_n(f) := \Omega^\infty(\Phi_n(f) \circ \iota)\colon \Omega^\infty F \to \Omega^\infty E.$$

If $f = \Omega^\infty g$ for a map $g\colon F \to E$ of spectra, then $\Phi_n(f) \circ \iota = g$. Thus, the function

$$\phi_n\colon h\mathrm{Spaces}_*(\Omega^\infty F, \Omega^\infty E) \xrightarrow{\Phi} h\mathrm{Spectra}(F, E) \xrightarrow{\Omega^\infty} h\mathrm{Spaces}_*(\Omega^\infty F, \Omega^\infty E)$$

is *idempotent*, with image precisely the set of homotopy classes of maps $\Omega^\infty F \to \Omega^\infty E$ which are infinite loop maps.

It turns out to be possible to compute something about the map $\phi_n(f)$ (as an *unstable* map), when E is a complex oriented cohomology theory to which the character theory of Hopkins-Kuhn-Ravenel [18] can be applied, such as Morava E-theory. For the purposes of stating a result, we recall that the Hopkins-Kuhn-Ravenel theory provides a natural ring homomorphism

$$\chi\colon E^0(X \times BG) \to \prod_{g \in G_{n,p}} D \otimes_{E^0} E^0(X),$$

for any finite group G, where: X is a finite CW-complex, $G_{n,p}$ is the set of conjugacy classes of homomorphism $\Lambda_N = (\mathbb{Z}/p^N)^n \to G$ (for N sufficiently large, depending on G), and D_N is a certain faithfully flat extension of E^0.

Let $f\colon \Omega^\infty F \to \Omega^\infty E$ be an H-map; i.e., the induced operation $F^0(-) \to E^0(-)$ is a group homomorphism. The following computes the operation $\phi_n(f)$.

Theorem 2.3. *Let E be a $K(n)$-local complex orientable theory such that π_*E is a complete local ring, and let $f\colon \Omega^\infty F \to \Omega^\infty E$ be an H-space map. Then for any finite CW-complex X, the map*

$$\phi_n(f)\colon F^0(X) \to E^0(X)$$

is given (modulo torsion in $E^0(X)$) by

$$(\phi_n f)(x) = \sum_{k=0}^{n} (-1)^k p^{\binom{k}{2}} \left(p^{-k} \sum_{A \subseteq \Lambda_1^*,\ |A|=p^k} \chi(f(\widetilde{x} \wedge t_A))(g_A). \right) \tag{2.1}$$

The inner sum is taken over all subgroups of $\Lambda_1^* = \mathrm{Hom}(\Lambda_1, U(1))$ of given order; the map $g_A\colon \Lambda_1 \to A^* = \mathrm{Hom}(A, U(1))$ is the dual homomorphism to the inclusion $A \subseteq \Lambda_1^*$; $t_A\colon \Sigma_+^\infty BA^* \to S^0$ is the stable transfer map, and $\widetilde{x}\colon \Sigma_+^\infty X \to F$ is the map of spectra representing $x \in F^0(X)$.

It turns out that the inner sum of (2.1) in fact takes values in $E^0(X) \subset D_1 \otimes_{E^0} E^0(X)$, and furthermore this value is divisible by p^k, so that the bracketed expression in (2.1) gives a well-defined element of $E^0(X)$ modulo torsion. The statement (2.3) has not appeared in print elsewhere, but it is a consequence of the methods of [36].

Example 2.6. Let $E = K_p$ be p-complete K-theory. Then the formula of (2.3) becomes

$$(\Phi f)(x) = f(x) - p^{-1}\chi(f(\widetilde{x} \wedge t_{Z/p}))(g_{\mathbb{Z}/p}).$$

In particular, if $f\colon \Omega^\infty F \to \Omega^\infty K_p$ is an H-map such that $\chi(f(\widetilde{x} \wedge t_{\mathbb{Z}/p}))(g_{\mathbb{Z}/p}) = 0$, then f admits the structure of an infinite loop map. This immediately recovers a well-known theorem of Madsen-Snaith-Tornehave [31].

There is a generalization of (2.1) for f which is not necessarily an H-map, though it is too cumbersome to give it here. Formulas of this nature, where the target spectrum is $E = K(n)$, are obtained in [42].

3. Units and orientations

The Bousfield-Kuhn idempotent can be usefully applied to the study of the units spectrum of a commutative S-algebra.

3.1. The units of a commutative ring spectrum. Let R be a homotopy associative ring spectrum. The **units space** of R is called $GL_1(R)$; it is defined by the pullback square of spaces

$$\begin{array}{ccc} GL_1(R) & \longrightarrow & \Omega^\infty R \\ \downarrow & & \downarrow \\ (\pi_0 R)^\times & \rightarrowtail & \pi_0 R \end{array}$$

For a space X, we have $h\mathrm{Spaces}(X, GL_1(R)) \approx R^0(X)^\times \subseteq R^0(X)$.

When R is a commutative S-algebra, then $GL_1(R)$ admits a canonical structure of a grouplike E_∞-space, induced by the multiplicative structure of R. Write $\mathrm{gl}_1(R)$ for the (-1)-connected spectrum which is the infinite delooping of $GL_1(R)$, called the **units spectrum** of R.

The units spectrum carries the obstruction to constructing orientations of commutative S-algebras, as shown by May, Quinn, Ray, and Tornehave in [26]; see [27] and [1] for recent treatments of this theory. Let $f\colon g \to o$ be a map of (-1)-connective spectra, where o is the infinite delooping of BO, the classifying space of the infinite dimensional orthogonal group. Let $BG = \Omega^\infty g$ denote the infinite delooping of g, and let MG denote the Thom spectrum of the virtual vector bundle classified by $B(\Omega^\infty f)\colon BG \to BO$; the spectrum MG admits (up to weak equivalence) the structure of a commutative S-algebra. Then one can show that space of commutative S-algebra maps $MG \to R$ is weakly equivalent to the space of null-homotopies of the composite map

$$g \xrightarrow{f} o \xrightarrow{j} \mathrm{gl}_1(S) \to \mathrm{gl}_1(R).$$

Thus, understanding the homotopy type of the spectrum $\mathrm{gl}_1(R)$ is essential to understanding G-orientations of R which are realized by maps of commutative S-algebras.

3.2. A "logarithmic" operation. We use the Bousfield-Kuhn functor to obtain information about the $K(n)$-localization of $\mathrm{gl}_1(R)$. To do this, we consider the "shift" map

$$s\colon GL_1(R) \xrightarrow{x \mapsto x-1} \Omega^\infty R.$$

This shift map is a based map between infinite loop spaces, and thus we may apply the idempotent operator of §2.4 to it. If R is a $K(n)$-local commutative S-algebra, we obtain in this way from this cohomology operation of the form

$$\ell_n = \phi_n(s)\colon R^0(X)^\times \to R^0(X),$$

which is "logarithmic", in the sense that $\ell_n(xy) = \ell_n(x) + \ell_n(y)$. The operation ℓ_n is represented by a map of spectra $\mathrm{gl}_1(R) \to R$.

Example 3.1. To get a sense of what such an operation provides, consider the following analogous situation, where E is a *rational* commutative S-algebra. For any pointed and *connected* space X, we can define a group homomorphism

$$\ell_{\mathbb{Q}}\colon (1 + \overline{E}^0(X))^\times \to E^0(X) \qquad \text{by} \qquad \ell_{\mathbb{Q}}(x) = -\textstyle\sum_{m\geq 1}(1-x)^m/m = \log(x).$$

The series defining $\ell_{\mathbb{Q}}$ is converges: because X is connected, $1 - x$ is nilpotent when restricted to any connected finite CW-complex mapping to X. The operation $\ell_{\mathbb{Q}}$ is in fact stable: it is represented by a map of spectra $(\mathrm{gl}_1 E)_{\geq 1} \to E$ (where $Z_{\geq n}$ denotes the $(n-1)$-connected cover of a spectrum Z).

The above theory applies in this case to give the following.

Theorem 3.1 ([36]). *Let E be a Morava E-theory* (2.4)*, associated to the Lubin-Tate universal deformation of a height n-formal group. Then its logarithmic operation is given (modulo*

torsion) by the formula

$$\ell_n(x) = \frac{1}{p}\log\left(\prod_{k=0}^{n}\Big(\prod_{A\subset\Lambda^*,\ |A|=p^k}\psi_A(x)\Big)^{(-1)^k p^{\binom{k}{2}-k+1}}\right). \tag{3.1}$$

The functions $\psi_A\colon E^0(X)\to D\otimes_{E^0}E^0(X)$ are certain natural additive and multiplicative cohomology operations (described below (4.1)*), and* $\log(x) = -\sum_{m\geq 1}(1-x)^m/m$.

The expression inside "log" in (3.1) is a multiplicative analog of (2.1), with the role of $x\mapsto\chi(f(\widetilde{x})\wedge t_A, g_A)$ in (2.1) replaced by the operation ψ_A. It turns out that the expression inside log in (3.1) is in fact contained in $E^0(X)\subseteq D\otimes_{E^0}E^0(X)$, and is congruent to 1 modulo p; thus evaluating the formal expansion of log at this expression converges p-adically to an element of $E^0(X)$.

Example 3.2. An example of a Morava E-theory spectrum at height 1 is KU_p, the p-completion of complex K-theory. In fact, it is possible to generalize (3.1) in the case of $n=1$ to any $K(1)$-local commutative S-algebra E, so we will describe the result in this case [36, Thm. 1.9]. The formula (3.1) takes the form

$$\ell_1(x) = \frac{1}{p}\log\big(x^p/\psi^p(x)\big) = -\sum_{m\geq 1}\frac{1}{pm}\big(1-x^p/\psi^p(x)\big)^m. \tag{3.2}$$

If E is KU_p or KO_p, the operation $\psi^p\colon E^0(-)\to E^0(-)$ is the usual pth Adams operation on p-complete real-or-complex K-theory.

We can do a little better in this case: the operation ψ^p on $E^0(-)$ satisfies a "Frobenius congruence" $\psi^p(x)\equiv x^p \mod pE^0(-)$; therefore the infinite series of (3.2) converges p-adically. The Frobenius congruence is "witnessed" by a cohomology operation $\theta^p\colon E^0(-)\to E^0(-)$, satisfying the identity $\psi^p(x) = x^p + p\,\theta^p(x)$. Thus we can write

$$\ell_1(x) = \sum_{m\geq 1}(-1)^m\frac{p^{m-1}}{m}(\theta^p(x)/x^p)^m, \tag{3.3}$$

and (3.3) in fact holds on the nose (i.e., not merely modulo torsion [36, Thm. 1.9]). The right-hand side of (3.3) recovers the **Artin-Hasse logarithm** of tom Dieck [43], who originally realized this operation as as spectrum maps $\mathrm{gl}_1(KU_p)\to KU_p$ and $\mathrm{gl}_1(KO_p)\to KO_p$ without reference to the Bousfield-Kuhn functor.

We can use (3.3), to compute the map ℓ_1 on homotopy groups, and we thus recover the well-known equivalences of connected covers $\mathrm{gl}_1(KU_p)_{\geq 3}\xrightarrow{\sim}(KU_p)_{\geq 3}$ and $\mathrm{gl}_1(KO_p)_{\geq 2}\xrightarrow{\sim}(KO_p)_{\geq 2}$.

To understand (3.1) in the general case, we can formally pull the operations ψ_A (which are ring homomorphisms) out of the logarithmic series, obtaining

$$\ell_n(x) = \sum_{k=0}^{n}(-1)^k p^{\binom{k}{2}}T_j(\log x) \qquad \text{where} \qquad T_j := p^{-k}\sum_{A\subseteq\Lambda^*,\ |A|=p^k}\psi_A. \tag{3.4}$$

For $x = 1+y\in E^0(X)^\times$ such that $y^2=0$, this becomes

$$\ell_n(x) = \sum_{k=0}^{n}(-1)^k p^{\binom{k}{2}}T_j(y). \tag{3.5}$$

In particular, taking X to be a sphere, we obtain a formula which computes the effect of $\ell_n\colon \mathrm{gl}_1(E) \to E$ on homotopy groups (up to torsion).

To understand how we can compute these operations, we must discuss "power operations" for $K(n)$-local commutative rings (such as Morava E-theory). The short answer is that such operations are controlled by certain isogenies of the formal group associated to the theory, and in particular the operators T_j are "Hecke operators" for the theory. We will come back to this in §4.

3.3. Application of the logarithm to orientation problems.

Example 3.3. Orientations of K-theory. Consider the composite

$$spin \to o \xrightarrow{j} \mathrm{gl}_1(S) \to \mathrm{gl}_1(KO_p) \xrightarrow{\ell_1} KO_p. \tag{3.6}$$

It is a standard calculation that all maps $spin = \Sigma^{-1}(KO_{\geq 4}) \to KO_p$ are null homotopic. As ℓ_1 is here an equivalence on 2-connected covers (3.2), we immediately see that the composite of (3.6) is null-homotopic, and thus there must exist a map $MSpin \to KO_p$ of commutative S-algebras. It can be shown that the Atiyah-Bott-Shapiro orientation can be realized by one such map; see [19, §6.1] for a sketch.

3.4. Application to the string orientation of tmf. With Matt Ando and Mike Hopkins, we have shown that tmf, the spectrum of **topological modular forms**, admits a commutative S-algebra map $MString \to \mathrm{tmf}$ which realizes the Witten genus. Our proof only exists in preprint form, though the result was announced in [19, §6], to which the reader is referred for background. Here we will only note the way in which the logarithmic operation enters into the proof.

The key point is to understand the homotopy type of $\mathrm{gl}_1(\mathrm{tmf}_p)$, where tmf_p is the completion of tmf at a prime p. General results localizations show that there is a commutative square of spectra

$$\begin{array}{ccc} \mathrm{gl}_1(\mathrm{tmf}_p) & \xrightarrow{\ell_2} & \mathrm{tmf}_{K(2)} \\ {\scriptstyle \ell_1}\downarrow & & \downarrow{\scriptstyle \iota_{K(2)}} \\ \mathrm{tmf}_{K(1)} & \xrightarrow{\gamma} & (\mathrm{tmf}_{K(2)})_{K(1)} \end{array}$$

which, after taking 3-connected covers, becomes a homotopy pullback. Both $\mathrm{tmf}_{K(2)}$ and $\mathrm{tmf}_{K(1)}$ are relatively well-understood objects: $\mathrm{tmf}_{K(2)}$ is closely related to Morava E-theory spectra at height 2, while $\mathrm{tmf}_{K(1)}$ is related to the theory of p-adic modular forms. To understand the homotopy type of $\mathrm{gl}_1(\mathrm{tmf}_p)$, we must get our hands on the map γ. It can be shown that maps $\mathrm{tmf}_{K(1)} \to (\mathrm{tmf}_{K(2)})_{K(1)}$ are characterized (up to homotopy) by their effect on homotopy groups. Thus, the key is to compute the effect of γ on homotopy groups.

Recall that there is a map $\pi_*\mathrm{tmf} \to MF_*$ to the ring of modular forms (with integer coefficients), which is an isomorphism up to torsion. Given an element in $\pi_{2k}\mathrm{tmf}$ corresponding to a modular form f of weight k, we use (3.2) to obtain

$$\ell_1(f) = f^*(q) := f(q) - p^{k-1}f(q^p),$$

where the result is stated in terms of the q-expansion of f. The series $f^*(q)$ is the q-expansion of a p-adic modular form, and thus corresponds to an element of $\pi_{2k}\mathrm{tmf}_{K(1)}$.

When we evaluate ℓ_2 at an element of $\pi_{2k}\mathrm{tmf}$ associated to a modular form f, the result turns out to be again a modular form; i.e., the image of $\ell_2\colon \pi_*\mathrm{tmf}_p \to \pi_*\mathrm{tmf}_{K(2)}$ is contained in the image of $\iota_{K(2)}\colon \pi_*\mathrm{tmf}_p \to \pi_*\mathrm{tmf}_{K(2)}$. In fact, (3.5) implies

$$\ell_2(f) = (1 - T_1 + p^{k-1})f,$$

where T_1 is a classical Hecke operator on modular forms (usually written $T(p)$ in this context).

Using these calculations, one can deduce that

$$\gamma = (\iota_{K(2)})_{K(1)} \circ (\mathrm{id} - U),$$

where $U\colon \mathrm{tmf}_{K(1)} \to \mathrm{tmf}_{K(1)}$ is topological lift of the **Atkin operator** on p-adic modular forms; see [5] for a construction of this topological lift. This calculation provides enough control on the homotopy type of $\mathrm{gl}_1(\mathrm{tmf}_p)$ to study the set of string-orientations of tmf.

Remark 3.2. These ideas actually allow one to construct ("by hand") a spectrum map $\ell_{\mathrm{tmf}_p}\colon\ \mathrm{gl}_1(\mathrm{tmf}_p) \to \mathrm{tmf}_p$, so that $\iota_{K(2)} \circ \ell_{\mathrm{tmf}_p} = \ell_2$ and $\iota_{K(1)} \circ \ell_{\mathrm{tmf}_p} = (\mathrm{id} - U) \circ \ell_1$. This fact is in need of a more natural explanation.

Remark 3.3. If $f = \sum a_n q^n$ is an *eigenform* of weight k, then $(1 - T_1 + p^{k-1})f = (1 - a_p + p^{k-1})f$. In particular, if f is an *Eisenstein series*, then $\ell_2(f) = 0$, an observation which is is key to realizing the Witten genus as a string-orientation.

We note in passing that for an eigenform which is a cusp form and normalized so that $a_1 = 1$, the expression $L(f, s) = \prod_p (1 - a_p p^{-s} + p^{k-1-2s})^{-1}$ is precisely the L-series associated to the form. The significance of this to homotopy theory remains unclear.

4. Power operations

The notion of a power operation originated in Steenrod's construction of the eponymously named operations in ordinary cohomology with coefficients in $\mathbb{F}_p$. A convenient modern formulation is in terms of structured commutative ring spectra. There are various equivalent models of such; I will not distinguish among them here, and I will call them **commutative S-algebras**; see [15] and [28] for introductions to some of these models.

A (generalized) cohomology theory $X \mapsto E^*(X)$ is represented by a spectrum E. If E is equipped with the structure of a commutative monoid in the homotopy category of spectra, then $X \mapsto E^*(X)$ takes values in graded commutative rings. For any $m \geq 0$, there is a resulting cohomology operation $x \mapsto x^m\colon E^0(-) \to E^0(-)$ defined by taking mth powers with respect to the product.

If E is equipped with the structure of a commutative S-algebra, then the mth power map admits a refinement to a "total mth power operation" of the form

$$P_m\colon E^0(X) \to E^0(X \times B\Sigma_m),$$

where $B\Sigma_m$ is the classifying space of the symmetric group on m letters. The function P_m is a multiplicative (but non-additive) natural transformation $E^0(-) \to E^0(- \times B\Sigma_m)$ of cohomology groups.

It is convenient to regard power operations as operations on the homotopy groups of commutative S-algebras. For a commutative S-algebra R, the power construction determines gives a function

$$P_m\colon \pi_0 R \to \pi_0 R^{B\Sigma_m^+}, \tag{4.1}$$

where $R^X := \underline{\mathrm{Hom}}(\Sigma^\infty X, R)$, the spectrum of maps from the suspension spectrum of a pointed space X to R. (Operations in dimensions other 0 can also be obtained, by replacing $B\Sigma_m^+$ with a suitable Thom spectrum. In the discussion below, I will concentrate on operations in dimension 0 for simplicity.) Cohomology operations for $E^*(X)$ (such as Steenrod's for ordinary cohomology) can be obtained by setting $R = E^{X_+}$, to be thought of as the ring of E-valued cochains on X.

Let us fix a commutative S-algebra E. To calculate power operations for commutative E-algebras R, one must understand the functor $R \mapsto \pi_0(R^{B\Sigma_m^+}) = R^0(B\Sigma_m)$, which in practice can be non-trivial. The best case scenario is to have a natural "Künneth isomorphism"

$$\pi_* R^{B\Sigma_m^+} \approx \pi_* R \ \otimes_{\pi_* E}\ \pi_* E^{B\Sigma_m^+}, \tag{4.2}$$

together with calculational control of the rings $\pi_* E^{B\Sigma_m^+} \approx E^{-*} B\Sigma_m$, the E-cohomology rings of symmetric groups.

This best case scenario is in fact relatively rare. It does hold for HF-algebras, where F is a field [9]. It holds also for $K(n)$-local commutative E-algebras, where E is a Morava E-theory spectrum.

4.1. Power operations in the $K(n)$-local setting. In 1993, Hopkins and Miller perceived that a Morava E-theory spectrum must admit an essentially unique commutative S-algebra structure; the proof is result is in [16]. Therefore Morava E-theories admit a theory of power operations; such operations were first originally by Ando [4][1].

Example 4.1. The operations ψ_A appearing in (3.1) are obtained as power operations for Morava E-theory, namely as the composite

$$E^0(X) \xrightarrow{P_{p^k}} E^0(X \times B\Sigma_{p^k}) \xrightarrow{(\mathrm{id}\times Bi)^*} E^0(X \times BA^*) \xrightarrow{\chi(-,g_A)} D \otimes_{E^0} E^0(X),$$

where P_{p^k} is the total power operation for the Morava E-theory, $i\colon A^* \to \Sigma_{p^k}$ is the inclusion defined by the left-action of A^* on its underlying set, where $p^k = |A^*|$. These are examples of the operations constructed in [4].

The theory of power operations for commutative algebras over Morava E-theories is now very largely understood, based mainly on work by Ando, Hopkins, and Strickland, who were motivated by the problem of rigidifying the Witten genus to a map of spectra [2], along with some contributions by the author [37].

Our goal in this section is two-fold: to show (i) the homotopy groups $\pi_* R$ of a $K(n)$-local commutative E-algebra R take values in a category $\mathrm{QCoh}(\mathrm{Def})$ of sheaves on a moduli problem of "formal groups and isogenies", and (ii) the category $\mathrm{QCoh}(\mathrm{Def})$ can in practice be described using a small amount of data, and in fact at small heights can be described completely explicitly. In addition to the references given below, the material in this section is developed in detail in the preprint [34].

[1] In fact, Ando did not make use of the commutative S-algebra structure of E, which was unavailable at the time, though he does show that the operations he constructs are the same as those obtained from any commutative S-algebra structure which might exist on E.

4.2. Deformations and Morava E-theory. We fix a height n formal group (commutative, one-dimensional) G_0 over a perfect field k.

Given a formal group G over a complete local ring B, a **(G_0-)deformation structure** on G/B is a pair (i, α) consisting of an inclusion $i\colon k \to B/\mathfrak{m}$ of fields and an isomorphism $\alpha\colon i^*G_0 \xrightarrow{\sim} G_{B/\mathfrak{m}}$ of formal groups over $B/\mathfrak{m}$. We write $\mathcal{D}(G/A) = \mathcal{D}_{G_0}(G/A)$ for the set of deformation structures on G/A. Note that if $g\colon A \to A'$ is a local homomorphism, there is map $g^*\colon \mathcal{D}(G/A) \to \mathcal{D}(g^*G/A')$ induced by base change.

An **isogeny** of formal groups over A is a homomorphism $f\colon G \to G'$ such that the induced map $\mathcal{O}_{G'} \to \mathcal{O}_G$ on function rings is finite and locally free; we write $\deg(f)$ for the rank of $\mathcal{O}_G$ as an $\mathcal{O}_{G'}$-module. Given such an isogeny, there is an induced pushforward map $f_!\colon \mathcal{D}(G/A) \to \mathcal{D}(G'/A)$ on sets of deformation structures, so that

$$f_*(i, \alpha) := (i \circ \phi^r, \alpha'),$$

where $\phi(a) = a^p$ is the absolute Frobenius on rings, $p^r = \deg f$, and α' is the unique isomorphism such that $\alpha' \circ F^r = f_{B/\mathfrak{m}} \circ \alpha$, where

$$F^r\colon G \to (\phi^r)^*G$$

denotes the **Frobenius isogeny**, i.e., the relative p^rth power Frobenius defined for any G over an $\mathbb{F}_p$-algebra.

Remark 4.1. An easy exercise shows that, when $\mathbb{F}_p \subseteq A$, there is an identity $F_* = \phi^*$ of maps $\mathcal{D}(G/A) \to \mathcal{D}(\phi^*G/A)$.

Given a complete local ring B, let $\mathrm{Def}^0(B) = \mathrm{Def}^0_{G_0}(B)$ denote the groupoid so that

- *objects* are pairs $(G, (i, \alpha) \in \mathcal{D}(G/B))$,
- *morphisms* are isomorphims $f\colon G \to G'$ such that $f_*(i, \alpha) = (i', \alpha')$.

Proposition 4.2 (Lubin-Tate [24]). *All automorphisms in* $\mathrm{Def}^0(B)$ *are identity maps (i.e.,* $\mathrm{Def}(B)$ *is equivalent to a discrete groupoid). There exists a ring* A_0 *and a natural bijection*

$$\{\textit{local homomorphisms } A_0 \to B\} \longleftrightarrow \{\textit{iso. classes of objects in } \mathrm{Def}^0(B)\}.$$

There is a (non-canonical) isomorphism $A_0 \approx \mathbb{W}_p k[\![a_1, \ldots, a_{n-1}]\!]$.

The tautological object of $\mathrm{Def}^0(A_0)$ is the **universal deformation** of G_0. It is the formal group of Morava E-theory, whose existence follows from the following.

Theorem 4.3 (Morava [30], Goerss-Hopkins-Miller [16]). *Given a formal group* G_0 *of height* n *over a perfect field, there exists an essentially unique commutative* S*-algebra* E*, which is a complex oriented cohomology theory with* $\pi_*E \approx A_0[u, u^{-1}]$ *with* $|u| = 2$*, whose formal group is the universal deformation of* G_0*.*

4.3. The "pile" of deformation structures. We enlarge the groupoid $\mathrm{Def}^0(B)$ to a category $\mathrm{Def}(B)$, with the same objects, but so that

- *morphisms* are isogenies $f\colon G \to G'$ such that $f_*(i, \alpha) = (i', \alpha')$.

To each continuous homomorphism $g\colon B \to B'$ there is an associated pullback functor $g^*\colon \mathrm{Def}(B') \to \mathrm{Def}(B)$. Thus, Def defines a (pseudo)functor

$$\{\text{complete local rings}\}^{\mathrm{op}} \to \{\text{categories}\}.$$

A *stack* is a (kind of) presheaf of groupoids. The functor Def_{G_0} gives rise to a more general kind of object, namely a presheaf of categories on the opposite category of complete local rings. This more general concept demands a new name; thus, we will speak of Def_{G_0} as the **pile**[2] of deformations of G_0 and its Frobenius isogenies.

There is a category $\mathrm{QCoh}(\mathrm{Def})$ of **quasicoherent (pre)sheaves** of modules over the structure sheaf $\mathcal{O}_{\mathrm{Def}}$ of the pile Def. An object of $\mathrm{QCoh}(\mathrm{Def})$ amounts to a choice of data $\{M_B, M_g\}$ consisting of

- for each complete local ring B, a functor $M_B\colon \mathrm{Def}(B)^{\mathrm{op}} \to \mathrm{Mod}_B$, and
- for each for each local homomorphism $g\colon B \to B'$ a natural isomorphism

$$M_g\colon B' \otimes_B M_B \Longrightarrow M_{B'} \circ g^*\colon \mathrm{Def}(B)^{\mathrm{op}} \to \mathrm{Mod}_{B'},$$

where $g^*\colon \mathrm{Def}(B) \to \mathrm{Def}(B')$ is the functor induced by base change along g,

together with coherence data equating $M_{g'g}$ with a composition of $M_{g'}$ and M_g.

Example 4.2. Given G/B, let $\omega_B(G/B)$ denote the B-module of invariant 1-forms on G. Because 1-forms can be pulled back along isogenies, this defines an object $\omega \in \mathrm{QCoh}(\mathrm{Def})$.

Example 4.3. Given G/B, let $\deg_B(G/B) := B$. To an isogeny $f\colon G \to G'$, we associate the map $\deg_B(f)\colon \deg_B(G'/B) \to \deg_B(G/B)$ induced by multiplication by the integer $\deg(f)$. This defines an object $\deg \in \mathrm{QCoh}(\mathrm{Def})$, the **degree sheaf**.

4.4. Power operations and $\mathbf{QCoh(Def)}$. Let E denote the Morava E-theory associated to our fixed formal group G_0/k.

Recall (4.1) the total power operation $P_m\colon \pi_0 R \to \pi_0 R \otimes_{\pi_0 E} E^0 B\Sigma_m$ defined for $K(n)$-local commutative E-algebras R. The function P_m is multiplicative (i.e., $P_m(ab) = P_m(a)P_m(b)$), but not additive. We may obtain a ring homomorphism by passing to the quotient $A_m = E^0 B\Sigma_m / I_{\mathrm{tr}}$ of $E^0 B\Sigma_m$ by the ideal $I_{\mathrm{tr}} \subseteq E^0 B\Sigma_m$ generated by the image of all transfers maps from inclusions of the form $\Sigma_i \times \Sigma_{m-i} \subset \Sigma_m$ with $0 < i < m$. The composite map

$$\overline{P}_m\colon \pi_0 R \xrightarrow{P_m} \pi_0 R^{B\Sigma_m^+} \approx \pi_0 R \otimes_{\pi_0 E} E^0 B\Sigma_m \to \pi_0 R \otimes_{\pi_0 E} E^0 B\Sigma_m / I_{\mathrm{tr}} \tag{4.3}$$

is a ring homomorphism.

The key to understanding power operations are the following result due to Strickland. To state it, it is useful to note that we can form a quotient category $\mathrm{Def}(B)/\sim$ of $\mathrm{Def}(B)$ by formally identifying isomorphic objects (possible exactly because there are no non-trivial automorphisms in this category), and the projection functor is an equivalence of categories.

We write $\mathrm{Def}^r(B)/\sim$ for the set of morphisms which correspond to isogenies of degree p^r. It is straightforward to show that elements of $\mathrm{Def}^r(B)/\sim$ are in bijective correspondence with pairs (G, H), where G is an object of $\mathrm{Def}^0(B)/\sim$ and $H \leq G$ is a finite subgroup scheme of rank p^k; the correspondence sends an isogeny to its kernel.

[2]This term was suggested by Matt Ando.

Theorem 4.4 (Strickland [39, 40]). *There exist complete local rings A_r (for $r \geq 0$), finite and free as A_0-modules, so that*

$$\{\textit{local homomorphisms } A_r \to B\} \longleftrightarrow \mathrm{Def}^r(B)/\sim .$$

Furthermore, there is a natural identification of rings

$$E^0 B\Sigma_{p^r}/I_{\mathrm{tr}} \approx A_r.$$

As a consequence, the functor $B \mapsto \mathrm{Def}(B)$ from complete local rings to (graded) categories is represented by a graded affine category object $\{A_r\}$ in $(\text{complete local rings})^{\mathrm{op}}$. Thus, $\mathrm{QCoh}(\mathrm{Def})$ is equivalent to a category of *comodules*, whose objects are A_0-modules M equipped with module maps

$$\psi_r \colon M \to {}^t A_r{}^s \otimes_{A_0} M,$$

which satisfy an evident coassociativity property. (There are ring maps $s, t \colon A_0 \to A_r$ corresponding to "source" and "target" in the graded category; we use superscripts to indicate the corresponding A_0-module structures on A_r.) Furthermore, the power operation maps $\overline{P}_{p^r}$ of (4.3) make $\pi_0 R$ into a comodule; i.e., (4.4) refines π_0 to a functor

$$\underline{\pi}_0 \colon h\mathrm{Com}(E)_{K(n)} \to \mathrm{QCoh}(\mathrm{Def})$$

from the homotopy category of $K(n)$-local commutative E-algebra spectra, to the category of quasi-coherent sheaves of modules on Def, so that the value of $\underline{\pi}_0(R)$ at the universal deformation in $\mathrm{Def}(A_0)$ precisely the ring $\pi_0 R$.

Remark 4.5. The existence of the functor $\underline{\pi}_0$ is essentially an observation of Ando, Hopkins, and Strickland (see [2]). A construction is given in [37].

4.5. Additional structure. The functor π_0 to sheaves on Def admits several additional refinements, which we pass over quickly. (Most are discussed in [37]; see [7] for a treatment of completion.)

- $\mathrm{QCoh}(\mathrm{Def})$ is a symmetric monoidal category, and $\underline{\pi}_0$ naturally takes values in $\mathrm{QCoh}(\mathrm{Def}, \mathrm{Com})$, the category of sheaves of commutative rings in $\mathrm{QCoh}(\mathrm{Def})$.
- There is an extension to a functor $\underline{\pi}_* \colon h\mathrm{Com}(E)_{K(n)} \to \mathrm{QCoh}^*(\mathrm{Def}, \mathrm{Com})$, where the target is a category of *graded* ring objects in $\mathrm{QCoh}(\mathrm{Def})$.
- The output of π_* is (in a suitable sense) complete with respect to the maximal ideal of A_0.
- The rings $\underline{\pi}_0 R$ satisfy a **Frobenius congruence**. We say that an object $M \in \mathrm{QCoh}(\mathrm{Def}, \mathrm{Com})$ satisfies this condition if, for all formal groups G/B with $\mathbb{F}_p \subseteq B$, the map

  $$B^{\phi} \otimes_B M_B(G, d) \approx M_B(\phi^* G, \phi^*(d)) = M_B(\phi^* G, M_*(d)) \xrightarrow{F^*} M_B(G, d)$$

  coincides with the relative pth power map on the ring $M_B(G, d)$, for any $d \in \mathcal{D}(G/B)$.

  In terms of the comodule formulation of $\mathrm{QCoh}(\mathrm{Def}, \mathrm{Com})$, this amounts to saying that the composite

  $$M \xrightarrow{\psi_1} A_1{}^s \otimes_{A_0} M \xrightarrow{\gamma \otimes \mathrm{id}} (A_0/p) \otimes_{A_0} M = M/p$$

is the pth power map on M, where $\gamma\colon A_1 \to A_0/p$ is the map representing $\mathrm{Def}^0 \to \mathrm{Def}^1$ sending $G \mapsto (F\colon G \to \phi^* G)$.

- The Frobenius congruence for $\underline{\pi}_0 R$ is *witnessed* by a non-additive operation on π_0. To state this, note that there is A_0-module homomorphism $\epsilon\colon A_1 \to A_0$ lifting $\gamma\colon A_1 \to A_0/p$. Using this, we define a homomorphism of abelian groups

$$Q\colon \pi_0 R \xrightarrow{\psi_1} A_1 \otimes_{A_0} \pi_0 R \xrightarrow{\epsilon\otimes \mathrm{id}} A_0 \otimes_{A_0} \pi_0 R = \pi_0 R,$$

which satisfies $Q(x) \equiv x^p \mod p$. The *witness* is a (non-additive) natural operation $\theta\colon \pi_0 R \to \pi_0 R$ satisfying $Q(x) = x^p + p\theta(x)$.

Remark 4.6. Mathew, Naumann, and Noel have observed [29] that the mere existence of a witness for the Frobenius congruence allows one to show that any p^r-torsion element in the homotopy of a $K(n)$-local commutative E-algebra is nilpotent. Using this together with the nilpotence theorem of Devinatz-Hopkins-Smith, they prove a conjecture of May: for any commutative S-algebra R the kernel of the Hurewicz map $\pi_* R \to H_*(R, \mathbb{Z})$ consists of nilpotent elements.

The outcome of the additional structure outlined above is that there exists a refinement of the homotopy functor $\pi_*\colon h\mathrm{Com}(E)_{K(n)} \to \mathrm{Mod}(E_*)$ to a functor

$$\underline{\pi}_*\colon h\mathrm{Com}(E_{G_0})_{K(n)} \to \mathcal{T}_{G_0}$$

to a certain algebraically defined category $\mathcal{T}_{G_0}$, whose construction depends only on the formal group G_0/k.

Example 4.4. If $G_0/k = G_m/\mathbb{F}_p$, the formal multiplicative group, then $E_{G_0} = KU_p$ is p-complete complex K-theory. The category $\mathcal{T}_{G_0}$ is the category of p-complete $\mathbb{Z}/2$-graded θ^p-rings described by Bousfield [12].

4.6. The quadratic nature of QCoh(Def). Remarkably, making calculations about objects in $\mathrm{QCoh}(\mathrm{Def})$ is far more tractable than the above suggests. This is because the representing coalgebra $\{A_r\}$ is "quadratic". This means the following: an object of $\mathrm{QCoh}(\mathrm{Def})$ is determined, up to canonical isomorphism, by its underlying module M and the structure map $\psi_1\colon M \to A_1 \otimes_{A_0} M$, which is subject to a single relation, namely that there *exists* a dotted arrow in the following diagram of $\pi_0 E$-modules:

$$\begin{array}{ccc} M & \xrightarrow{\quad\psi_1\quad} & {}^t A_1{}^s \otimes_{A_0} M \\ \vdots & & \downarrow{\scriptstyle \mathrm{id}\otimes\psi_1} \\ {}^t A_2{}^s \otimes_{A_0} M & \xrightarrow{\nabla\otimes\mathrm{id}} & {}^t A_1{}^s \otimes_{A_0} {}^t A_1{}^s \otimes_{A_0} M \end{array} \tag{4.4}$$

where ∇ encodes composition of two morphisms of degree p in Def. In particular, the category $\mathrm{QCoh}(\mathrm{Def})$ can be reconstructed using only knowledge of the rings $\pi_0 E$, A_1, and A_2, and the ring homomorphisms s, t, and ∇.

Example 4.5. *Multiplicative group.* For $G_0/k = G_m/\mathbb{F}_p$, the rings $A_r \approx \mathbb{Z}_p$ for all r. An object in $\mathrm{QCoh}(\mathrm{Def})$ amounts to a $\mathbb{Z}_p$-module M equipped with an endomorphism $\psi\colon M \to M$.

Example 4.6. *Height 2.* When E is associated to a formal group of height 2, it is possible to give a completely explicit description of $\mathrm{QCoh}(\mathrm{Def})$, by using explicit formulas obtained from the theory of elliptic curves. For instance, let G_0 be the formal completion of the supersingular elliptic curve over $\mathbb{F}_2$. In this case, $A_0 = \mathbb{Z}_2[\![a]\!]$, $A_1 = \pi_0 E[d]/(d^3 - ad - 2)$, and the ring homomorphisms $s, t\colon A_0 \to A_1$ are given by $s(a) = a$ and $t(a) = a^2 + 3d - ad^2$. The ring A_2 is the pullback of

$$A_1 \overset{t}{\otimes}_{A_0} \overset{s}{A_1} \xrightarrow{w\otimes \mathrm{id}} A_1 \xleftarrow{s} A_0$$

where $w\colon A_1 \to A_1$ sends $w(a) = t(a)$ and $w(d) = a - d^2$. (The map w classifies the operation of sending a p-isogeny of elliptic curves to its dual isogeny.) The map Δ is the evident inclusion map. The above description is outlined (admittedly in very rough form) in [33]. Zhu [44] has calculated a similar example at the prime 3.

Example 4.7. *Height 2, modulo p.* It is possible to give a uniform description of this structure at height 2, if we work modulo the prime. Fix a supersingular elliptic curve C_0 over $\mathbb{F}_p$ whose Frobenius isogeny satisfies $F^2 = -p$ (such always exist), and let G_0 be its formal completion. Then, following an observation of [21, 13.4.6], we see that $A_1/p \approx \mathbb{F}_p[\![a_1, a_2]\!]/(\,(a_1^p - a_2)(a_1 - a_2^p)\,)$, so that $s, t\colon A_0/p = \mathbb{F}_p[\![a]\!] \to A_1/p$ send $s(a) = a_1$ and $t(a) = a_2$; the rings A_r/p can be described similarly. See [38], especially §3.

In the general case, the quadraticity of $\mathrm{QCoh}(\mathrm{Def})$ is a consequence of a stronger theorem: that the algebra of power operations for Morava E-theory is Koszul.

4.7. The ring of power operations is Koszul. We observe that $\mathrm{QCoh}(\mathrm{Def})$ is equivalent to a category of modules over an associative ring $\Gamma := \bigoplus \mathrm{Hom}_{A_0}(A_r, A_0)$. In particular, it is an abelian category with enough projectives and injectives. In their work, Ando, Hopkins, and Strickland perceived that the ring Γ should have finite homological dimension (see discussion at the end of §14 in [39]). That this is so is a consequence of the following theorem.

Theorem 4.7 ([35]). *The ring Γ is Koszul, and thus objects of $\mathrm{QCoh}(\mathrm{Def}_{G_0})$ admit a functorial resolution by a "Koszul complex". More precisely, there is a functor $\mathcal{C}\colon \mathrm{QCoh}(\mathrm{Def}) \to \mathrm{Ch}(\mathrm{QCoh}(\mathrm{Def}))$ together with a natural augmentation $\epsilon\colon \mathcal{C}(M) \to M$ which is a quasi-isomorphism if M is projective as a $\pi_0 E$-module. Furthermore,*

$$\mathcal{C}_k(M) = \Gamma \otimes_{\pi_0 E} C_k \otimes_{\pi_0 E} M,$$

where C_k is a $\pi_0 E$-module which is (i) free and finitely generated as a right $\pi_0 E$-module, and (ii) $C_k = 0$ if $k > n$, where n is the height of the formal group G_0.

As a consequence, Γ has global dimension $2n$, where n is the height of the formal group.

Remark 4.8. The proof of (4.7) given in [35] is purely topological, making no reference to the interpretation of $\mathrm{QCoh}(\mathrm{Def})$ in terms of isogenies of formal groups. The proof is inspired by the theory of the Goodwillie calculus of the identity tower, and in particular by the work of Arone-Mahowald [3] on the $K(n)$-local homotopy type of the layers of the tower of the identity functor evaluated at odd spheres. They show that the $K(n)$-local homotopy type of an odd sphere is concentrated purely at Goodwillie layers p^k for $0 \le k \le n$.

Remark 4.9. The statement of (4.7) is purely a statement about deformations about formal groups and their isogenies, and thus should in particular admit a proof which does not use topology. I do not know such a proof in general, but such a purely algebro-geometric proof exists in the cases $n = 1$ and $n = 2$; see [38] for the height 2 case.

Remark 4.10. Ando, Hopkins, and Strickland originally conjectured a particular form for a finite complex such as that in terms of (4.7), in terms of a "Tits building" associated to subgroups of $\mathbb{G}_E[p]$, the p-torsion subgroup of the formal group $\mathbb{G}_E$. Their original complex in the height 2 case can be constructed using the arguments of [38]. Recently, Jacob Lurie has shown how (4.7) can be used to recover the original proposal of Ando, Hopkins, and Strickland.

4.8. Computing maps of $K(n)$-local E-algebras. We can use the theory described above to describe the E_2-term of a spectral sequence computing the space of maps between commutative E-algebras. We describe how this works in a special case.

Let R, F be two $K(n)$-local commutative E-algebras equipped with an augmentation to E. There is a spectral sequence

$$E_2^{s,t} \Longrightarrow \pi_{t-s}\mathrm{Com}(E)^{\mathrm{aug}}_{K(n)}(R, F) \tag{4.5}$$

computing homotopy groups of the derived space of maps in the category of augmented $K(n)$-local commutative E-algebras. When π_*R is *smooth* over π_*E, the E_2-term takes the form

$$E_2^{s,t} \approx \begin{cases} \mathcal{T}_{/E_*}(\pi_*R, \pi_*F) & \text{if } (s,t) = (0,0), \\ \mathrm{Ext}^s_{\mathrm{QCoh(Def)}}(\omega^{-1/2} \otimes \widehat{Q}(\pi_*R), \omega^{(t-1)/2} \otimes \pi_*\overline{F}) & \text{otherwise.} \end{cases} \tag{4.6}$$

Here $\widehat{Q}(\pi_*R)$ is the module of indecomposables of the augmented ring π_*R (completed with respect to the maximal ideal of π_*E), $\pi_*\overline{F}$ is the augmentation ideal of π_*F, and ω is the module of invariant 1-forms (4.2). In this situation, the spectral sequence is strongly convergent, and is non-zero for only finitely many values of s.

5. Tangent spaces to cochains and $\Phi_n(S^{2d-1})$

5.1. Derived indecomposables of commutative ring spectra. Fix a commutative ring A, and consider an augmented commutative A-algebra R; i.e., an A-algebra equipped with an A-algebra map $\pi\colon R \to A$. We can consider the A-module $T^*_{A,\pi}(R) := I/I^2$ of **indecomposables** with respect to the augmentation, where $I = \mathrm{Ker}(\pi)$. In geometrical terms, $\mathrm{Indec}(R)$ is the cotangent space to $\mathrm{Spec}(R)$ at the point corresponding to π. The dual module $T_\pi(R) := \underline{\mathrm{Hom}}_A(T^*_{A,\pi}(R), A)$ can be viewed as a tangent space at π.

This cotangent space construction admits a derived generalization to commutative ring spectra. Given a commutative S-algebra A, and an augmented commutative A-algebra R, there is an A-module of **derived indecomposables** constructed by Basterra [6], and which we will also denote by $T^*_A(R)$ (taking the map π to be understood).[3] We write $T_A(R) := \underline{\mathrm{Hom}}_A(T^*_A(R), A)$ for the corresponding "tangent space".

[3]This functor is also called "reduced topological Andre-Quillen cohomology".

We note two alternate descriptions of these constructions, which follow from work of Basterra and Mandell ([8], especially §2).

- The cotangent functor $T^*_A\colon \mathrm{Com}^{\mathrm{aug}}_A \to \mathrm{Mod}_A$ is a kind of stabilization functor. It is most conveniently expressed in terms of an equivalence $\mathrm{Com}^{\mathrm{aug}}_A \approx \mathrm{Com}^{\mathrm{nu}}_A$ between augmented and non-unital algebras, so that
$$T^*_A(R) \approx \mathrm{hocolim}_n\, \Omega^n_{\mathrm{nu}}\Sigma^n_{\mathrm{nu}}(I),$$
where I is the homotopy fiber of the augmentation $R \to A$ viewed as a non-unital algebra, and Σ_{nu} and Ω_{nu} are loop and suspension functors in the homotopy theory of $\mathrm{Com}^{\mathrm{nu}}_A$.
- The tangent space module can also be described as "functions to the dual numbers". That is, the underlying spaces of the spectrum $T_A(R)$ can be identified as
$$\Omega^{\infty+t}T_A(R) \approx \mathrm{Com}^{\mathrm{aug}}_A(R, A \ltimes \Omega^t A),$$
where $A \ltimes \Omega^t A$ is a split square-zero extension of A by a shift of A.

Given a based space X and a commutative S-algebra A, we can apply these constructions to the cochain algebra $A^{X_+} := \underline{\mathrm{Hom}}(\Sigma^\infty(X_+), A)$, which is a commutative A-algebra equipped with an augmentation corresponding to the basepoint of X.

Example 5.1. Take $A = H\mathbb{Q}$, the rational Eilenberg-Mac Lane spectrum. For spaces X which are simply connected and of finite-type, we have a natural isomorphism
$$\pi_* T_{H\mathbb{Q}}(H\mathbb{Q}^{X_+}) \approx \pi_*(X) \otimes \mathbb{Q}$$
from the homotopy of the tangent space spectrum to the rational homotopy groups of X. This is a modern restatement of a well-known fact of rational homotopy theory (e.g., [41, Thm. 10.1].

Example 5.2. Take $A = H\overline{\mathbb{F}}_p$, the Eilenberg-Mac Lane spectrum of the algebraic closure of $\mathbb{F}_p$. Then $T_{H\overline{\mathbb{F}}_p}(H\overline{\mathbb{F}}_p^{X_+}) \approx 0$ by [25, Prop. 3.4]. Mandell's work shows that the cochain spectrum $H\overline{\mathbb{F}}_p^{X_+}$ contains complete information about the mod p homotopy type of simply connected finite-type X, but this information cannot be extracted from the tangent space.

It turns out that for $K(n)$-local rings, the (co)tangent space behaves more like rational homology than mod p-homology, where the role of rational homotopy groups is replaced with the Bousfield-Kuhn functor.

5.2. The tangent space to cochains for $K(n)$-local rings. Let A be a $K(n)$-local commutative S-algebra. For a based space X, we can construct **comparison maps** which relate the A cohomology/homology of the spectrum $\Phi_n X$ with the tangent/cotangent space of the cochain ring A^{X_+}. These take the form
$$c^*_X\colon T^*_A(A^{X_+}) \to \underline{\mathrm{Hom}}_A(\Phi_n X, A) \quad \text{and} \quad c_X\colon A \wedge \Phi_n X \to T_A(A^{X_+}).$$

Remark 5.1. Here is an idea of how to build c^*_X (the map c_X is obtained by taking A-linear duals). Given a space X, apply Φ_n to the tautological map $u\colon X \to \Omega^\infty\Sigma^\infty X$, obtaining
$$\Phi_n X \xrightarrow{\Phi_n(u)} \Phi(\Omega^\infty\Sigma^\infty X) \approx (\Sigma^\infty X)_{K(n)}.$$

Taking functions into a $K(n)$-local ring A gives

$$\kappa_X \colon A^X \approx \underline{\mathrm{Hom}}((\Sigma^\infty X)_{K(n)}, A) \to \underline{\mathrm{Hom}}(\Phi_n X, A).$$

The object A^X is the augmentation ideal of A^{X_+}, and its stabilization as a non-unital A-algebra is $T^*_A(A^{X_+})$. The map c^*_X is constructed as the limit of the collection of maps

$$\Sigma^n_{\mathrm{nu}}(A^X) \to A^{\Omega^n X} \xrightarrow{\kappa_X} \underline{\mathrm{Hom}}_A(\Phi_n(\Omega^n X), A) \approx \Omega^{-n}\underline{\mathrm{Hom}}_A(\Phi_n X, A),$$

where we have used the fact that Φ_n commutes with Ω up to weak equivalence.

Mark Behrens and I have recently proved the following result, which shows the comparison map is an isomorphism for odd-dimensional spheres.

Theorem 5.2. *For any $K(n)$-local commutative ring A, and $X = S^{2d-1}$, the maps c_X and c^*_X induce isomorphisms in $K(n)$-homology.*

Remark 5.3. A consequence of the proof is a natural identification of E_*-modules

$$C_k \approx E_*^\wedge \partial_{p^k}(S^1)_{K(n)},$$

where C_k is the module in the Koszul resolution of (4.7), with the E-homology of the p^kth layer of the Goodwillie tower of the identity functor, evaluated at the circle S^1.

Remark 5.4. Combining (5.2) with remarks from §5.1, we see that we can use the spectral sequence (4.5) to compute $\pi_*(E \wedge \Phi_n(S^{2d+1})$. By (4.6), the E_2-term is

$$E_2^{s,t} \approx \mathrm{Ext}^s_{\mathrm{QCoh(Def)}}(\omega^{d-1}, \omega^{(t-1)/2} \otimes \mathrm{nul}) \Longrightarrow E^\wedge_{t-s}\Phi_n S^{2d-1},$$

where $\mathrm{nul} \in \mathrm{QCoh(Def)}$ is the object corresponding to the comodule $M = A_0$ whose coaction maps $\psi_r \colon M \to A_r \otimes_{A_0} M$ are identically 0.

Explicit calculations show that, for $n = 1, 2$, the only non-vanishing groups are when $s = n$, and thus this gives a complete calculation in that case. For $n = 1$, this recovers calculations of Bousfield [13]. Details are provided in [34].

Quasi-morphisms and quasi-states in symplectic topology

Michael Entov

Abstract. We discuss certain "almost homomorphisms" and "almost linea" functionals that have appeared in symplectic topology and their applications concerning Hamiltonian dynamics, functional-theoretic properties of Poisson brackets and algebraic and metric properties of symplectomorphism groups.

Mathematics Subject Classification (2010). Primary 53D35, 53D40, 53D45; Secondary 17B99, 20F69, 46L30.

Keywords. Symplectic manifold, Poisson brackets, Hamiltonian symplectomorphism, quantum homology, quasi-morphism, quasi-state, symplectic rigidity.

1. Introduction

Symplectic manifolds carry several interesting mathematical structures of different flavors, coming from algebra, geometry, topology, dynamics and analysis. In this survey we discuss certain "almost homomorphisms" (called *Calabi quasi-morphisms*) on groups of symplectomorphisms of symplectic manifolds and certain "almost linear" functionals (called *symplectic quasi-states*) on the spaces of smooth functions on symplectic manifolds that have been useful in finding new relations between these structures. In particular, we describe applications of these new tools to Hamiltonian dynamics, functional-theoretic properties of Poisson brackets as well as algebraic and metric properties of the groups of symplectomorphisms. We also briefly discuss a relation between the symplectic quasi-states and von Neumann's mathematical foundations of quantum mechanics. We end the survey with a discussion on the function theory approach to symplectic topology.

A detailed introduction to the subject can be found in the forthcoming book [58] by L.Polterovich and D.Rosen.

2. Quasi-morphisms and quasi-states - generalities

2.1. Quasi-morphisms. Let G be a group. A function $\mu : G \to \mathbb{R}$ is called a *quasi-morphism*, if there exists a constant $C > 0$ so that $|\mu(xy) - \mu(x) - \mu(y)| \leq C$ for any $x, y \in G$. We say that a quasi-morphism $\mu : G \to \mathbb{R}$ is *homogeneous*[1], if $\mu(x^k) = k\mu(x)$ for any $x \in G$, $k \in \mathbb{Z}$.

[1] Proceedings of the International Congress of Mathematicians, Seoul, 2014

Clearly, any $\mathbb{R}$-valued homomorphism on G is a homogeneous quasi-morphism but finding homogeneous quasi-morphisms that are not homomorphisms is usually a non-trivial task. Let us also note that any homogeneous quasi-morphism μ is conjugacy-invariant and satisfies $\mu(xy) = \mu(x) + \mu(y)$ for any commuting elements x, y (in particular, any homogeneous quasi-morphism on an abelian group is a homomorphism). For more on quasi-morphisms see e.g. [16].

2.2. Quasi-states and quantum mechanics. Roughly speaking, quasi-states are "almost linear" functionals on algebras of a certain kind. The term "quasi-state" comes from the work of Aarnes (see [1] and the references to the Aarnes' previous work therein) but its history goes back to the mathematical model of quantum mechanics suggested by von Neumann [72]. A basic object of this model is a real Lie algebra of observables that will be denoted by $\mathcal{A}_q$ (q for quantum): its elements (in the simplest version of the theory) are Hermitian operators on a finite-dimensional complex Hilbert space H and the Lie bracket is given by $[A, B]_\hbar = \frac{i}{\hbar}(AB - BA)$, where $\hbar$ is the Planck constant. Observables represent physical quantities such as energy, position, momentum etc. In von Neumann's model a state of a quantum system is given by a functional $\zeta : \mathcal{A}_q \to \mathbb{R}$ which satisfies the following axioms:

Additivity: $\zeta(A + B) = \zeta(A) + \zeta(B)$ for all $A, B \in \mathcal{A}_q$.

Homogeneity: $\zeta(cA) = c\zeta(A)$ for all $c \in \mathbb{R}$ and $A \in \mathcal{A}_q$.

Positivity: $\zeta(A) \geq 0$ provided $A \geq 0$..

Normalization: $\zeta(Id) = 1$.

As a consequence of these axioms von Neumann proved that for every state ζ there exists a non-negative Hermitian operator U_ζ with trace 1 so that $\zeta(A) = \mathrm{tr}(U_\zeta A)$ for all $A \in \mathcal{A}_q$. An easy consequence of this formula is that for every state ζ there exists an observable A such that

$$\zeta(A^2) - (\zeta(A))^2 > 0 \, . \tag{2.1}$$

In his book [72] von Neumann adopted a statistical interpretation of quantum mechanics according to which the value $\zeta(A)$ is considered as the expectation of a physical quantity represented by A in the state ζ. In this interpretation the equation (2.1) says that there are no dispersion-free states. This result led von Neumann to a conclusion which can be roughly described as the impossibility to present random quantum-mechanical phenomena as an observable part of some "hidden" underlying deterministic mechanism. This conclusion caused a major discussion among physicists (see e.g. [6]) some of whom disagreed with the additivity axiom of a quantum state. Their reasoning was that the formula $\zeta(A+B) = \zeta(A)+\zeta(B)$ makes sense *a priori* only if observables A and B are simultaneously measurable, that is, commute: $[A, B]_\hbar = 0$.

In 1957 Gleason [36] proved his famous theorem which can be viewed as an additional argument in favor of von Neumann's additivity axiom. Recall that two Hermitian operators on a finite-dimensional Hilbert space commute if and only if they can be written as polynomials of the same Hermitian operator. Let us define a *quasi-state* on $\mathcal{A}_q$ as an $\mathbb{R}$-valued functional which satisfies the homogeneity, positivity and normalization axioms above, while the additivity axiom is replaced by one of the two *equivalent* axioms:

[1]Sometimes homogeneous quasi-morphisms are also called *pseudo-characters* – see e.g. [66].

Quasi-additivity-I: $\zeta(A+B) = \zeta(A) + \zeta(B)$, provided A and B commute: $[A, B]_\hbar = 0$;

Quasi-additivity-II: $\zeta(A + B) = \zeta(A) + \zeta(B)$, provided A and B belong to a singly generated subalgebra of $\mathcal{A}_q$.

According to the Gleason theorem, every quasi-state ζ on $\mathcal{A}_q$ is linear, that is, a state, provided the complex dimension of the Hilbert space H is at least 3 (it is an easy exercise to show that in the two-dimensional case there are plenty of non-linear quasi-states).

Let us turn now to the mathematical model of classical mechanics. Here the algebra $\mathcal{A}_c$ of observables (c for classical) is the space $C^\infty(M)$ of smooth functions on a symplectic manifold M. The space $C^\infty(M)$ carries two structures. On one hand, it is a Lie algebra with respect to the Poisson bracket (see Section 3.1). On the other hand, it is a dense subset (in the uniform norm) of the commutative Banach algebra $C(M)$ of continuous functions on M. For both frameworks one can define its own version of the notion of a quasi-state adapting, respectively, the first or the second definition of quasi-additivity – as a result one gets the so-called *Lie quasi-states* and *topological quasi-states* (see Section 2.3).

Symplectic quasi-states that appear in symplectic topology and will be discussed below in Section 3 belong to both of these worlds – they are simultaneously Lie and topological quasi-states[2]. Note that for the Lie algebra $C^\infty(M)$ the first definition of quasi-additivity fits in with the physical Correspondence Principle according to which the bracket $[\ ,\ ]_\hbar$ corresponds to the Poisson bracket $\{\ ,\ \}$ in the classical limit $\hbar \to 0$. The existence of non-linear symplectic quasi-states on certain symplectic manifolds (see Section 3) can be viewed as an "anti-Gleason phenomenon" in classical mechanics. Interestingly, at least for $M = S^2$, the symplectic quasi-state that we construct is dispersion-free (see Example 3.3), unlike states in von Neumann's model of quantum mechanics. For more information on the connection of symplectic quasi-states to physics see [29] and Remark 4.21 below.

2.3. Lie and topological quasi-states. Here is the precise definition of a Lie quasi-state. Let $\mathfrak{g}$ be a (possibly infinite-dimensional) Lie algebra over $\mathbb{R}$ and let $W \subset \mathfrak{g}$ be a vector subspace. A function $\zeta : W \to \mathbb{R}$ is called a *Lie quasi-state*, if it is linear on every abelian subalgebra of $\mathfrak{g}$ contained in W.

Finding non-linear Lie quasi-states is, in general, a non-trivial task: for instance, the difficult Gleason theorem mentioned above is essentially equivalent – in the finite-dimensional setting – to the claim that any Lie quasi-state on the unitary Lie algebra $\mathfrak{u}(n)$, $n \geq 3$, which is bounded on a neighborhood of zero, has to be linear [24]. Choosing an appropriate regularity class of Lie quasi-states is essential for this kind of results: if $\mathfrak{g}$ is finite-dimensional, then any Lie quasi-state on $\mathfrak{g}$ which is differentiable at 0 is automatically linear while the space of all, not necessarily continuous, Lie quasi-states on $\mathfrak{g}$ might be infinite-dimensional [24].

Another source of interest to Lie quasi-states lies in their connection to quasi-morphisms on Lie groups: if $\mathfrak{g}$ is the Lie algebra of a Lie group G and $\mu : G \to \mathbb{R}$ is a homogeneous quasi-morphism continuous on 1-parametric subgroups, then *the derivative of* μ, that is, the composition of μ with the exponential map, is a Lie quasi-state on $\mathfrak{g}$, invariant under the adjoint action of G on $\mathfrak{g}$. Symplectic quasi-states that we will discuss below appear as a particular case of this construction.

Unfortunately, rather little is known about non-linear (continuous) Lie quasi-states and

[2]Interestingly, symplectic quasi-states had appeared in an infinite-dimensional setting in symplectic topology before Lie quasi-states were properly studied in the finite-dimensional setting.

their connections to quasi-morphisms in general – almost all known facts (in particular, a non-trivial description of the space of all non-linear continuous Lie quasi-states on $\mathfrak{sp}(2n, \mathbb{R})$, $n \geq 3$) and some basic open questions on the subject can be found in [24].

Let us now define the notion of a topological quasi-state – it is due to Aarnes [1] (who called it just a "quasi-state"). Let X be a compact Hausdorff topological space and let $C(X)$ be the space of continuous functions on X equipped with the uniform norm. For a function $F \in C(X)$ denote by $\mathcal{A}_F$ the closure in $C(X)$ of the set of functions of the form $p \circ F$, where p is a real polynomial. A functional $\zeta : C(X) \to \mathbb{R}$ is called a *topological quasi-state* [1], if it satisfies the following axioms:

Quasi-linearity: ζ is linear on $\mathcal{A}_F$ for every $F \in C(X)$ (in particular, ζ is homogeneous).

Monotonicity: $\zeta(F) \leq \zeta(G)$ for $F \leq G$.

Normalization: $\zeta(1) = 1$.

A linear topological quasi-state is called a *state* (similarly to states in von Neumann's model of quantum mechanics – see Section 2.2). The existence of non-linear topological quasi-states was first proved by Aarnes [1].

By the classical Riesz representation theorem, states on $C(X)$ are in one-to-one correspondence with regular Borel probability measures on X. In [1] Aarnes proved a generalized Riesz representation theorem that associates to each topological quasi-state ζ a *quasi-measure*[3] τ on X which is defined only on sets that are either open or closed and is finitely additive but not necessarily sub-additive. The relation between ζ and τ extends the relation between states and measures given by the Riesz representation theorem. In particular, if A is closed, $\tau(A)$ can be thought of as the "value" of ζ on the (discontinuous) characteristic function of A.

3. Calabi quasi-morphisms, symplectic quasi-states

3.1. Symplectic preliminaries. Referring the reader to [47] for the foundations of symplectic geometry we briefly recall the basic notions needed for the further discussion.

Let M^{2n} be a closed connected manifold equipped with a symplectic form ω, that is, a closed and non-degenerate differential 2-form. In terms of classical mechanics, M can be viewed as the phase space of a mechanical system and smooth functions on M (possibly depending smoothly on an additional parameter, viewed as time) are called Hamiltonians. Whenever we consider a time-dependent Hamiltonian we assume that it is 1-periodic in time, i.e. has the form $F : M \times S^1 \to \mathbb{R}$. Set $F_t := F(\cdot, t)$. The support of F is defined as $\operatorname{supp} F := \cup_{t \in S^1} \operatorname{supp} F_t \subset M$. We say that F is *normalized*, if $\int_M F_t \omega^n = 0$ for any $t \in S^1$.

We denote by $C(M)$ (respectively, $C^\infty(M)$), the space of continuous (respectively, smooth) functions on M and by $\|\cdot\|$ the uniform norm on these spaces: $\|F\| := \max_M |F|$.

Given a (time-dependent) Hamiltonian F, define its *Hamiltonian vector field* X_{F_t} by $\omega(\cdot, X_{F_t}) = dF_t(\cdot)$. Denote the flow of X_{F_t} by ϕ_F^t – it preserves ω and is called the *Hamiltonian flow of* F. Symplectomorphisms of M (that is, diffeomorphisms of M preserving ω) that can be included in such a flow are called *Hamiltonian symplectomorphisms* and form a

[3] Quasi-measures are sometimes also called *topological measures*.

group $Ham(M)$ which is a subgroup of the identity component $Symp_0(M)$ of the full symplectomorphism group $Symp(M)$. Its universal cover is denoted by $\widetilde{Ham}(M)$. We say that $\phi_F := \phi_F^1$ is *the Hamiltonian symplectomorphism generated by* F. The Hamiltonian F also generates an element of $\widetilde{Ham}(M)$ that will be denoted by $\widetilde{\phi}_F$: it is given by the homotopy class (with the fixed end-points) of the path ϕ_F^t, $0 \leq t \leq 1$, in $Ham(M)$.

The space of smooth functions on M will be denoted by $C^\infty(M)$. Given $F, G \in C^\infty(M)$, define the *Poisson bracket* $\{F, G\}$ by $\{F, G\} := \omega(X_G, X_F)$. Together with the Poisson bracket $C^\infty(M)$ becomes a Lie algebra whose center is $\mathbb{R}$ (the constant functions).

It is instructive to view $Ham(M)$ and $\widetilde{Ham}(M)$ as infinite-dimensional Lie groups whose Lie algebra (the algebra of time-independent Hamiltonian vector fields on M) is naturally isomorphic to $C^\infty(M)/\mathbb{R}$, or to the subalgebra of $C^\infty(M)$ formed by normalized functions, with the map $F \mapsto \phi_F$ being viewed as the exponential map and the natural action of $Ham(M)$ on $C^\infty(M)$ being viewed as the adjoint action.

Similarly to the closed case, for an open symplectic manifold (U^{2n}, ω) one can define $Ham(U)$ as the group formed by Hamiltonian symplectomorphisms generated by (time-dependent) Hamiltonians supported in U and $\widetilde{Ham}(U)$ as its universal cover. The group $\widetilde{Ham}(U)$ admits the *Calabi homomorphism* $\widetilde{Cal}_U : \widetilde{Ham}(U) \to \mathbb{R}$ defined by $\widetilde{Cal}_U(\widetilde{\phi}_F) := \int_{S^1} \int_M F_t \omega^n dt$, where $\operatorname{supp} F \subset U$. If ω is exact, $\widetilde{Cal}_U$ descends to a homomorphism $Cal_U : Ham(U) \to \mathbb{R}$. If U is an open subset of M, then there are natural inclusion homomorphisms $Ham(U) \to Ham(M)$, $\widetilde{Ham}(U) \to \widetilde{Ham}(M)$, whose images will be denoted by G_U and $\widetilde{G}_U$[4].

Let U be an open subset of M. Each $\phi \in Ham(M)$ (respectively, $\widetilde{\phi} \in \widetilde{Ham}(M)$) can be represented as a product of elements of the form $\psi\theta\psi^{-1}$ with θ lying in G_U (respectively, $\widetilde{G}_U$). Moreover, assuming that $\widetilde{Cal}_U$ descends to a homomorphism Cal_U on $Ham(U)$, one can make sure that each such θ satisfies $Cal_U(\theta) = 0$. This follows from Banyaga's fragmentation lemma [5]. Denote the minimal number of factors in such a product by $\|\phi\|_U$ (respectively, $\|\widetilde{\phi}\|_U$), if there is no condition on $Cal_U(\theta)$, and $\|\phi\|_{U,0}$, if the condition $Cal_U(\theta) = 0$ is imposed. All the norms are defined as 0 on the identity elements.

Let T^k be a torus. A *Hamiltonian T^k-action* on M is a homomorphism $T^k \to Ham(M)$. (We will always assume that such an action is effective). In such a case the action of the i-th S^1-factor of $T^k = S^1 \times \ldots \times S^1$, $i = 1, \ldots, k$, is a Hamiltonian flow generated by a Hamiltonian H_i. The Hamiltonians $H_1, \ldots, H_k$ commute with respect to the Poisson bracket. The map $\Phi = (H_1, \ldots, H_k) : M \to \mathbb{R}^k$ is called the *moment map* of the Hamiltonian T^k-action. If all H_i are normalized, we say that Φ is the normalized moment map.

A submanifold L of (M^{2n}, ω) is called *Lagrangian*, if $\dim L = n$ and $\omega|_L \equiv 0$.

A (closed) symplectic manifold (M, ω) admits a preferred class of almost complex structures compatible in a certain sense with ω. All these almost complex structures have the same first Chern class c_1, called the first Chern class of M. A closed symplectic manifold (M, ω) is called *monotone*, if $[\omega]$ and c_1 are positively proportional on spherical homology classes and *symplectically aspherical*, if $[\omega]$ vanishes on such classes.

Finally, we say that a subset $X \subset M$ is *displaceable from* $Y \subset M$ *by a group* G (where G is either $Ham(M)$, or $Symp_0(M)$, or $Symp(M)$), if there exists $\phi \in G$ such that $\phi(X) \cap \overline{Y} = \emptyset$. If X can be displaced from itself by G, we say that it is *displaceable by* G

[4]Note that the homomorphism $\widetilde{Ham}(U) \to \widetilde{Ham}(M)$ does not have to be injective and, accordingly, $\widetilde{G}_U$ does not have to be the preimage of G_U under the universal cover $\widetilde{Ham}(M) \to Ham(M)$ – see [40].

or just *displaceable*, if $G = Ham(M)$.

Consider $T^*S^1 = \mathbb{R} \times S^1$ with the coordinates (r, θ) and the symplectic form $dr \wedge d\theta$. We say that $X \subset M$ is *stably displaceable*, if $X \times \{r = 0\}$ is displaceable in $M \times T^*S^1$ equipped with the split symplectic form $\omega \oplus (dr \wedge d\theta)$. Any displaceable set is stably displaceable (but not necessarily vice versa).

3.2. Quantum homology and spectral numbers. A closed symplectic manifold M carries a rich algebraic structure called the *quantum homology* of M: additively it is just the singular homology of M with coefficients in a certain ring, while multiplicatively the quantum product is a deformation of the classical intersection product on homology which is defined using a count of certain pseudo-holomorphic spheres[5] in M. In fact, there are several possible algebraic setups for this structure – we refer the reader to [48], as well as [22, 70], for the precise definitions and more details. In any case, the resulting algebraic object is a ring with unity given by the fundamental class $[M]$. Passing, if needed (depending on M and the algebraic setup of the construction), to an appropriate subring with unity one gets a finite-dimensional commutative algebra with unity over a certain field that we will denote by $\mathcal{K}$. Typically, $\mathcal{K}$ is the field of semi-infinite (Laurent-type) power series with coefficients in a base field $\mathcal{F}$, where $\mathcal{F}$ is one of the fields $\mathbb{Z}_p$, $\mathbb{Q}$, $\mathbb{R}$, $\mathbb{C}$. Abusing the terminology we will denote the latter finite-dimensional commutative algebra by $QH(M)$ and still call it the quantum homology of M.

Let us also mention the constructions of Usher [70] and Fukaya-Oh-Ohta-Ono [31] (the so-called *deformed quantum homology*) that, roughly speaking, use certain homology classes of M for an additional deformation of the quantum homology product and sometimes allow to obtain *different* finite-dimensional commutative algebras as above for a given M – abusing the terminology we will still call any of these different algebras the quantum homology of M and denote it by $QH(M)$ and emphasize the difference between them only when needed.

Given a non-zero $a \in QH(M)$ and a Hamiltonian $F : M \times S^1 \to \mathbb{R}$, one can define the *spectral number* $c(a, F)$ [53, 61] (see [51, 52, 71] for earlier versions of the construction and [68, 69] for additional important properties of the spectral numbers). It generalizes the following classical minimax quantity: given a singular non-zero (rational) homology class a of M and a continuous function F on M, consider the smallest value c of F so that a can be realized by a cycle lying in $\{F \leq c\}$ – for a smooth Morse function F this definition can be reformulated in terms of the Morse homology of F. The construction of the spectral number $c(a, F)$ is based on the same concept, where the singular homology is replaced by the quantum homology of M and the Morse homology of F is replaced by its *Floer homology*. The latter can be viewed as an infinite-dimensional version of the Morse homology for a certain functional, associated with F, on a covering of the space of free contractible loops in M, with the critical points of the functional being pre-images of contractible 1-periodic orbits of the Hamiltonian flow of F under the covering (see e.g. [48] for a detailed introduction to the subject).

If $F, G : M \times S^1 \to \mathbb{R}$ are normalized and $\widetilde{\phi}_F = \widetilde{\phi}_G$, then $c(a, F) = c(a, G)$. Thus, given $\widetilde{\phi} \in \widetilde{Ham}(M)$, one can define $c(a, \widetilde{\phi}) := c(a, F)$ for any normalized F generating $\widetilde{\phi}$.

[5] Pseudo-holomorphic spheres are (j, J)-holomorphic maps $(\mathbb{C}P^1, j) \to (M, J)$ for the standard complex structure j on $\mathbb{C}P^1$ and an almost complex structure J on M compatible with the symplectic form.

3.3. The main theorem. Assume $a \in QH(M)$ is an idempotent (for instance, $a = [M]$). **Here and further on, whenever we mention an idempotent, we assume that it is non-zero.** Define $\mu_a : \widetilde{Ham}(M) \to \mathbb{R}$ by

$$\mu_a(\widetilde{\phi}) := -\mathrm{vol}(M) \lim_{k\to+\infty} \frac{c(a, \widetilde{\phi}^k)}{k},$$

where $\mathrm{vol}(M) := \int_M \omega^n$, and $\zeta_a : C^\infty(M) \to \mathbb{R}$ by

$$\zeta_a(F) := \lim_{k\to+\infty} \frac{c(a, kF)}{k}.$$

One can check [21] that the limits exist and

$$\zeta_a(F) = \frac{\int_M F\omega^n - \mu_a(\widetilde{\phi}_F)}{\mathrm{vol}(M)}.$$

The next theorem shows that under certain conditions on $QH(M)$ and a the function μ_a is a homogeneous quasi-morphism and accordingly ζ_a is a Lie quasi-state invariant under the adjoint action of $\widetilde{Ham}(M)$ on $C^\infty(M)$, since, up to a scaling factor and an addition of a linear map invariant under the adjoint action of $\widetilde{Ham}(M)$, it is the derivative of μ_a (see Section 2.3).

We will say that $QH(M)$ is *field-split*, if it can be represented, in the category of $\mathcal{K}$-algebras, as a direct sum of two subalgebras at least one of which is a field. Such a field will be called *a field factor* of $QH(M)$.

Theorem 3.1. *Assume $QH(M)$ is field-split and a is the unity in a field factor of $QH(M)$. Then μ_a satisfies the following properties:*

(A) **(Stability)** $\int_0^1 \min_M(F_t - G_t)\, dt \le \mu_a(\widetilde{\phi}_G) - \mu_a(\widetilde{\phi}_F) \le \int_0^1 \max_M(F_t - G_t)\, dt$.

(B) *The function $\mu_a : \widetilde{Ham}(M) \to \mathbb{R}$ is a homogeneous quasi-morphism, that is,*

(B1) **(Homogeneity)** $\mu_a(\widetilde{\phi}^k) = k\mu_a(\widetilde{\phi})$ *for any $\widetilde{\phi} \in \widetilde{Ham}(M)$ and $k \in \mathbb{Z}$.*

(B2) **(Quasi-additivity)** *There exists $C > 0$ such that $|\mu_a(\widetilde{\phi}\widetilde{\psi}) - \mu_a(\widetilde{\phi}) - \mu_a(\widetilde{\psi})| \le C$ for any $\widetilde{\phi}, \widetilde{\psi} \in \widetilde{Ham}(M)$.*

(C) **(Calabi property)** *If $U \subset M$ is stably displaceable and $\operatorname{supp} F \subset U$, then $\mu_a(\widetilde{\phi}_F) = \int_0^1 \int_U F_t \omega^n dt$. In other words, the Calabi homomorphism $\widetilde{Cal}_U$ descends from $\widetilde{Ham}(U)$ to $\widetilde{G}_U \subset \widetilde{Ham}(M)$[6] and $\mu|_{\widetilde{G}_U} = \widetilde{Cal}_U$.*

At the same time, ζ_a satisfies the following properties:

(a) **(Monotonicity)** $\min_M(F - G) \le \zeta_a(F) - \zeta_a(G) \le \max_M(F - G)$ *for any $F, G \in C^\infty(M)$ and, in particular, if $F \le G$, then $\zeta_a(F) \le \zeta_a(G)$. Hence, ζ_a is 1-Lipschitz with respect to the uniform norm and extends to a functional on $C(M)$ that we will still denote by ζ_a.*

[6] This was tacitly assumed in [20].

(b) *The functional ζ_a is a Lie quasi-state, that is*

(b1) **(Homogeneity)** $\zeta_a(\lambda F) = \lambda \zeta_a(F)$ *for any* $F \in C(M)$ *and* $\lambda \in \mathbb{R}$.

(b2) **(Strong quasi-additivity)** *If* $F, G \in C^\infty(M)$ *and* $\{F, G\} = 0$, *then* $\zeta_a(F+G) = \zeta_a(F) + \zeta_a(G)$. *In fact,* ζ_a *satisfies a stronger property: for any* $F, G \in C^\infty(M)$ *one has*

$$|\zeta_a(F+G) - \zeta_a(F) - \zeta_a(G)| \leq \sqrt{2C||\{F,G\}||},$$

where $C > 0$ *is the constant from (*B2).

(c) **(Vanishing property)** *If* $U \subset M$ *is stably displaceable and* $F \in C(M)$ *with* $\operatorname{supp} F \subset U$, *then* $\zeta_a(F) = 0$.

(d) **(Normalization)** $\zeta_a(1) = 1$.

(e) **(Invariance)** $\zeta_a : C(M) \to \mathbb{R}$ *is invariant under the action of* $Symp_0(M)$ *on* $C(M)$.

The functionals $\mu_a : \widetilde{Ham}(M) \to \mathbb{R}$ and $\zeta_a : C(M) \to \mathbb{R}$ satisfying the properties listed in Theorem 3.1 are called, respectively, a *Calabi quasi-morphism* and a *symplectic quasi-state*. In particular, the restriction of a symplectic quasi-state to $C^\infty(M)$ is always a Lie quasi-state. Moreover, one can readily check that any symplectic quasi-state is also a topological quasi-state. The converse is true only if $\dim M = 2$ [21]. The quasi-measure associated to a symplectic quasi-state is $Symp_0(M)$-invariant and vanishes on stably displaceable open sets.

For an arbitrary M and an arbitrary idempotent $a \in QH(M)$ (for instance, $a = [M]$) one gets a weaker set of properties of μ_a and ζ_a.

Theorem 3.2. *Assume* $a \in QH(M)$ *is an arbitrary idempotent. Then* μ_a *satisfies the properties* (A) *and* (C) *from Theorem 3.1 and a weaker version of the properties* (B1) *and* (B2)*:*

(B1') **(Partial homogeneity)** $\mu_a(\widetilde{\phi}^k) = k\mu_a(\widetilde{\phi})$ *for any* $\widetilde{\phi} \in \widetilde{Ham}(M)$ *and* $k \in \mathbb{Z}_{\geq 0}$.

(B2') **(Partial quasi-additivity)** *Given a displaceable open set* $U \subset M$, *there exists* $C = C(\mu_a, U) \geq 0$, *so that* $|\mu_a(\widetilde{\phi}\widetilde{\psi}) - \mu_a(\widetilde{\phi}) - \mu_a(\widetilde{\psi})| \leq C \min\{\|\widetilde{\phi}\|_U, \|\widetilde{\psi}\|_U\}$ *for any* $\widetilde{\phi}, \widetilde{\psi} \in \widetilde{Ham}(M)$.

At the same time, ζ_a *satisfies the properties* (a), (c), (d), (e) *from Theorem 3.1 and a weaker version of the properties* (b1) *and* (b2)*:*

(b1') **(Partial homogeneity)** $\zeta_a(\lambda F) = \lambda \zeta_a(F)$ *for any* $F \in C(M)$ *and* $\lambda \in \mathbb{R}_{\geq 0}$.

(b2') **(Partial strong quasi-additivity)** *If* $F, G \in C^\infty(M)$ *and* $\{F, G\} = 0$ *and either* $\operatorname{supp} G$ *is displaceable or* G *is constant, then* $\zeta_a(F+G) = \zeta_a(F) + \zeta_a(G)$. *In fact,* ζ_a *satisfies a stronger property: for any* $F, G \in C^\infty(M)$ *one has*

$$|\zeta_a(F+G) - \zeta_a(F) - \zeta_a(G)| \leq \sqrt{2C||\{F,G\}||},$$

where $C > 0$ *is a constant depending on* ζ_a *and on the supports of* F *and* G.

The functionals μ_a and ζ_a satisfying the properties listed in Theorem 3.2 are called, respectively, a *partial Calabi quasi-morphism* and a *partial symplectic quasi-state*. Clearly, a genuine Calabi quasi-morphism or a genuine symplectic quasi-state is also a partial one.

Theorems 3.1 and 3.2 were proved under various additional restrictions on M in [20], [21]. In [45, 54, 68, 69] (see also [22, 23]) the restrictions were removed and the theorems were proved for new classes of closed symplectic manifolds. The stronger part of the property (b2) in Theorems 3.1 was proved in [28]. The stronger part of the property (b2') in Theorems 3.2 was proved in [57]. The Calabi and vanishing properties (C) and (c) in Theorems 3.1, 3.2 were originally proved for a displaceable U – it was later observed by Borman [10] that the displaceability assumption on U can be weakened to stable displaceability.

Examples of closed manifolds with a field-split $QH(M)$ (for an appropriate algebraic setup of $QH(M)$) include complex projective spaces (or, more generally, complex Grassmanians and symplectic toric manifolds), as well as blow-ups of symplectic manifolds – all with appropriate (and, in a certain sense, generic [70]) symplectic structures [20, 22, 31, 32, 44, 45, 54, 55, 70]. The direct product of symplectic manifolds with field-split quantum homology algebras also has this property – possibly under some additional assumptions on the manifolds, depending on the algebraic setup of the quantum homology [22]. As an example of M whose quantum homology $QH(M)$ is *not* field-split one can take any symplectically aspherical manifold – in such a case there are no pseudo-holomorphic spheres in M and hence there is no difference between quantum and singular homology. Let us emphasize that, in general, the question whether $QH(M)$ is field-split may depend not only on M but also on the algebraic setup of the quantum homology (and on a choice of the deformation in case of the deformed quantum homology).

Example 3.3 ([20]). Assume $M = S^2$ and $a = [S^2]$. Then $\zeta_a : C(S^2) \to \mathbb{R}$ is a symplectic quasi-state and its restriction to the set of smooth Morse functions on S^2 (which is dense in $C(S^2)$ in the uniform norm) can be described in combinatorial terms.

Namely, assume that the symplectic (that is, area) form ω on S^2 is normalized so that the area of S^2 is 1 and let F be a smooth Morse function on S^2. Consider the space Δ of connected components of the level sets of F as a quotient space of S^2. As a topological space Δ is homeomorphic to a tree. The function F descends to Δ and the push-forward of the measure defined by ω on S^2 yields a non-atomic Borel probability measure on Δ. There exists a unique point $x \in \Delta$ such that each connected component of $\Delta \setminus x$ has measure $\leq 1/2$ (such a point x is called *the median* of the measured tree Δ). Then $\zeta_a(F) = F(x)$.

Let us note that the symplectic quasi-state $\zeta_a : C(S^2) \to \mathbb{R}$ in Example 3.3 is *dispersion-free*, that is, satisfies $\zeta_a(F^2) = (\zeta_a(F))^2$. Equivalently, the corresponding quasi-measure takes only values 0 and 1. The following open question is of utmost importance for the study of symplectic quasi-states:

Question 3.4. *Is it true that the (partial) symplectic quasi-states constructed in Theorems 3.1 and 3.2 are always dispersion-free?*

Remark 3.5. Sometimes the (partial) Calabi quasi-morphism $\mu_a : \widetilde{Ham}(M) \to \mathbb{R}$ descends to $Ham(M)$ (that is, vanishes on $\pi_1 Ham(M)$). Abusing the notation we will denote the resulting (partial) Calabi quasi-morphism on $Ham(M)$ also by μ_a. The list of manifolds for which μ_a is known to descend to $Ham(M)$ for *all* a includes symplectically aspherical manifolds [61], complex projective spaces [20] and their monotone products [13, 20], a monotone blow-up of $\mathbb{C}P^2$ at three points and the complex Grassmannian $Gr(2, 4)$ [13].

The list of manifolds for which it is known that μ_a does *not* descend to $\mathit{Ham}(M)$ at least for *some* a includes various symplectic toric manifolds and, in particular, the monotone blow-ups of $\mathbb{C}P^2$ at one or two points [23, 54].

Let us note that if (M,ω) is monotone, the restriction of μ_a to $\pi_1\mathit{Ham}(M)$ does not depend on the choice of a (for a fixed algebraic setup of $QH(M)$) [23]. This is not necessarily true if M is not monotone [55].

Remark 3.6. For a closed connected M the group $\mathit{Ham}(M)$ is simple and the group $\widetilde{\mathit{Ham}}(M)$ is perfect [5]. Hence, these groups do not admit non-trivial homomorphisms to $\mathbb{R}$ and therefore partial Calabi quasi-morphisms on $\widetilde{\mathit{Ham}}(M)$ and $\mathit{Ham}(M)$ are never homomorphisms (they are non-trivial because of the Calabi property). Also, partial symplectic quasi-states are never linear (use a partition of unity with displaceable supports to check it). Moreover, in certain cases one can verify that a partial symplectic quasi-state ζ_a is not a genuine quasi-state (and, accordingly, μ_a is not a genuine quasi-morphism) – see Section 4.1.

Remark 3.7. Denote by $\mathcal{E}$ the collection of all open displaceable $U \subset (M,\omega)$ such that $\omega|_U$ is exact. For any $U \in \mathcal{E}$ the Calabi homomorphism $\mathit{Cal}_U : G_U \to \mathbb{R}$ is well-defined and, by Banyaga's theorem [5], the group $\operatorname{Ker}\mathit{Cal}_U$ is simple, meaning that, up to a scalar factor, Cal_U is the unique non-trivial $\mathbb{R}$-valued homomorphism on G_U continuous on 1-parametric subgroups. If $U, V \in \mathcal{E}$ and $U \subset V$, then $G_U \subset G_V$ and $\mathit{Cal}_U = \mathit{Cal}_V$ on G_U. Thus, if a partial Calabi quasi-morphism μ_a descends to $\mathit{Ham}(M)$, we get the following picture: there is a family $\mathcal{E}$ of subgroups of $\mathit{Ham}(M)$, with each subgroup $G_U \in \mathcal{E}$ carrying the unique $\mathbb{R}$-valued homomorphism Cal_U (continuous on 1-parametric subgroups), and while it is impossible to patch up all these homomorphisms into an $\mathbb{R}$-valued homomorphism on $\mathit{Ham}(M)$, it is possible to patch them up into a partial Calabi quasi-morphism μ_a (which may be non-unique).

Now let us discuss the existence and uniqueness of genuine Calabi quasi-morphisms and symplectic quasi-states on a given symplectic manifold and, in particular, the dependence of μ_a and ζ_a on a and the algebraic setup of $QH(M)$.

The set of idempotents in $QH(M)$ carries a partial order: namely, given idempotents $a, b \in QH(M)$, we write $a \succeq b$ if $ab = b$. Clearly, $[M] \geq b$ for any idempotent $b \in QH(M)$. If $a \succeq b$, then $a - b$ is also an idempotent and $a \succeq a - b$. Conversely, if $b, b' \in QH(M)$ are two idempotents such that $bb' = 0$, then $b + b'$ is also an idempotent and $b + b' \succeq b, b'$.

The following theorem follows from basic properties of spectral numbers (cf. [23], Theorem 1.5).

Theorem 3.8. *Assume $a, b \in QH(M)$ are idempotents, so that $a \succeq b$. Then*

(a) $\mu_a \leq \mu_b$, $\zeta_a \geq \zeta_b$.

(b) *If μ_a is a genuine (i.e. not only partial) Calabi quasi-morphism, then $\mu_a = \mu_b$, $\zeta_a = \zeta_b$ and thus μ_b is also a genuine Calabi quasi-morphism and ζ_b is a genuine symplectic quasi-state.*

At the same time it is possible that $a \succeq b$, μ_a is a partial Calabi quasi-morphism while μ_b is a genuine Calabi quasi-morphism – see Examples 4.13, 4.14.

In fact, different idempotents may define linearly independent Calabi quasi-morphisms and symplectic quasi-states. For instance, if M is a blow-up of $\mathbb{C}P^2$ at one point with an appropriate non-monotone symplectic structure, one can find Calabi quasi-morphisms μ_a and

μ_b on $\widetilde{Ham}(M)$ (for some idempotents $a, b \in QH(M)$) that have linearly independent restrictions to $\pi_1 Ham(M)$ [55], and if M is $S^2 \times S^2$ with a monotone symplectic structure, one can find linearly independent[7] symplectic quasi-states ζ_a, ζ_b on $C(M)$ – see Example 4.14.

Moreover, a change of the algebraic setup of $QH(M)$ may yield new Calabi quasi-morphisms and symplectic quasi-states on the same M. For instance, if $M = \mathbb{C}P^n$, one can choose algebraic setups of $QH(\mathbb{C}P^n)$, both for $\mathcal{F} = \mathbb{Z}_2$ and $\mathcal{F} = \mathbb{C}$, so that *in both cases* $QH(\mathbb{C}P^n)$ is a field and thus the *only* idempotent in $QH(\mathbb{C}P^n)$ is the unity $a = [\mathbb{C}P^n]$. By Theorem 3.1, in both cases $a = [\mathbb{C}P^n]$ defines a Calabi quasi-morphism μ_a on $\widetilde{Ham}(\mathbb{C}P^n)$ that descends to $Ham(\mathbb{C}P^n)$ (for $\mathcal{F} = \mathbb{C}$ this is proved in [20], the same proof works also for $\mathcal{F} = \mathbb{Z}_2$). However, it follows from [73] for $n = 2$ and from [50] for $n = 3$ that the symplectic quasi-states defined by $[\mathbb{C}P^n]$ in both cases are *different* (see Example 4.12).

Remark 3.9. Let us note that historically the first Calabi quasi-morphism on $\widetilde{Ham}(\mathbb{C}P^n)$ was implicitly constructed by Givental in [34, 35] in a completely different way; the fact that it is indeed a Calabi quasi-morphism was proved by Ben Simon [7] (the stability property of the quasi-morphism is proved in [12]). Givental's Calabi quasi-morphism descends from $\widetilde{Ham}(\mathbb{C}P^n)$ to $Ham(\mathbb{C}P^n)$ [64]. It would be interesting to find out whether this quasi-morphism on $Ham(\mathbb{C}P^n)$ can be expressed as μ_a for some $a \in QH(\mathbb{C}P^n)$ (for some algebraic setup of $QH(\mathbb{C}P^n)$).

Question 3.10. *Is the quasi-morphism μ_a for $a = [\mathbb{C}P^1]$ the only Calabi quasi-morphism on $Ham(\mathbb{C}P^1)$?*

Let us note that in the case of $\mathbb{C}P^1$ the symplectic quasi-state ζ_a for $a = [\mathbb{C}P^1]$, described in Example 3.3, is known to be the unique symplectic quasi-state on $C(S^2)$ [20].

In some cases the non-uniqueness can be prove by using the different algebras $QH(M)$ appearing in the deformed quantum homology construction – see [31] for examples of symplectic manifolds with infinitely many linearly independent Calabi quasi-morphisms and symplectic quasi-states constructed in this way.

Let us also mention a construction due to Borman [10, 11] (also see [12]) that allows to use a Calabi quasi-morphism on $\widetilde{Ham}(N)$ in order to build a Calabi quasi-morphism on $\widetilde{Ham}(M)$ if M is obtained from N by a symplectic reduction or if M is a symplectic submanifold of N. Using different presentations of a symplectic manifold as a symplectic reduction one can construct examples of M with infinitely many linearly independent Calabi quasi-morphisms on $\widetilde{Ham}(M)$ (the corresponding symplectic quasi-states are also linearly independent).

Let us also note that apart from the Calabi quasi-morphisms from Theorem 3.1, the Givental quasi-morphism mentioned in Remark 3.9 and the quasi-morphisms produced from them by Borman's reduction method, there are no known examples of homogeneous quasi-morphisms on $\widetilde{Ham}(M)$ satisfying the stability property (A) from Theorem 3.1, though otherwise there are many homogeneous quasi-morphisms on $\widetilde{Ham}(M)$ (that sometimes descend to $Ham(M)$) – see [19, 33, 59, 60, 65]. Let us also note that for symplectic manifolds of dimension greater than 2 the constructions above are the only currently known constructions of partial symplectic quasi-states on closed manifolds. (As it was mentioned above,

[7] Note that Calabi quasi-morphisms and symplectic quasi-states on a given manifold form convex sets respectively in the vector spaces of all homogeneous quasi-morphisms and all Lie quasi-states and their linear dependence is considered in these vector spaces.

in dimension 2 any topological quasi-state is also symplectic. There is a number of ways to construct topological quasi-states in any dimension – see e.g. [2, 41]). The basic open case for the existence of a (stable) Calabi quasi-morphism on $\widetilde{Ham}(M)$ is $M = T^2$ and for symplectic quasi-states it is $M = T^4$. It is also unknown whether any symplectic quasi-state has to come from a Calabi quasi-morphism and whether different Calabi quasi-morphisms may define the same symplectic quasi-state.

Remark 3.11. There is a straightforward extension of the notion of a (partial) Calabi quasi-morphism to the case of an open symplectic manifold M and there are several constructions of such quasi-morphisms.

First, one can consider a conformally symplectic embedding[8] of M in a closed symplectic manifold N carrying a Calabi quasi-morphism defined on $Ham(N)$ and use the homomorphism $Ham(M) \to Ham(N)$ induced by the embedding to pullback the quasi-morphism from $Ham(N)$ to $Ham(M)$. (Of course, one then has to prove that the resulting quasi-morphism on $Ham(M)$ is non-trivial). In this way one can, for instance, use conformally symplectic embeddings of a standard round ball B^{2n} in $\mathbb{C}P^n$ in order to construct a continuum of linearly independent Calabi quasi-morphisms on $Ham(B^{2n})$ [9].

There are also *intrinsic* constructions of (partial) Calabi quasi-morphisms for certain open symplectic manifolds following the lines of the construction presented above – see [42, 49] for more details as well as for extensions of the notion of a (partial) symplectic quasi-state to the open case. These constructions allow to extend many of the results mentioned in this survey to the open case.

4. Applications

4.1. Quasi-states and rigidity of symplectic intersections. A key phenomenon in symplectic topology is rigidity of intersections of subsets of symplectic manifolds: namely, sometimes a subset X of a symplectic manifold M cannot be displaced from a subset Y by $Ham(M)$ (or $Symp_0(M)$, or $Symp(M)$), even though X can be displaced from Y by a smooth isotopy. A central role in the applications of partial symplectic quasi-states is played by their connection to this phenomenon. Namely, to each partial symplectic quasi-state, and, in particular, to each idempotent $a \in QH(M)$, one can associate a certain hierarchy of non-displaceable sets in M. The interplay between the hierarchies associated to different a is an interesting geometric phenomenon in itself.

The key definitions describing the hierarchy are as follows [23]. Let $\zeta : C(M) \to \mathbb{R}$ be a partial symplectic quasi-state. We say that a closed subset $X \subset M$ is *heavy with respect to* ζ, if $\zeta(F) \geq \inf_X F$ for all $F \in C(M)$, and *superheavy with respect to* ζ, if $\zeta(F) \leq \sup_X F$ for all $F \in C(M)$. Equivalently, X is superheavy with respect to ζ, if $\zeta(F) = F(X)$ for any $F \in C(M)$ which is constant on X. If $\zeta = \zeta_a$ for an idempotent $a \in QH(M)$ (and a prefixed algebraic setup of $QH(M)$), we use the terms *a-heavy* and *a-superheavy* for the heavy and superheavy sets with respect to ζ_a. Clearly, a closed set containing a heavy/superheavy subset is itself heavy/superheavy. The basic properties of heavy and superheavy sets are summarized in the following theorems.

[8] A map $f : (M, \omega) \to (N, \Omega)$ between symplectic manifolds is called *conformally symplectic* if $f^*\Omega = c\omega$ for some non-zero constant c.

Theorem 4.1 ([23]). *Heavy and superheavy sets with respect to a fixed partial symplectic quasi-state ζ satisfy the following properties:*

(a) *Every superheavy set is heavy, but, in general, not vice versa.*

(b) *The classes of heavy and superheavy sets are Symp$_0(M)$-invariant.*

(c) *Every superheavy set has to intersect every heavy set. Therefore, in view of (b), any superheavy set cannot be displaced from any heavy set by Symp$_0(M)$. In particular, any superheavy set is non-displaceable by Symp$_0(M)$. On the other hand, two heavy sets may be disjoint.*

(d) *Every heavy subset is stably non-displaceable. However, it may be displaceable by Symp$_0(M)$.*

(e) *If ζ is a genuine (that is, not partial) symplectic quasi-state, then the classes of heavy and superheavy sets are identical: they coincide with the class of closed sets of full quasi-measure (that is, of quasi-measure 1) for the quasi-measure on M associated with ζ.*

Theorem 4.2 ([23]). *Assume that X_i is an a_i-heavy (resp. a_i-superheavy) subset of a closed connected symplectic manifold M_i for some idempotent $a_i \in QH(M_i)$, $i = 1, 2$. Then the product $X_1 \times X_2 \subset M_1 \times M_2$ is $a_1 \otimes a_2$-heavy (resp. $a_1 \otimes a_2$-superheavy)*[9].

Changing an idempotent a or changing the algebraic setup of $QH(M)$ may completely change the heaviness/superheaviness property of a set: there are examples of disjoint sets that are superheavy with respect to different idempotents in $QH(M)$ (see Example 4.14) and there is an example of a set that is $[M]$-superheavy, if $QH(M)$ is set up over $\mathcal{F} = \mathbb{Z}_2$, and is disjoint from an $[M]$-superheavy set, if $QH(M)$ is set up over $\mathcal{F} = \mathbb{C}$ (see Example 4.12).

The partial order on the set of idempotents mentioned in Section 3 yields the following relation between the corresponding collections of heavy and superheavy sets which follows immediately from Theorem 3.8 and the examples below.

Theorem 4.3. *Assume $a, b \in QH(M)$ are idempotents and $a \succeq b$. Then*

(a) *Every a-superheavy set is also b-superheavy (but not necessarily vice versa).*

(b) *Every b-heavy set is also a-heavy (but not necessarily vice versa).*

Remark 4.4. There is a natural action of *Symp* (M) on $QH(M)$. The subgroup *Symp*$_0(M)$ $\subset$ *Symp* (M) acts on $QH(M)$ trivially and this explains the *Symp*$_0(M)$-invariance of the partial symplectic quasi-states ζ_a and, accordingly, of the classes of a-heavy and a-superheavy sets. If an idempotent $a \in QH(M)$ is invariant under the action of the full group *Symp* (M) (e.g. if $a = [M]$), then *Symp*$_0(M)$ can be replaced by *Symp* (M) everywhere in Theorems 3.1, 3.2, 4.1. In particular, *any* $[M]$-superheavy set cannot be displaced from *any* a-heavy set (for *any* idempotent $a \in QH(M)$) by *Symp* (M).

Remark 4.5. The reason why every superheavy set X (with respect to a partial quasi-state ζ) must intersect every heavy set Y is very simple: If $X \cap Y = \emptyset$, pick a function F so that $F|_X \equiv 0$ and $F|_Y \equiv 1$. Then, by the definition of heavy and superheavy sets, $\zeta(F) = 0$ and $\zeta(F) \geq 1$, which is impossible.

[9] There is an analogue of the Künneth formula for quantum homology – in particular, to each pair of idempotents $a_1 \in QH(M_1)$, $a_2 \in QH(M_2)$, one can associate an idempotent $a_1 \otimes a_2 \in QH(M_1 \times M_2)$. Let us note that even if ζ_{a_1} and ζ_{a_2} are genuine symplectic quasi-states, $\zeta_{a_1 \otimes a_2}$ may be only a partial one – see Example 4.14.

Remark 4.6. For certain Lagrangian submanifolds X and Y of M one can prove the non-displaceability of X from Y by means of the Lagrangian Floer homology of the pair (X, Y) (see e.g. [30]). The advantage of this method is that, unlike Theorem 4.1, it gives a non-trivial lower bound on the number of transverse intersection points of $\phi(X)$, $\phi \in \mathit{Ham}\,(M)$, and Y. On the other hand, unlike the Lagrangian Floer theory, symplectic quasi-states allow to prove non-displaceability results for singular sets (see the examples below).

The most basic examples of heavy and superheavy sets are an equator in S^2 (that is, an embedded circle dividing S^2 into two parts of equal area) which is $[S^2]$-superheavy and a meridian in T^2 which is $[T^2]$-heavy but not $[T^2]$-superheavy, since it is displaceable by $\mathit{Symp}_0(T^2)$ – in particular, it implies that the partial symplectic quasi-state on $C(T^2)$ defined by $[T^2]$ is not a genuine symplectic quasi-state [23] (cf. Remark 3.6). The union of a meridian and a parallel in T^2 is $[T^2]$-superheavy [38]. More complicated examples come from the following constructions.

Let $\mathbb{A} \subset C^\infty(M)$ be a finite-dimensional Poisson-commutative vector subspace (meaning that $\{F, G\} = 0$ for any $F, G \in \mathbb{A}$) . The map $\Phi : M \to \mathbb{A}^*$ defined by $\langle \Phi(x), F\rangle = F(x)$ is called *the moment map* of $\mathbb{A}$. As an example of such a moment map one can consider the moment map of a Hamiltonian torus action on M, or a map $M \to \mathbb{R}^N$ whose components have disjoint supports.

A non-empty fiber $\Phi^{-1}(p)$ is called a *stem* of $\mathbb{A}$ (see [21]), if all non-empty fibers $\Phi^{-1}(q)$ with $q \neq p$ are displaceable, and a *stable stem*, if they are stably displaceable. If a subset of M is a (stable) stem of *some* finite-dimensional Poisson-commutative subspace of $C^\infty(M)$, it will be called just *a (stable) stem*. Any stem is a stable stem but possibly not vice versa [10].

Theorem 4.7 ([21, 23]). *A stable stem is superheavy with respect to any partial symplectic quasi-state ζ on $C(M)$.*

Using the partial symplectic quasi-state $\zeta_{[M]}$ we get

Corollary 4.8 ([21]). *For any finite-dimensional Poisson-commutative subspace of $C^\infty(M)$ its moment map Φ has at least one non-displaceable fiber.*

The following question is closely related to Question 3.4.

Question 4.9. *Is it true that for any finite-dimensional Poisson-commutative subspace of $C^\infty(M)$ its moment map Φ has at least one heavy fiber (at least with respect to some symplectic quasi-state ζ on $C(M)$)?*

Remark 4.10. If ζ a genuine symplectic quasi-state on $C(M)$, then Theorem 4.7 can be proved using the quasi-measure τ associated to ζ [21]. Namely, the push-forward of τ to $\mathbb{A}^*$ by the moment map Φ of a Poisson commutative subspace $\mathbb{A}$ is a Borel probability measure ν on $\mathbb{A}^*$ [21]. As we already noted above, the vanishing property of ζ implies that τ vanishes on stably displaceable open subsets of M. Therefore if a fiber $\Phi^{-1}(p)$ of Φ is a stable stem, the support of ν has to be concentrated at p, meaning that $\tau(\Phi^{-1}(p)) = 1$ or, in other words (see Theorem 4.1), $\Phi^{-1}(p)$ is superheavy with respect to ζ.

Here are a few examples of (stable) stems [21, 23]. The Lagrangian Clifford torus in $\mathbb{C}P^n$, defined as $L = \{[z_0 : \ldots : z_n] \in \mathbb{C}P^n \mid |z_0| = \ldots = |z_n|\}$, is a stem, hence $[\mathbb{C}P^n]$-superheavy (this generalizes the example of an equator in S^2 mentioned above). The

[10] There are no known examples of a stable stem that is not a stem, i.e. not a stem of *any* $\mathbb{A}$.

codimension-1 skeleton of a triangulation of a closed symplectic manifold M^{2n} all of whose $2n$-dimensional simplices are displaceable is a stem. A fiber $\Phi^{-1}(0)$ of the normalized moment map Φ of a compressible[11] Hamiltonian torus action on M is a stable stem[12]. A direct product of (stable) stems is a (stable) stem and that the image of a (stable) stem under *any* symplectomorphism is again a (stable) stem.

In case when the Hamiltonian torus action is not compressible, much less is known about (stable) displaceability of fibers of the moment map of the action (aside from the case of symplectic toric manifolds where many results have been obtained in recent years by different authors). If (M, ω) is monotone, one can explicitly find a so-called *special fiber* of the moment map Φ of the action which is a-superheavy for *any* idempotent $a \in QH(M)$ [23]. For a Hamiltonian T^n-action torus on a monotone (M^{2n}, ω) (that is, for a monotone symplectic toric manifold) the special fiber (which in this case is a Lagrangian torus) can be described in simple combinatorial terms involving the moment polytope (that is, the image of the moment map which is a convex polytope) – see [23]. It is not known whether in the latter case the special fiber is always a stem – see [46] for a detailed investigation of this question. Interestingly enough, the question whether the special fiber of the *normalized* moment map for a monotone symplectic toric manifold M coincides with the fiber over zero is related to the existence of a Kähler-Einstein metric on M – see [23, 64].

Finally, heaviness/superheaviness of Lagrangian submanifolds can be proved using various versions of Lagrangian Floer homology. Namely, to certain Lagrangian submanifolds L of M one can associate the *quantum homology* (or the *Lagrangian Floer homology*) $QH(L)$ that comes with an *open-closed map* $i_L : QH(L) \to QH(M)$ [3, 8, 30, 31]. If $i_L(x)$ is non-zero for certain $x \in QH(L)$, then L is $[M]$-heavy[13], and if $i_L(x)$ divides an idempotent $a \in QH(M)$, then L is a-superheavy – this is shown in [23] in the monotone case, cf. [8, 30, 31].

Here are a few examples where this method can be applied. Let us emphasize that the applications to specific L do depend on a proper choice of the algebraic setup for the quantum homology in each case – see e.g. Example 4.12; we will ignore this issue in the other examples below and refer the reader to [8, 23, 31] for details.

Example 4.11 ([23]). Assume that $L \subset M$ is a Lagrangian submanifold and $\pi_2(M, L) = 0$. Then L is $[M]$-heavy. Note that in this case heaviness may not be improved to superheaviness: the meridian in T^2 is $[T^2]$-heavy but not $[T^2]$-superheavy.

Example 4.12. The real projective space $\mathbb{R}P^n$, which is a Lagrangian submanifold of $\mathbb{C}P^n$, is $[\mathbb{C}P^n]$-superheavy, *as long as* $QH(\mathbb{C}P^n)$ *is set up over* $\mathcal{F} = \mathbb{Z}_2$ [8, 23]. In particular, this implies that $\mathbb{R}P^n$ is not displaceable by *Symp* $(\mathbb{C}P^n)$ from the Clifford torus (see [4, 67] for other proofs of this fact).

On the other hand, $\mathbb{R}P^n$ may not be $[\mathbb{C}P^n]$-superheavy, if $QH(\mathbb{C}P^n)$ is set up over $\mathcal{F} = \mathbb{C}$ – for $n = 2$ this follows from [73] and for $n = 3$ from [50]. This implies that the symplectic quasi-states defined by $[\mathbb{C}P^n]$ for the setups of $QH(M)$ over $\mathcal{F} = \mathbb{Z}_2$ and $\mathcal{F} = \mathbb{C}$ are different for $n = 2, 3$.

---

[11] An effective Hamiltonian T^k-action on (M, ω) is called *compressible* if the image of the homomorphism $\pi_1(T^k) \to \pi_1(Ham\,(M))$, induced by the action, is a finite group.

[12] Stable stems appearing in this way potentially may not be genuine stems.

[13] The a-heaviness for an arbitrary idempotent $a \in QH(M)$ can also be proved by the same method under a stronger non-vanishing assumption.

Example 4.13 ([23]). Consider the torus T^{2n} equipped with the standard symplectic structure $\omega = dp \wedge dq$. Let $M^{2n} = T^{2n} \sharp \overline{\mathbb{C}P^n}$ be a symplectic blow-up of T^{2n} at one point (the blow-up is performed in a small ball B around the point). Assume that the Lagrangian torus $L \subset T^{2n}$ given by $q = 0$ does not intersect B.

Then the proper transform of L is a Lagrangian submanifold of M which is $[M]$-heavy but *not* a-heavy for some other idempotent $a \in QH(M)$ (that, roughly speaking, depends on the exceptional divisor of the blow-up). In this case the functional $\zeta_{[M]}$ is a partial (but not genuine) symplectic quasi-state while ζ_a is a genuine symplectic quasi-state.

Example 4.14 ([18, 23]). Let S^2 be the standard unit sphere in $\mathbb{R}^3$ with the standard area form σ. Let $M := S^2 \times S^2$ be equipped with the symplectic form $\sigma \oplus \sigma$. Denote by x_1, y_1, z_1 and x_2, y_2, z_2 the Euclidean coordinates on the two S^2-factors.

Consider the following three Lagrangian submanifolds of M: the anti-diagonal $\Delta := \{(u, v) \in S^2 \times S^2 \ : \ u = -v\}$, the Clifford torus $L = \{z_1 = z_2 = 0\}$ and the torus $K = \{z_1 + z_2 = 0, \ x_1x_2 + y_1y_2 + z_1z_2 = -1/2\}$. Clearly, L intersects both K and Δ, while $K \cap \Delta = \emptyset$.

For a certain algebraic setup of $QH(M)$ (with $\mathcal{F} = \mathbb{C}$) the algebra $QH(M)$ is a direct sum of two fields whose unities will be denoted by a_- and a_+ (in particular, $a_- + a_+ = [M]$). The idempotents a_- and a_+ define symplectic quasi-states ζ_{a_-}, ζ_{a_+}. At the same time $\zeta_{[M]}$ is only a partial, not genuine, symplectic quasi-state. The submanifolds Δ and L are a_--superheavy, while K is not. At the same time K and L are a_+-superheavy, while Δ is not. All three sets Δ, K, L are $[M]$-heavy but L is the only one of them that is $[M]$-superheavy.

In particular, the Lagrangian tori L and K cannot be mapped into each other by any symplectomorphism of M. See [50] and the references therein for more results on the Lagrangian torus K.

For more examples of heavy and superheavy Lagrangian submanifolds obtained by means of an open-closed map see [23, 31].

4.2. Quasi-states and connecting trajectories of Hamiltonian flows. Here is an application of symplectic quasi-states to Hamiltonian dynamics. As above, we assume that M is a closed connected symplectic manifold.

Theorem 4.15 ([14]). *Let $X_0, X_1, Y_0, Y_1 \subset M$ be a quadruple of closed sets so that $X_0 \cap X_1 = Y_0 \cap Y_1 = \emptyset$ and the sets $X_0 \cup Y_0, Y_0 \cup X_1, X_1 \cup Y_1, Y_1 \cup X_0$ are all a-superheavy for an idempotent $a \in QH(M)$. Let $G \in C^\infty(M \times S^1)$ be a 1-periodic Hamiltonian with $G_t|_{Y_0} \leq 0$, $G_t|_{Y_1} \geq 1$ for all $t \in S^1$.*

Then there exists a point $x \in M$ and time moments $t_0, t_1 \in \mathbb{R}$ so that $\phi_G^{t_0}(x) \in X_0$ and $\phi_G^{t_1}(x) \in X_1$. Furthermore, $|t_0 - t_1|$ can be bounded from above by a constant depending only on a, if G is time-independent, and both on a and the oscillation $\max_{M \times S^1} G - \min_{M \times S^1} G$ of G, if G is time-dependent.

Remark 4.16. The proof of Theorem 4.15 uses the following important notion [14]: Given a quadruple X_0, Y_0, X_1, Y_1 of compact subsets of a (possibly open) symplectic manifold such that $X_0 \cap X_1 = Y_0 \cap Y_1 = \emptyset$, define $pb_4(X_0, Y_0, X_1, Y_1)$ (where pb stands for the "Poisson brackets" and 4 for the number of sets) by $pb_4(X_0, Y_0, X_1, Y_1) = \inf_{F,G} ||\{F, G\}||$, where the infimum is taken over all compactly supported smooth F, G satisfying $F|_{X_0} \leq 0$, $F|_{X_1} \geq 1$, $G|_{Y_0} \leq 0$, $G|_{Y_1} \geq 1$.

Given a quadruple X_0, Y_0, X_1, Y_1 as in Theorem 4.15, one can use the strong form of the property (b2) in Theorem 3.1 to prove the positivity of pb_4 for certain stabilizations [14]

of the four sets. The existence of a connecting trajectory of the Hamiltonian flow is then deduced from the positivity of pb_4 using an averaging argument [14].

Example 4.17 ([14]). Consider an open tubular neighborhood U of the zero-section T^n in T^*T^n. Pick $q_0, q_1 \in T^n$ and consider the open cotangent disks $D_i = T^*_{q_i}T^n \cap U$, $i = 0, 1$. Let $M = S^2 \times \ldots \times S^2$ be the product of n copies of S^2 equipped with the split symplectic structure $\omega = \sigma \oplus \ldots \oplus \sigma$. Let $Y_1 \subset M$ be the product of equators in the S^2 factors. It is a Lagrangian torus. If $\int_{S^2} \sigma$ is sufficiently large, then, by the Weinstein neighborhood theorem (see [47]), U can be symplectically identified with a tubular neighborhood of Y_1 in M. Using the identification we consider $X_i := \overline{D}_i$, $i = 0, 1$, Y_1 and U as subsets of M. Set $Y_0 := M \setminus U$.

If $\int_{S^2} \sigma$ is sufficiently large, the quadruple $X_0, Y_0, X_1, Y_1 \subset M$ satisfies the assumptions of Theorem 4.15 [14]. In particular, let $G : T^*T^n \times S^1 \to \mathbb{R}$ be a Hamiltonian supported in $U \subset T^*T^n$ which is ≥ 1 on $T^n \times S^1$. Theorem 4.15 implies the existence of a trajectory of the Hamiltonian flow of G passing through D_0 and D_1.

Switching the pair X_0, X_1 with the pair Y_0, Y_1 and applying Theorem 4.15 to the switched pairs one can show in a similar way that if $F : T^*T^n \times S^1 \to \mathbb{R}$ is a compactly supported Hamiltonian such that $F|_{D_0 \times S^1} \leq 0$, $F|_{D_1 \times S^1} \geq 1$, then there exists a trajectory of the Hamiltonian flow of F connecting the zero-section of T^*T^n with ∂U. It would be interesting to find out whether this fact can be related to the well-known Arnold diffusion phenomenon in Hamiltonian dynamics that concerns trajectories of a similar kind.

4.3. Quasi-states and C^0-rigidity of Poisson brackets. In this section we still assume that (M, ω) is a closed connected symplectic manifold.

The Poisson brackets of two smooth functions on (M, ω) depend on their first derivatives. Nevertheless, as it was first discovered in [17], the Poisson bracket displays a certain rigidity with respect to the *uniform* norm of the functions. This rigidity is best expressed in terms of the *profile function* defined as follows [14].

Equip the space $\Pi := C^\infty(M) \times C^\infty(M)$ with the product uniform metric:

$$d((F, G), (H, K)) = ||F - H|| + ||G - K||.$$

For each $s \geq 0$ define $\Pi_s := \{(H, K) \in \Pi \mid ||\{H, K\}|| \leq s\}$. In particular, Π_0 is the set of Poisson-commuting pairs. Given a pair $(F, G) \in \Pi$, define the *profile function* $\rho_{F,G} : \mathbb{R}_{\geq 0} \to \mathbb{R}_{\geq 0}$ by $\rho_{F,G}(s) = d((F, G), \Pi_s)$.

Question 4.18. *Given a pair $(F, G) \in \Pi$, what can be said of $\rho_{F,G}(0)$? In other words, how well can (F, G) be approximated with respect to d by a Poisson-commuting pair?*

Let us note that similar approximation questions have been extensively studied for matrices – see e.g. [37] and the references therein. It follows from [25] that the sets Π_s, $s \geq 0$, are closed with respect to d and therefore $\rho_{F,G}(s) > 0$ for $s \in [0, ||\{F, G\}||)$. Symplectic quasi-states help to give a more precise answer in certain cases.

Theorem 4.19 ([14]). *Let $\zeta : C(M) \to \mathbb{R}$ be a symplectic quasi-state.*

(a) *Assume $X, Y, Z \subset M$ are closed sets that are superheavy with respect to ζ and satisfy $X \cap Y \cap Z = \emptyset$. Assume $F|_X \leq 0$, $G|_Y \leq 0$, $(F + G)|_Z \geq 1$ and at least one of the functions F, G has its range in $[0, 1]$. Then $\rho_{F,G}(0) = 1/2$ and for some positive*

constant C, independent of F, G, and for all $s \in [0; ||\{F, G\}||]$

$$\frac{1}{2} - C\sqrt{s} \leq \rho_{F,G}(s) \leq \frac{1}{2} - \frac{s}{2||\{F, G\}||}.$$

(b) *Let $X_0, X_1, Y_0, Y_1 \subset M$ be closed sets so that $X_0 \cap X_1 = Y_0 \cap Y_1 = \emptyset$ and the sets $X_0 \cup Y_0, Y_0 \cup X_1, X_1 \cup Y_1, Y_1 \cup X_0$ are all superheavy with respect to ζ. Assume $F, G \in C^\infty(M)$, $F|_{X_0} \leq 0$, $F|_{X_1} \geq 1$, $G|_{Y_0} \leq 0$, $G|_{Y_1} \geq 1$ and at least one of the functions F, G has its range in $[0, 1]$. Then $\rho_{F,G}(0) = 1/2$ and for some positive constant C, independent of F, G, and for all $s \in [0; ||\{F, G\}||]$*

$$\frac{1}{2} - Cs \leq \rho_{F,G}(s) \leq \frac{1}{2} - \frac{s}{2||\{F, G\}||}.$$

The proof of part (b) uses the fact that $pb_4(X_0, Y_0, X_1, Y_1) > 0$ (see Remark 4.16) and part (a) is based on the positivity of a similar Poisson bracket invariant $pb_3(X, Y, Z)$ – see [14] for more details, as well as for examples where the theorem can be applied, including an example where the lower bound in part (a) is asymptotically sharp. For a version of Theorem 4.19 for *iterated* Poisson brackets see [27].

Here is another fact concerning the C^0-rigidity of Poisson brackets whose proof uses partial symplectic quasi-states and the strong version of their partial quasi-additivity (see Theorem 3.2). Let $\mathcal{U} = \{U_1, \dots, U_N\}$ be a finite cover of M by displaceable open sets. Given a partition of unity $\vec{F} = \{F_1, \dots, F_N\}$ subordinated to $\mathcal{U}$ (that is, $\operatorname{supp} F_i \subset U_i$ for every i), consider the following measure of its Poisson non-commutativity:

$$\kappa(\vec{F}) := \inf_{x,y \in [-1,1]^N} \Big\| \Big\{ \sum_{i=1}^N x_i F_i, \sum_{j=1}^N y_j F_j \Big\} \Big\|,$$

where the infimum is taken over all $x = (x_1, \dots, x_N), y = (y_1, \dots, y_N) \in [-1, 1]^N$. Set $pb(\mathcal{U}) := \inf_{\vec{F}} \kappa(\vec{F})$, where the infimum is taken over all partitions of unity $\vec{F}$ subordinated to $\mathcal{U}$. We say that $\mathcal{U}$ is *dominated by an open set* $U \subset M$ if for each $i = 1, \dots, N$ there exists $\phi_i \in Ham\,(M)$ so that $U_i \subset \phi_i(U)$.

Theorem 4.20 ([57]). *Assume $\mathcal{U}$ is dominated by a displaceable open set U. Then there exists a constant $C = C(U) > 0$ so that*

$$pb(\mathcal{U}) \geq C/N^2. \tag{4.1}$$

The theorem strengthens a similar result proved previously in [28]. It is not clear whether the inequality (4.1) can be improved – see [57] for a discussion.

Remark 4.21. Amazingly, Theorem 4.20 that belongs to the mathematical formalism of classical mechanics can be used to prove results about mathematical objects of quantum nature appearing in the Berezin-Toeplitz quantization of a symplectic manifold – see [56–58].

4.4. Quasi-morphisms and metric properties of *Ham* (M). The group *Ham* (M) carries various interesting metrics. Here we will discuss how Calabi quasi-morphisms can be used to study these metrics.

The most remarkable metric on *Ham* (M) is the Hofer metric. Namely, define the *Hofer norm* $||\phi||_H$ of $\phi \in$ *Ham* (M) as $||\phi||_H = \inf_F \int_0^1 (\max_M F_t - \min_M F_t)dt$, where the infimum is taken over all (time-dependent) Hamiltonians F generating ϕ (if M is open, F is also required to be compactly supported). The *Hofer metric* is defined by $\varrho(\phi, \psi) = ||\phi\psi^{-1}||_H$. It is a deep result of symplectic topology that ϱ is a bi-invariant metric – see e.g. [47] and the references therein.

Assume *Ham* (M) admits a partial Calabi quasi-morphism μ. Then the stability property of μ (see Theorem 3.1) implies that μ is Lipschitz with respect to ϱ and therefore the diameter of *Ham* (M) with respect to ϱ is infinite [20]. Moreover, the Lipschitz property of μ with respect to ϱ allows to obtain the following result on the growth of 1-parametric subgroups of *Ham* (M) with respect to the Hofer norm.

Theorem 4.22 ([58], cf. [20]). *Assume Ham* (M) *admits a partial Calabi quasi-morphism. Then there exists a set* $\Xi \subset C^\infty(M)$ *which is* C^0*-open and* C^∞*-dense in* $C^\infty(M)$ *so that* $\lim_{t\to+\infty} \frac{||\phi_F^t||_H}{t||F||} > 0$ *for any* $F \in \Xi$.

Calabi quasi-morphisms can be also applied to the study of the metric induced by ϱ on certain spaces of Lagrangian submanifolds of M – see [39, 63].

The group *Ham* (M) also carries the C^0-topology: equip M with a distance function d, given by a Riemannian metric on M, and define the C^0-topology on *Ham* (M) as the one induced by the metric $dist(\phi, \psi) = \max_{x\in M} d(\phi(x), \psi(x))$. The relation between the C^0-topology and the Hofer metric on *Ham* (M) is rather delicate (for instance, the C^0-metric is never continuous with respect to the Hofer metric). One can use the Calabi quasi-morphisms on *Ham* (B^{2n}) (see Remark 3.11) in order to construct infinitely many linearly independent homogeneous quasi-morphisms on *Ham* (B^{2n}) that are both Lipschitz with respect to the Hofer metric and continuous in the C^0-topology [26]. This yields the following corollary answering a question of Le Roux [43]:

Corollary 4.23 ([26]). *For any* $c \in \mathbb{R}$ *the set* $\{\phi \in$ *Ham* $(B^{2n}) \mid ||\phi||_H \geq c\}$ *has a non-empty interior in the* C^0*-topology.*

See [62] for an extension of this result to a wider class of open symplectic manifolds.

(Partial) Calabi quasi-morphisms can be also applied to the study of the norms $\|\phi\|_U$ and $\|\phi\|_{U,0}$ on *Ham* (M) (see Section 3.1) and the metrics defined by them. Namely, let $U \subset M$ be a displaceable open set. Assume *Ham* (M) admits a Calabi quasi-morphism μ. A standard fact about quasi-morphisms bounded on a generating set yields that there exists a constant $C = C(\mu) > 0$ so that $\|\phi\|_{U,0} \geq C|\mu(\phi)|$ for any $\phi \in$ *Ham* (M). In particular, *Ham* (M) is unbounded with respect to the norm $\|\cdot\|_{U,0}$.

On the other hand, if $\mu :$ *Ham* $(M) \to \mathbb{R}$ is only a partial *but not genuine* Calabi quasi-morphism, it can be used to show the unboundedness of *Ham* (M) with respect to the norm $\|\cdot\|_U$ [15]. Namely, assume $X, Y = \varphi(X) \subset M$, $\varphi \in$ *Symp* $_0(M)$, are heavy[14] disjoint[15]

[14]With respect to the partial symplectic quasi-state ζ associated to μ. If X is heavy with respect to ζ, then so is $\varphi(X)$, since ζ is *Symp* $_0(M)$-invariant.

[15]This is possible only if μ is *not* a genuine Calabi quasi-morphism, since otherwise each heavy set (with respect to ζ) is also superheavy and therefore must intersect any other heavy set.

closed subsets of M and V, W are their disjoint open neighborhoods (for instance, X and Y can be two meridians on a standard symplectic torus). Let F, G be smooth functions supported, respectively, in V, W so that $F|_X \equiv 1 = \max_M F$, $G|_Y \equiv 1 = \max_M G$. One can easily show that

$$k = |\mu(\phi_F^k \phi_G^k) - \mu(\phi_F^k) - \mu(\phi_G^k)| \leq C\|\phi_F^k\|_U$$

for any $k \in \mathbb{N}$ and a constant $C > 0$ depending only on μ and U. Thus in such a case $\|\phi_F^k\|_U$ grows asymptotically linearly with k and the norm $\|\cdot\|_U$ is unbounded on $Ham\,(M)$.

Question 4.24. *Does there exist a closed symplectic manifold M for which $\|\cdot\|_U$ is bounded on $Ham\,(M)$?*

4.5. First steps of symplectic function theory – discussion. A smooth manifold M and various geometric structures on it can be described in terms of the function space $C^\infty(M)$ – for instance, subsets of M correspond to ideals in $C^\infty(M)$, tangent vectors to derivations on $C^\infty(M)$ etc. In particular, a symplectic structure on M is completely determined by the corresponding Poisson brackets on $C^\infty(M)$ which means that, in principle, any symplectic phenomenon has a counterpart in the *symplectic function theory*, that is, the function theory of the Poisson brackets. The key feature of symplectic topology is C^0-rigidity appearing in various forms for smooth objects on symplectic manifolds. Its counterpart in the symplectic function theory is the rigidity of the Poisson brackets with respect to the C^0-norm on functions – see e.g. [58] for a deduction of the foundational Eliashberg-Gromov theorem on the C^0-closedness of $Symp(M)$ from the C^0-rigidity of the Poisson brackets.

The results and methods presented in this survey show that thinking about symplectic phenomena in terms of the function theory may have a number of advantages. First, it allows to use the "Lie group - Lie algebra" connection between $\widetilde{Ham}\,(M)$ and $C^\infty(M)/\mathbb{R}$: most of the properties of symplectic quasi-states are proved using the properties of Calabi quasi-morphisms. Second, it allows to deal with singular sets (see Remark 4.6). Third, it allows to apply functional methods, like averaging, to Hamiltonian dynamics (see Remark 4.16). Fourth, it helps to find connections between symplectic topology and quantum mechanics since it is the Poisson algebra $C^\infty(M)$ that is being quantized in various quantization constructions (see e.g. Remark 4.21). Moreover, one may hope to discover new geometric and dynamical phenomena by studying the function theory of the Poisson bracket. For instance, the behavior of the profile function $\rho(t)$ as $t \to 0$ (see Section 4.3 and [14]) is obviously of interest in symplectic function theory but its geometric or dynamical implications are absolutely unclear.

Acknowledgements. Most of the material presented in this survey is based on our joint papers with Leonid Polterovich – I express my deep gratitude to Leonid for the long and enjoyable collaboration. Some of the results were obtained jointly with Paul Biran, Lev Buhovsky, Frol Zapolsky, Pierre Py and Daniel Rosen – I thank them all. The author was partially supported by the Israel Science Foundation grant # 723/10.

Representation stability

Benson Farb

Abstract. Representation stability is a phenomenon whereby the structure of certain sequences X_n of spaces can be seen to stabilize when viewed through the lens of representation theory. In this paper I describe this phenomenon and sketch a framework, the theory of FI-modules, that explains the mechanism behind it.

Mathematics Subject Classification (2010). 11T06, 14F20, 55N99.

Keywords. Configuration space, symmetric group, cohomology, representation, character.

1. Introduction

Sequences V_n of representations of the symmetric group S_n occur naturally in topology, combinatorics, algebraic geometry and elsewhere. Examples include the cohomology of configuration spaces $\mathrm{Conf}_n(M)$, moduli spaces of n-pointed Riemann surfaces and congruence subgroups $\Gamma_n(p)$; spaces of polynomials on rank varieties of $n \times n$ matrices; and n-variable diagonal co-invariant algebras.

Any S_n-representation is a direct sum of irreducible representations. These are parameterized by partitions of n. Following a 1938 paper of Murnaghan, one can pad a partition $\lambda = \sum_{i=1}^{r} \lambda_i$ of any number d to produce a partition $(n - |\lambda|) + \lambda$ of n for all $n \geq |\lambda| + \lambda_1$. The decomposition of V_n into irreducibles thus produces a sequence of multiplicities of partitions λ, recording how often λ appears in V_n.

A few years ago Thomas Church and I discovered that for many important sequences V_n arising in topology including the examples mentioned above, these multiplicities become constant once n is large enough. With Jordan Ellenberg and Rohit Nagpal, we built a theory to explain this stability, converting it to a finite generation property for a single object. We applied this to prove stability in these and many other examples. As a consequence, the character of V_n is given (for all $n \gg 1$) by a single polynomial, called a *character polynomial*, studied by Frobenius but not so widely known today. One of the main points of our work is that the mechanism for this stability comes from a common structure underlying all of these examples.

After giving an overview of this theory, we explain how it applies and connects to an array of counting problems for polynomials over finite fields, and for maximal tori in the finite groups $\mathrm{GL}_n \mathbb{F}_q$. In particular, the stability of such counts reflects, and is reflected in, the representation stability of the cohomology of an associated algebraic variety. We begin with a motivating example.

Proceedings of the International Congress of Mathematicians, Seoul, 2014

2. Configuration spaces and representation theory

Let M be any connected, oriented manifold. For any $n \geq 1$ let $\mathrm{Conf}_n(M)$ be the space of configurations of ordered n-tuples of distinct points in M:

$$\mathrm{Conf}_n(M) := \{(z_1, \ldots, z_n) \in M^n : z_i \neq z_j \text{ if } i \neq j\}.$$

The symmetric group S_n acts freely on $\mathrm{Conf}_n(M)$ by permuting the coordinates:

$$\sigma \cdot (z_1, \ldots, z_n) := (z_{\sigma(1)}, \ldots, z_{\sigma(n)}).$$

This action induces for each $i \geq 0$ an action of S_n on the complex vector space $H^i(\mathrm{Conf}_n(M); \mathbb{C})$, making $H^i(\mathrm{Conf}_n(M); \mathbb{C})$ into an S_n-representation. Here we have chosen $\mathbb{C}$ coefficients for simplicity of exposition.

2.1. Cohomology of configuration spaces. The study of configuration spaces and their cohomology is a classical topic. We concentrate on the following fundamental problem.

Problem 2.1 (Cohomology of configuration spaces). Let M be a connected, oriented manifold. Fix a ring R. Compute $H^*(\mathrm{Conf}_n(M); R)$ as an S_n-representation.

Problem 2.1 was considered in special cases by Brieskorn, F. Cohen, Stanley, Orlik, Lehrer-Solomon and many others; see, e.g. [20] and the references contained therein.

What exactly does "compute as an S_n-representation" mean? Well, by Maschke's Theorem, any S_n-representation over $\mathbb{C}$ is a direct sum of irreducible S_n-representations. In 1900, Alfred Young gave an explicit bijection between the set of (isomorphism classes of) irreducible S_n-representations and the set of partitions $n = n_1 + \cdots + n_r$ of n with $n_1 \geq \cdots \geq n_r > 0$.

Let $\lambda = (a_1, \ldots, a_r)$ be an r-tuple of integers with $a_1 \geq \cdots \geq a_r > 0$ and such that $n - \sum a_i \geq a_1$. We denote by $V(\lambda)$, or $V(\lambda)_n$ when we want to emphasize n, the representation in Young's classification corresponding to the partition $n = (n - \sum_{i=1}^r a_i) + a_1 + \cdots + a_r$. With this terminology we have, for example, that $V(0)$ is the trivial representation, $V(1)$ is the $(n-1)$-dimensional irreducible representation $\{(z_1, \ldots, z_n) \in \mathbb{C}^n : \sum z_i = 0\}$, and $V(1,1,1)$ is the irreducible representation $\bigwedge^3 V(1)$. For each $n \geq 1$ and each $i \geq 0$ we can write

$$H^i(\mathrm{Conf}_n(M); \mathbb{C}) = \bigoplus_{\lambda} d_{i,n}(\lambda) V(\lambda)_n \tag{2.1}$$

for some integers $d_{i,n}(\lambda) \geq 0$. The sum on the right-hand side of (2.1) is taken over all partitions λ of numbers $\leq n$ for which $V(\lambda)_n$ is defined. The coefficient $d_{i,n}(\lambda)$ is called the *multiplicity* of $V(\lambda)$ in $H^i(\mathrm{Conf}_n(M); \mathbb{C})$.

Problem 2.1 over $\mathbb{C}$, restated: Compute the multiplicities $d_{i,n}(\lambda)$.

Why should we care about solving this problem? Here are a few reasons:

1. Even the multiplicity $d_{i,n}(0)$ of the trivial representation $V(0)$ is interesting: it computes the i^{th} Betti number of the space $\mathrm{UConf}_n(M) := \mathrm{Conf}_n(M)/S_n$ of unordered n-tuples of distinct points in M. In other words,

$$\dim_{\mathbb{C}} H^i(\mathrm{UConf}_n(M); \mathbb{C}) = d_{i,n}(0). \tag{2.2}$$

This follows from transfer applied to the finite cover $\mathrm{Conf}_n(M) \to \mathrm{UConf}_n(M)$.

2. More generally, the $d_{i,n}(\lambda)$ for other partitions λ of n compute the Betti numbers of other (un)labelled configuration spaces. For example, for fixed $a, b, c \geq 0$, consider the space $\mathrm{Conf}_n(M)[a, b, c]$ of configurations of n distinct labelled points on M where one colors a of the points blue, b red, and c yellow, and where points of the same color are indistinguishable from each other. Then $H_i(\mathrm{Conf}_n(M)[a, b, c]; \mathbb{C})$ can be determined from $d_{i,n}(\mu)$ for certain $\mu = \mu(a, b, c)$. See [6] for a discussion, and see [32] for an explanation of how these spaces arise naturally in algebraic geometry.
3. The representation theory of S_n provides strong constraints on the possible values of $\dim_{\mathbb{C}} H^i(\mathrm{Conf}_n(M); \mathbb{C})$. As a simple example, if the action of S_n on $H^i(\mathrm{Conf}_n(M); \mathbb{C})$ is *essential* in a specific sense (cf. §2.3) for $n \gg 1$, then one can conclude for purely representation-theoretic reasons that $\lim_{n\to\infty} \dim_{\mathbb{C}} H^i(\mathrm{Conf}_n(M); \mathbb{C}) = \infty$. This happens for example for every $i \geq 1$ when $M = \mathbb{C}$. See §2.3 below.
4. For certain special smooth projective varieties M, the multiplicities $d_{i,n}(\lambda)$ encode and are encoded by delicate information about the combinatorial statistics of the $\mathbb{F}_q$-points of M or related varieties; see §5 below for two specific applications.
5. The decomposition (2.1) can have geometric meaning, and can point the way for us to guess at meaningful topological invariants. We now discuss this in a specific example.

2.2. A case study: the invariants of loops of configurations. Consider the special case where M is the complex plane $\mathbb{C}$. Elements of $H^1(\mathrm{Conf}_n(\mathbb{C}); \mathbb{C})$ are homomorphisms $\pi_1(\mathrm{Conf}_n(\mathbb{C})) \to \mathbb{C}$. Computing $H^1(\mathrm{Conf}_n(\mathbb{C}); \mathbb{C})$ is thus answering the basic question:

What are the ways of attaching a complex number to each loop of configurations of n points in the plane, in a way that is natural (= additive)?

To construct examples, pick $1 \leq i, j \leq n$ with $i \neq j$. Given any loop $\gamma(t) = (z_1(t), \ldots, z_n(t))$ in $\mathrm{Conf}_n(\mathbb{C})$, we can ignore all points except for $z_i(t)$ and $z_j(t)$ and measure how much $z_j(t)$ winds around $z_i(t)$; namely we let $\alpha_{ij} : [0, 1] \to \mathbb{C}$ be the loop $\alpha_{ij}(t) := z_j(t) - z_i(t)$ and set

$$\omega_{ij}(\gamma) := \frac{1}{2\pi i} \int_{\alpha_{ij}} \frac{dz}{z}$$

It is easy to verify that $\omega_{ij} : \pi_1(\mathrm{Conf}_n(\mathbb{C})) \to \mathbb{C}$ is indeed a homomorphism, that $\omega_{ij} = \omega_{ji}$, and that the set $\{\omega_{ij} : i < j\}$ is linearly independent in $H^1(\mathrm{Conf}_n(\mathbb{C}); \mathbb{C})$; see Figure 2.1.

Linear combinations of the ω_{ij} are in fact the only natural invariants of loops of configurations in $\mathbb{C}$.

$$\omega_{ij}(\alpha) = 1, \text{ but } \omega_{k\ell}(\alpha) = 0, \text{ for all other } k, \ell.$$

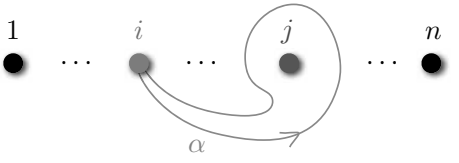

Figure 2.1. The proof that $\{\omega_{ij} : i < j\}$ is linearly independent in $H^1(\mathrm{Conf}_n(\mathbb{C}); \mathbb{C})$.

Theorem 2.2 (Artin(1925), Arnol'd(1968) [1]). *The set* $\{\omega_{ij} : 1 \leq i < j \leq n\}$ *is a basis for* $H^1(\mathrm{Conf}_n(\mathbb{C}); \mathbb{C})$ *for any* $n \geq 2$. *Thus* $H^1(\mathrm{Conf}_n(\mathbb{C}); \mathbb{C}) \approx \mathbb{C}^{\binom{n}{2}}$.

There is more to say. The S_n action on $H^1(\mathrm{Conf}_n(\mathbb{C}); \mathbb{C})$ is determined by its action on the basis via $\sigma \cdot \omega_{ij} = \omega_{\sigma(i)\sigma(j)}$, from which we can deduce that

$$H^1(\mathrm{Conf}_n(\mathbb{C}); \mathbb{C}) = V(0) \oplus V(1) \oplus V(2) \quad \text{for } n \geq 4 \tag{2.3}$$

using only elementary representation theory. We can see from this algebraic picture that the subspace of vectors fixed by all of S_n is 1-dimensional, spanned by the vector

$$\Omega := \sum_{1 \leq i < j \leq n} \omega_{ij} \in H^1(\mathrm{Conf}_n(\mathbb{C}); \mathbb{C}).$$

This implies the following geometric statement: the only natural invariant of loops of configurations of n distinct *unordered* points in $\mathbb{C}$ is total winding number Ω; in particular, $H^1(\mathrm{Conf}_n(\mathbb{C})/S_n; \mathbb{C}) \approx \mathbb{C}$.

Looking again at (2.3) we see a copy of the standard permutation representation $\mathbb{C}^n = V(0) \oplus V(1)$ given by $\sigma \cdot u_i = u_{\sigma(i)}$, with $u_i = \sum_{j \neq i} \omega_{ij}$. This indicates that the u_i should be geometrically meaningful, which indeed they are: u_i gives the total winding number of all points z_j around the point z_i.

I hope that even the simple example of $\mathrm{Conf}_n(\mathbb{C})$ convinces the reader that understanding $H^i(\mathrm{Conf}_n(M); \mathbb{C})$ as an S_n-representation and not just as a naked vector space gives us a much richer geometric picture.

2.3. Homological (in)stability. The above discussion fits in to a broader context. Let X_n be a sequence of spaces or groups. The classical theory of (co)homological stability (over a fixed ring R) in topology produces results of the form: the homology $H_i(X_n; R)$ (resp. $H^i(X_n; R)$) does not depend on n for $n \gg i$. This converts an *a priori* infinite computation to a finite one. Examples of such sequences X_n include symmetric groups S_n (Nakaoka), braid groups B_n (Arnol'd and F. Cohen), the space $\mathrm{UConf}_n(M)$ of n-point subsets of the interior of a compact, connected manifold M with nonempty boundary (McDuff, Segal), special linear groups $\mathrm{SL}_n \mathbb{Z}$ (Borel and Charney), the moduli space $\mathcal{M}_n$ of genus $n \geq 2$ Riemann surfaces (Harer), and automorphism groups of free groups (Hatcher-Vogtmann-Wahl) ; see [15] for a survey.

For many natural sequences X_n homological stability fails in a strong way. We saw above that $H^1(\mathrm{Conf}_n(\mathbb{C}); \mathbb{C}) \approx \mathbb{C}^{\binom{n}{2}}$ for all $n \geq 4$. In fact, one can prove for each $i \geq 1$ that

$$\lim_{n \to \infty} \dim_{\mathbb{C}}(H^i(\mathrm{Conf}_n(\mathbb{C}); \mathbb{C})) = \infty. \tag{2.4}$$

The underlying mechanism behind this instability is symmetry. Call a representation V of S_n *not essential* if each $\sigma \in S_n$ acts on V with every eigenvalue ± 1. Basic representation theory of S_n implies that any essential representation V of $S_n, n \geq 5$ satisfies $\dim(V) \geq n - 1$. It is not hard to check that the S_n-representation $H^i(\mathrm{Conf}_n(\mathbb{C}); \mathbb{C}))$ is essential, implying the blowup (2.4). One hardly needs to know topology to prove (2.4)! The driving force behind this is the representation theory of S_n.

More generally, whenever we have a sequence of larger and larger groups G_n, and a sequence V_n of "essential" G_n-representations, one expects that $\dim(V_n) \to \infty$. The general slogan of representation stability is: in many situations the *names* of the representations V_n

should stabilize as $n \to \infty$. The question is, how can we formalize this slogan, and how can we use such information? We focus on the case $G_n = S_n$; see §7 for a discussion of other examples, such as $G_n = \mathrm{SL}_n \mathbb{F}_p, \mathrm{GL}_n \mathbb{Z}$ and $\mathrm{Sp}_{2n} \mathbb{Z}$.

3. Representation stability (the S_n case)

With our notation, the description of $H^1(\mathrm{Conf}_n(\mathbb{C}); \mathbb{C})$ given in (2.3) does not depend on n once $n \geq 4$. In 2010 Thomas Church and I guessed that such a phenomenon might be true for cohomology in all degrees. Using an inductive description of $H^*(\mathrm{Conf}_n(\mathbb{C}); \mathbb{C})$ as a sum of induced representations (a weak form of a theorem of Lehrer-Solomon [20]), one can convert this question into a purely representation-theoretic one. After doing this, we asked David Hemmer about the case $i = 2$. He wrote a computer program that produced the following output; we use the notation C_n for $\mathrm{Conf}_n(\mathbb{C})$ to save space.

$$
\begin{aligned}
H^2(C_4; \mathbb{C}) &= V(1)^{\oplus 2} \oplus V(1,1) \oplus V(2) \\
H^2(C_5; \mathbb{C}) &= V(1)^{\oplus 2} \oplus V(1,1)^{\oplus 2} \oplus V(2)^{\oplus 2} \oplus V(2,1) \\
H^2(C_6; \mathbb{C}) &= V(1)^{\oplus 2} \oplus V(1,1)^{\oplus 2} \oplus V(2)^{\oplus 2} \oplus V(2,1)^{\oplus 2} \oplus V(3) \\
H^2(C_7; \mathbb{C}) &= V(1)^{\oplus 2} \oplus V(1,1)^{\oplus 2} \oplus V(2)^{\oplus 2} \oplus V(2,1)^{\oplus 2} \oplus V(3) \oplus V(3,1) \\
H^2(C_8; \mathbb{C}) &= V(1)^{\oplus 2} \oplus V(1,1)^{\oplus 2} \oplus V(2)^{\oplus 2} \oplus V(2,1)^{\oplus 2} \oplus V(3) \oplus V(3,1) \\
H^2(C_9; \mathbb{C}) &= V(1)^{\oplus 2} \oplus V(1,1)^{\oplus 2} \oplus V(2)^{\oplus 2} \oplus V(2,1)^{\oplus 2} \oplus V(3) \oplus V(3,1) \\
H^2(C_{10}; \mathbb{C}) &= V(1)^{\oplus 2} \oplus V(1,1)^{\oplus 2} \oplus V(2)^{\oplus 2} \oplus V(2,1)^{\oplus 2} \oplus V(3) \oplus V(3,1)
\end{aligned}
\tag{3.1}
$$

This was compelling. Indeed, it turns out that this decomposition holds for $H^2(C_n; \mathbb{C})$ for all $n \geq 7$, so the decomposition of $H^2(\mathrm{Conf}_n(\mathbb{C}); \mathbb{C})$ into irreducible S_n-representations *stabilizes*. The most useful way we found to encode this type of behavior was via the notion of a representation stable sequence, which we now explain.

3.1. Representation stability and $H^i(\mathrm{Conf}_n(M); \mathbb{C})$. Let V_n be a sequence of S_n–representations equipped with linear maps $\phi_n \colon V_n \to V_{n+1}$ so that following diagram commutes for each $g \in S_n$:

$$
\begin{array}{ccc}
V_n & \xrightarrow{\phi_n} & V_{n+1} \\
{\scriptstyle g}\downarrow & & \downarrow{\scriptstyle g} \\
V_n & \xrightarrow[\phi_n]{} & V_{n+1}
\end{array}
$$

Here g acts on V_{n+1} by its image under the standard inclusion $S_n \hookrightarrow S_{n+1}$. We call such a sequence of representations *consistent*. We made the following definition in [11].

Definition 3.1 (Representation stability for S_n-representations). A consistent sequence $\{V_n\}$ of S_n–representations is *representation stable* if there exists $N > 0$ so that for all $n \geq N$, each of the following conditions holds:

1. **Injectivity:** The maps $\phi_n \colon V_n \to V_{n+1}$ are injective.
2. **Surjectivity:** The span of the S_{n+1}–orbit of $\phi_n(V_n)$ is all of V_{n+1}.
3. **Multiplicities:** Decompose V_n into irreducible S_n–representations as

$$V_n = \bigoplus_{\lambda} c_n(\lambda) V(\lambda)_n$$

with multiplicities $0 \leq c_n(\lambda) \leq \infty$. Then $c_n(\lambda)$ does not depend on n.

The number N is called the *stable range*. The sequence $V_n := \wedge^* \mathbb{C}^n$ of exterior algebras is an example of a consistent sequence of S^n-representations that is not representation stable.

It is not hard to check that, given Condition 1 for ϕ_n, Condition 2 for ϕ_n is equivalent to the following : ϕ_n is a composition of the inclusion $V_n \hookrightarrow \mathrm{Ind}_{S_n}^{S_{n+1}} V_n$ with a surjective S_{n+1}–module homomorphism $\mathrm{Ind}_{S_n}^{S_{n+1}} V_n \to V_{n+1}$. This point of view leads to the stronger condition of *central stability*, a very useful concept invented by Putman [26] at around the same time, which he applied in his study of the cohomology of congruence subgroups.

There are variations on Definition 3.1. For example one can allow the stable range N to depend on the partition λ. In [11] we define representation stability for other sequences G_n of groups, with a definition analogous to Definition 3.1 with $G_n = S_n$ replaced by

$$G_n = \mathrm{GL}_n \mathbb{Z}, \mathrm{Sp}_{2g} \mathbb{Z}, \mathrm{GL}_n \mathbb{F}_q, \mathrm{Sp}_{2g} \mathbb{F}_q,$$

and hyperoctahedral groups W_n; see §7 below. In each case one needs a coherent naming system for representations of G_n as n varies.

Remark 3.2. We originally stumbled onto representation stability in [12] while making some computations in the homology of the Torelli group $\mathcal{I}_g$. In this situation the homology $H_i(\mathcal{I}_g; \mathbb{C})$ is a representation of the integral symplectic group $\mathrm{Sp}_{2g} \mathbb{Z}$. We found some $\mathrm{Sp}_{2g} \mathbb{Z}$-submodules of $H_i(\mathcal{I}_g; \mathbb{C})$ whose names did not depend on g for $g \gg 1$. Representation stability (for sequences of $\mathrm{Sp}_{2g} \mathbb{Z}$-representations) arose from our attempt to formalize this. See [12]. After [11, 12] appeared, Richard Hain kindly shared with us some of his unpublished notes from the early 1990s, where he also developed a conjectural picture of the homology $H_i(\mathcal{I}_g; \mathbb{C})$ as an $\mathrm{Sp}_{2g} \mathbb{Z}$-representation that is similar to the idea of representation stability for $\mathrm{Sp}_{2g} \mathbb{Z}$-representations presented in [11].

Using in a crucial way a result of Hemmer [16], we proved in [11] the following.

Theorem 3.3 (Representation stability for $\mathbf{Conf}_n(\mathbb{C})$). *For any fixed $i \geq 0$, the sequence $\{H^i(\mathrm{Conf}_n(\mathbb{C}); \mathbb{C})\}$ is representation stable with stable range $n \geq 4i$.*

The stable range $n \geq 4i$ given in Theorem 3.3 predicts that $H^2(\mathrm{Conf}_n(\mathbb{C}); \mathbb{C})$ will stabilize once $n = 8$; in truth it stabilizes starting at $n = 7$.

The problem of computing all of the stable multiplicities $d_{i,n}(\lambda)$ in the decomposition of $H^i(\mathrm{Conf}_n(\mathbb{C}); \mathbb{C})$ is thus converted to a problem which is finite and in principle solvable by a computer. However, putting this into practice is a delicate matter, and the actual answers can be quite complicated. For example, for $n \geq 16$:

$$
\begin{aligned}
&H^4(\mathrm{Conf}_n(\mathbb{C});\mathbb{C}) = \\
&\quad V(1)^{\oplus 2} \oplus V(2)^{\oplus 6} \oplus V(1,1)^{\oplus 6} \oplus V(3)^{\oplus 8} \oplus V(1,1,1)^{\oplus 9} \oplus V(2,1)^{\oplus 16} \\
&\oplus V(4)^{\oplus 6} \oplus V(1,1,1,1)^{\oplus 5} \oplus V(5)^{\oplus 2} \oplus V(2,2)^{\oplus 12} \oplus V(3,1)^{\oplus 19} \\
&\oplus V(2,1,1)^{\oplus 17} \oplus V(4,1)^{\oplus 12} \oplus V(2,1,1,1)^{\oplus 7} \oplus V(3,2)^{\oplus 14} \oplus V(2,2,1)^{\oplus 10} \\
&\oplus V(5,1)^{\oplus 3} \oplus V(3,3)^{\oplus 4} \oplus V(3,1,1)^{\oplus 16} \oplus V(2,2,2)^{\oplus 2} \oplus V(4,2)^{\oplus 7} \\
&\oplus V(4,1,1)^{\oplus 8} \oplus V(5,2) \oplus V(2,2,1,1)^{\oplus 2} \oplus V(3,1,1,1)^{\oplus 5} \oplus V(5,1,1)^{\oplus 2} \\
&\oplus V(4,3)^{\oplus 2} \oplus V(3,2,1)^{\oplus 9} \oplus V(4,1,1,1)^{\oplus 2} \oplus V(3,3,1)^{\oplus 2} \oplus V(3,2,2) \\
&\oplus V(4,2,1)^{\oplus 3} \oplus V(3,2,1,1) \oplus V(5,1,1,1) \oplus V(4,3,1)
\end{aligned}
$$

Theorem 3.3 was greatly extended by Church in [6] from $M = \mathbb{C}$ to M any connected, oriented manifold, as follows.

Theorem 3.4 (Representation stability for configuration spaces). *Let M be any connected, oriented manifold with $\dim(M) \geq 2$ and with $\dim_{\mathbb{C}} H^*(M;\mathbb{C}) < \infty$. Fix $i \geq 0$. Then the sequence $\{H^i(\mathrm{Conf}_n(M);\mathbb{C})\}$ is representation stable with stable range $n \geq 2i$ if $\dim(M) \geq 3$ and $n \geq 4i$ if $\dim(M) = 2$.*

This of course leaves open the following.

Problem 3.5 (Computing stable multiplicities). Given a connected, oriented manifold M, compute explicitly the stable multiplicities $d_{i,n}(\lambda)$ for the decomposition of $H^i(\mathrm{Conf}_n(M);\mathbb{C})$ into irreducibles. Give geometric interpretations of these numbers, as in the case of $H^1(\mathrm{Conf}_n(\mathbb{C});\mathbb{C})$ discussed in §2 above.

The problem of computing the $d_{i,n}(\lambda)$ seems to have been solved in very few cases. For example, I do not know the answer even for M a closed surface of genus $g \geq 1$.

The paper [11] gives many other examples of representation stable sequences V_n that arise naturally in mathematics, from the cohomology of Schubert varieties to composition of Schur functors to many of the examples given in §4.3 below.

3.2. An application to classical homological stability. Consider the space $\mathrm{UConf}_n(M) := \mathrm{Conf}_n(M)/S_n$ of unordered n-tuples of distinct points in M. As mentioned above, when M is the interior of a compact manifold with nonempty boundary, classical homological stability for $H_i(\mathrm{UConf}_n(M);\mathbb{Z})$ was proved by McDuff and Segal, generalizing earlier work of Arnol'd and F. Cohen. The reason that the assumption $\partial M \neq \emptyset$ is needed is that in this case one has a map $\psi_n : \mathrm{Conf}_n(M) \to \mathrm{Conf}_{n+1}(M)$ for each $n \geq 0$ given by "injecting a point at infinity" (see Proposition 4.6 of [8] for details). While ψ_n is really just defined up to homotopy, it induces for each $i \geq 0$ a well-defined homomorphism

$$(\psi_n)_* : H_i(\mathrm{UConf}_n(M);\mathbb{Z}) \to H_i(\mathrm{UConf}_{n+1}(M);\mathbb{Z}) \tag{3.2}$$

which McDuff and Segal prove is an isomorphism for $n \geq 2i+2$. This is the typical way one proves classical homological stability for a sequence of spaces X_n, namely one finds maps $X_n \to X_{n+1}$ and proves that they eventually induce isomorphisms on homology.

What about the case when M is closed? In this case there are no natural maps between $\mathrm{UConf}_n(M)$ and $\mathrm{UConf}_{n+1}(M)$. A natural thing to do would be to consider the S_n-cover $\mathrm{Conf}_n(M) \to \mathrm{UConf}_n(M)$, where there are maps (in fact $n+1$ of them) ϕ_n :

$\mathrm{Conf}_{n+1}(M) \to \mathrm{Conf}_n(M)$ given by "forget the point labeled i", where $1 \leq i \leq n+1$. The problem is, as we've seen above, the maps ϕ_n typically do not induce isomorphisms on homology. What to do?

Representation stability allowed Church to analyze this situation. It provided him with a language so that he could prove (Theorem 3.4) that the maps ϕ_n stabilize. The power of this point of view can be seen by applying Church's theorem (Theorem 3.4) to the trivial representation $V(0)$, which gives (for $\dim(M) \geq 3$) that $d_{i,n}(0)$ is constant for $n \geq 2i$. Transfer implies (see (2.2) above) that $\dim_{\mathbb{C}} H_i(\mathrm{UConf}_n(M); \mathbb{C})$ is constant for $n \geq 2i$, giving classical stability without maps between the spaces! Church actually obtains the better stable range of $n > i$ by a more careful analysis.

One might notice that Church only obtains homological stability over $\mathbb{Q}$, while McDuff and Segal's theorem works over $\mathbb{Z}$. One crucial place where $\mathbb{Q}$ is needed is the use of transfer. However, this is not just an artifact of Church's proof, it is a feature of the situation: classical homological stability for $\mathrm{UConf}_n(M)$ with M closed is *false* for general closed manifolds M! For example, $H_1(\mathrm{UConf}_n(S^2); \mathbb{Z}) = \mathbb{Z}/(2n-2)\mathbb{Z}$. After Church's paper appeared, other proofs of homological stability over for $H_i(\mathrm{UConf}_n(M); \mathbb{Q})$ were given by Randal-Williams [27] and then by Bendersky-Miller [2].

By plugging other representations into Theorem 3.4, Church deduces classical homological stability for a number of other colored configuration spaces. The above discussion illustrates how representation stability can be used as a useful method to discover and prove classical homological stability theorems.

3.3. Murnaghan's theorem. The stabilization of names of natural sequences of representations is not new. The notation $V(\lambda)$ that we gave in §2 above goes back at least to the 1938 paper [24] of Murnaghan, where he discovered the following theorem, first proved by Littlewood [21] in 1957.

Theorem 3.6 (Murnaghan's theorem). *For any two partitions λ, μ there is a finite set P of partitions so that for all sufficiently large n:*

$$V(\lambda)_n \otimes V(\mu)_n = \bigoplus_{\nu \in P} d_{\lambda\mu}(\nu) V(\nu)_n \tag{3.3}$$

for some non-negative integers $d_{\lambda\mu}(\nu)$.

The integers $d_{\lambda\mu}(\nu)$ are called *Kronecker coefficients*. In his original paper [24] Murnaghan computes the $d_{\lambda\mu}(\nu)$ explicitly for 58 of the simplest pairs μ, ν. The study of Kronecker coefficients remains an active direction for research. It is central to combinatorial representation theory and geometric complexity theory, among other areas. See, for example, [3] and the references contained therein.

One can deduce from Murnaghan's Theorem that the sequence $V(\lambda)_n \otimes V(\mu)_n$ is multiplicity stable in the sense of Definition 3.1; see [11]. In the following section we will describe a theory where Murnaghan's Theorem pops out as a structural feature of the theory.

4. FI-modules

Representation stability for symmetric groups S_n grew in power and applicability in [8], where Thomas Church, Jordan Ellenberg and I developed a theory of FI-modules.

When looking at the sequence $H^i(\mathrm{Conf}_n(M);\mathbb{C})$, we broke symmetry by only considering the map $\mathrm{Conf}_{n+1}(M) \to \mathrm{Conf}_n(M)$ given by "forget the $(n+1)^{\mathrm{st}}$ point". Of course there are really $n+1$ equally natural maps, given by "forget the j^{th} point" for $1 \leq j \leq n+1$. Taking cohomology switches the direction of arrows, and we have $n+1$ homomorphisms $H^i(\mathrm{Conf}_n(M);\mathbb{C}) \to H^i(\mathrm{Conf}_{n+1}(M);\mathbb{C})$, each one corresponding to an injective map $\{1,\dots,n\} \to \{1,\dots,n+1\}$; namely, the injective map whose image misses j. It is useful to consider all of these maps at once. This is the starting point for the study of FI-modules.

4.1. FI-module basics. An *FI-module* V is a functor from the category FI of finite sets and injections to the category of modules over a fixed Noetherian ring k. Thus to each set $\mathbf{n} := \{1,\dots,n\}$ with n elements the functor V associates a k-module $V_n := V(\mathbf{n})$, and to each injection $\mathbf{m} \to \mathbf{n}$ the functor V associates a linear map $V_m \to V_n$. The set of self-injections $\mathbf{n} \to \mathbf{n}$ is the symmetric group S_n. Thus an FI-module gives a sequence of S_n-representations V_n and linear maps between them, one for each injection of finite sets:

$$\begin{array}{ccccccccc}
\{1\} & \longrightarrow & \{1,2\} & \longrightarrow & \{1,2,3\} & \longrightarrow & \cdots \longrightarrow & \{1,\dots,n\} & \longrightarrow & \cdots \\
\circlearrowleft & & \circlearrowleft & & \circlearrowleft & & & \circlearrowleft & & \\
S_1 & & S_2 & & S_3 & & & S_n & &
\end{array}$$

$$V \downarrow$$

$$\begin{array}{ccccccccc}
V_1 & \longrightarrow & V_2 & \longrightarrow & V_3 & \longrightarrow & \cdots \longrightarrow & V_n & \longrightarrow & \cdots \\
\circlearrowleft & & \circlearrowleft & & \circlearrowleft & & & \circlearrowleft & & \\
S_1 & & S_2 & & S_3 & & & S_n & &
\end{array}$$

Of course each single horizontal arrow really represents many arrows, one for each injection between the corresponding finite sets. Using functors from the category FI to study sequences of objects is not new: FI-spaces were known long ago (under different names) to homotopy theorists.

A crucial observation is that one should think of an FI-module as a module in the classical sense. Many of the familiar notions from the theory of modules, such as submodule and quotient module, carry over to FI-modules in the obvious way: one performs the operations pointwise. So, for example, W is an FI-submodule of V if $W_n \subset V_n$ for each $n \geq 1$. One theme of [8] is that there is conceptual power in the encoding of this large amount of (potentially complicated) data into a single object V.

The property of being an FI-module itself does not guarantee much structure. One of the main insights in [8] was to find a finite generation condition that has strong implications but that one can also prove to hold in many examples.

Definition 4.1 (Finite generation). An FI-module V is *finitely generated* if there is a finite set S of elements in $\coprod_i V_i$ so that no proper sub-FI-module of V contains S.

Example 4.2. Let $k[x_1,\dots,x_n]_{(3)}$ denote the vector space of homogeneous polynomials of degree 3 in n variables over a field k. It is not hard to check that $\{1,\dots,n\} \mapsto k[x_1,\dots,x_n]_{(3)}$ is an FI-module. We claim that this FI-module is finitely generated by the elements $x_1^3, x_1^2x_2$ and $x_1x_2x_3$:

$$\begin{array}{llll} k[x_1]_{(3)} \longrightarrow & k[x_1,x_2]_{(3)} \longrightarrow & k[x_1,x_2,x_3]_{(3)} \longrightarrow & k[x_1,x_2,x_3,x_4]_{(3)} \longrightarrow \cdots \\ \boxed{x_1^3} & x_1^3, x_2^3 & x_1^3, x_2^3, x_3^3 & x_1^3, x_2^3, x_3^3, x_4^3 \\ & \boxed{x_1^2x_2}, x_2^2x_1 & x_1^2x_2, x_1^2x_3, x_2^2x_1 & \vdots \\ & & x_2^2x_3, x_3^2x_1, x_3^2x_2 & \\ & & \boxed{x_1x_2x_3} & \end{array}$$

Here we have written below each $k[x_1,\dots,x_n]_{(3)}$ its basis as a vector space. Finite generation of the FI-module $k[x_1,\dots,x_n]_{(3)}$ is simply the fact that every vector in every $k[x_1,\dots,x_n]_{(3)}$ lies in the k-span of the set of vectors that can be obtained from the three boxed vectors by performing all possible morphisms, i.e. by changing the labels of the x_i. In other words, there are, up to labeling and taking linear combinations, only three homogeneous degree three polynomials in any number $n \geq 3$ of variables: $x_1^3, x_1^2x_2$ and $x_1x_2x_3$. Note that we need $n \geq 3$ to obtain all of the generators. Similarly, $k[x_1,\dots,x_n]_{(87)}$ is finitely generated, but the full generating set appears only for $n \geq 87$.

The connection of FI-modules with representation stability is the following, proved in [8].

Theorem 4.3 (Finite generation vs. representation stable). *Let V be an FI-module over a field k of characteristic 0. Then V is finitely generated if and only if $\{V_n\}$ is a representation stable sequence of S_n-representations with $\dim_k V_n < \infty$ for all n.*

Theorem 4.3 thus converts a somewhat complicated property about a sequence V_n of representations into a single property – finite generation – of a single object V. One example of the power of this viewpoint is the following.

Proof of Murnaghan's Theorem (Theorem 3.6). Since $V(\lambda)$ and $V(\mu)$ are finitely generated FI-modules [8, §2.8], so is $V(\lambda) \otimes V(\mu)$. Theorem 4.3 implies that $V(\lambda)_n \otimes V(\mu)_n$ is representation stable, and so the theorem follows. □

Thus a combinatorial theorem about an infinite list of numbers falls out of a basic structural property of FI-modules.

4.2. Character polynomials. One of the main discoveries of [8] is that character polynomials, studied by Frobenius but not so widely known today, are ubiquitous, and are an incredibly concise way to encode stability phenomena for sequences of S_n-representations.

Fix the ground field $\mathbb{C}$. Recall that the *character* of a representation $\rho : G \to \mathrm{GL}(V)$ of a finite group G over $\mathbb{C}$ is defined to be the function $\chi_V : G \to \mathbb{C}$ given by

$$\chi_V(g) := \mathrm{Trace}(\rho(g)).$$

We view χ_V as an element of the vector space $\mathcal{C}(G)$ of *class functions* on G; that is, those functions that are constant on each conjugacy class in G. A fundamental theorem in the representation theory of finite groups is that any G-representation is determined by its character:

$$\chi_V = \chi_W \text{ in } \mathcal{C}(G) \text{ if and only if } V \approx W \text{ as } G\text{-representations.}$$

For each $i \geq 1$ let $X_i \colon \coprod_n S_n \to \mathbb{N}$ be the class function defined by

$$X_i(\sigma) = \text{number of } i\text{-cycles in the cycle decomposition of } \sigma.$$

A *character polynomial* is any polynomial $P \in \mathbb{Q}[X_1, X_2, \ldots]$. Such a polynomial gives a class function on all the S_n at once. The study of character polynomials goes back to work of Frobenius, Murnaghan, Specht, and Macdonald; see, e.g. [23, Example I.7.14]).

It is easy to see for any fixed $n \geq 1$ that $\mathcal{C}(S_n)$ is spanned by character polynomials, so the character of any representation can be described by such a polynomial. For example, if $\mathbb{C}^n$ is the standard permutation representation of S_n then the character $\chi_{\mathbb{C}^n}(\sigma)$ is the number of fixed points of σ, so $\chi_{\mathbb{C}^n} = X_1$ for any $n \geq 1$. As another example, consider the S_n-representation $\bigwedge^2 \mathbb{C}^n$. Since $\sigma \cdot (e_i \wedge e_j) = \pm e_i \wedge e_j$ according to whether σ contains $(i)(j)$ or (ij), respectively, it follows that

$$\chi_{\bigwedge^2 \mathbb{C}^n} = \binom{X_1}{2} - X_2 = \frac{1}{2}X_1^2 - \frac{1}{2}X_1 - X_2$$

for any $n \geq 1$. These descriptions of characters are uniform in n. On the other hand, if one fixes r then for $n \gg r$ it is incredibly rare for an S_n-representation to be given by a character polynomial $P(X_1, \ldots, X_r)$ depending only on cycles of length at most r. A simple example is the sign representation: for $n \gg r$ one cannot determine the sign of an arbitrary $\sigma \in S_n$ just by looking at cycles in σ of length at most r.

One of the main discoveries in [8] is that finitely-generated FI-modules in characteristic 0 admit such a uniform description.

Theorem 4.4 (Polynomiality of characters). *Let V be a finitely-generated FI-module over a field k of characteristic 0. Then the sequence of characters χ_{V_n} of the S_n-representations V_n is* eventually polynomial*: there exists $N \geq 0$ and a polynomial $P(X_1, \ldots, X_r)$ for some $r > 0$ so that*

$$\chi_{V_n} = P(X_1, \ldots, X_r) \quad \textit{for all } n \geq N$$

In particular $\dim_k(V_n)$ is a polynomial in n for $n \geq N$.

The claim on $\dim_k(V_n)$ is obtained by noting that

$$\dim_k(V_n) = \chi_{V_n}(\mathrm{Id}) = P(n, 0, \ldots, 0).$$

The fact that $\dim_k(V_n)$ is eventually a polynomial was extended to the case $\mathrm{char}(k) > 0$ in [10]. In situations of interest one can often give explicit bounds on r and N. This converts the problem of finding all the characters χ_{V_n} into a concrete finite computation. In some cases one can even get $N = 0$.

We again emphasize that the impact of Theorem 4.4 comes not just from the fact that a single polynomial gives all characters of all V_n with $n \gg 1$ at the same time, but it gives an extremely strong constraint on each individual V_n for $n \gg r$, since $\chi_{V_n} = P(X_1, \ldots, X_r)$ depends only on cycles of length at most r.

4.3. Examples/Applications. Part of the usefulness of finitely generated FI-modules is that they are common. This is illustrated in Table 4.1. We define only a few of these examples here; see [8] for a detailed discussion.

Theorem 4.5 (Finite generation). *Each of the FI-modules (1)-(9) given in Table 4.1 is finitely generated.*

FI-module $V = \{V_n\}$	Description
1. $H^i(\mathrm{Conf}_n(M);\mathbb{Q})$	$\mathrm{Conf}_n(M) =$ configuration space of n distinct ordered points on a connected, oriented manifold M, $\dim(M) > 1$
2. $R_J^{(r)}(n)$	$J = (j_1, \dots j_r)$, $R^{(r)}(n) = \bigoplus_J R_J^{(r)}(n)$= r-diagonal coinvariant algebra on r sets of n variables
3. $H^i(\mathcal{M}_{g,n};\mathbb{Q})$	$\mathcal{M}_{g,n} =$ moduli space of n-pointed genus $g \geq 2$ curves
4. $\mathcal{R}^i(\mathcal{M}_{g,n})$	i^{th} graded piece of the tautological ring of $\mathcal{M}_{g,n}$
5. $\mathcal{O}(X_{P,r}(n))_i$	space of degree i polynomials on the rank variety $X_{P,r}(n)$ of $n \times n$ matrices of P-rank $\leq r$
6. $G(A_n/\mathbb{Q})_i$	degree i part of the Bhargava–Satriano Galois closure of $A_n = \mathbb{Q}[x_1, \dots, x_n]/(x_1, \dots, x_n)^2$
7. $\langle H^1(\mathcal{I}_n;\mathbb{Q})\rangle_{(i)}$	degree i part of the subalgebra of $H^*(\mathcal{I}_n;\mathbb{Q})$ generated by $H^1(\mathcal{I}_n;\mathbb{Q})$, where $\mathcal{I}_n =$ genus n Torelli group
8. $H^i(\mathrm{BDiff}_n(M);\mathbb{Q})$	$\mathrm{BDiff}_n(M) =$ Classifying space of diffeos leaving a given set of n points invariant, for many manifolds M (see [18])
9. $\mathrm{gr}(\Gamma_n)_i$	ith graded piece of associated graded Lie algebra of many groups Γ_n, including $\mathcal{I}_n$, IA_n and the pure braid group P_n

Table 4.1. Some examples of finitely generated FI-modules. Any parameter not equal to n should be considered fixed and nonnegative.

Items 3 and 8 of Theorem 4.5 are due to Jimenez Rolland [17, 18]; the other items are due to Church-Ellenberg-Farb [8].

That each of (1)-(9) in Table 4.1 is an FI-module is not difficult to prove. More substantial is proving finite generation. To do this one of course needs detailed information about the specific example. In some of the cases this involves significant (but known) results; see below.

Except for a few special (e.g. $M = \mathbb{R}^d$) and low-complexity (i.e. small i, d, g, J, etc.) cases, explicit formulas for the characters (or even the dimensions) of the vector spaces (1)-(9) of Table 4.1 do not seem to be known, or even conjectured. Exact computations may be quite difficult. Applying Theorem 4.4 and Theorem 4.5 to these examples gives us an answer, albeit a non-explicit one, in all cases.

Theorem 4.6 (Ubiquity of character polynomials). *For each of the sequences V_n in Table 4.1 there are numbers $N \geq 0, r \geq 1$ and a polynomial $P(X_1, \dots, X_r)$ so that*

$$\chi_{V_n} = P(X_1, \dots, X_r) \quad \textit{for all } n \geq N$$

In particular $\dim(V_n)$ is a polynomial in n for $n \geq N$.

We emphasize that we are claiming eventual *equality* to a polynomial, not just polynomial growth. As a contrasting example, if $\overline{\mathcal{M}}_{g,n}$ is the Deligne-Mumford compactification of the moduli space of n-pointed genus g curves, the dimension of $H^2(\overline{\mathcal{M}}_{g,n};\mathbb{Q})$ grows exponentially with n; in particular the character of $H^2(\overline{\mathcal{M}}_{g,n};\mathbb{Q})$ is not given by a character polynomial. Although $V_n := H^2(\overline{\mathcal{M}}_{g,n};\mathbb{Q})$ is an FI-module, this FI-module is not finitely generated.

As an explicit example of Theorem 4.6, the character of the S_n-representation $H^2(\mathrm{Conf}_n(\mathbb{C});\mathbb{Q})$ is given for all $n \geq 0$ by the character polynomial

$$\chi_{H^2(\mathrm{Conf}_n(\mathbb{R}^2);\mathbb{C})} = 2\binom{X_1}{3} + 3\binom{X_1}{4} + \binom{X_1}{2}X_2 - \binom{X_2}{2} - X_3 - X_4. \quad (4.1)$$

Note that for general finitely-generated FI-modules we only know such information for $n \gg 1$. Recall from (3.1) of §3 how decomposition into irreducibles of $H^2(\mathrm{Conf}_n(\mathbb{R}^2);\mathbb{C})$ was shown to change with n, only to stabilize once $n \geq 7$. I encourage the reader to try to see this via (4.1), which holds for all $n \geq 0$.

Although we can sometimes give explicit upper bounds on their degree, the polynomials produced by Theorem 4.6 are known explicitly in only a few special cases. Thus the following is one of the main open problems in this direction.

Problem 4.7. Compute the polynomials $P(X_1,\ldots,X_r)$ produced by Theorem 4.6.

One difficulty in solving this problem is that, in many examples, the proof of finite generation of the corresponding FI-module uses a Noetherian property (see below), and the proof of this property is not effective.

4.4. The Noetherian property. The following theorem, joint work with Thomas Church, Jordan Ellenberg, and Rohit Nagpal, is central to the theory of FI-modules; it is perhaps the most useful general tool for proving that a given FI-module is finitely generated.

Theorem 4.8 (Noetherian property). *Let V be a finitely-generated FI-module over a Noetherian ring k. Then any sub-FI-module of V is finitely generated.*

Theorem 4.8 was proved in this generality by Church-Ellenberg-Farb-Nagpal [10]. For fields k of characteristic 0 it was proved earlier by Church-Ellenberg-Farb [8, Theorem 2.60] and by Snowden [29, Theorem 2.3], who actually proved a version (in a different language) for modules for many twisted commutative algebras, of which FI-modules are an example. The Noetherian property for FI-modules over fields k of positive characteristic is crucial for the study of the cohomology of congruence subgroups from this point of view; see §6 below. Lück proved a version of Theorem 4.8 for finite categories in [22], but since FI is infinite these do not occur in our context.

One can see how Theorem 4.8 is used in practice via the following.

Theorem 4.9. *Suppose $E_*^{p,q}$ is a first-quadrant spectral sequence of FI-modules over a Noetherian ring k, and that $E_*^{p,q}$ converges to an FI-module $H^{p+q}(X;k)$. If the FI-module $E_2^{p,q}$ is finitely generated for each $p,q \geq 0$, then the FI-module $H^i(X;k)$ is finitely generated for each fixed $i \geq 0$.*

See [6] and [8] for earlier versions of Theorem 4.9, and the paper [18], where Jimenez Rolland gives explicit bounds on the stability degree, etc.

Spectral sequences as in Theorem 4.9 arise in many computations. For example, following Cohen-Taylor [14] and Totaro [31], one computes $H^i(\mathrm{Conf}_n(M);k)$ by using the Leray spectral sequence for the natural inclusion $\mathrm{Conf}_n(M) \to M^n$. As n varies we obtain a sequence of spectral sequences, one for each n. In fact this gives a spectral sequence of FI-modules. Another example is the computation of the homology of congruence subgroups (see §6 below).

The proof of Theorem 4.9 is that, while we have no idea what the differentials might be, or at which page the spectral sequence stabilizes (and this may depend on n), the terms $E_\infty^{p,q}$ are obtained from the $E_2^{p,q}$ terms by repeatedly taking submodules and quotient modules. Since the property of finite generation for an FI-module is preserved by taking submodules (by the Noetherian property Theorem 4.8) and quotients, then if $E_2^{p,q}$ is finitely generated so is $E_j^{p,q}$ for every $j \geq 2$.

4.5. Some remarks on the general theory. There are many other aspects of the general theory of FI-modules that I am not describing due to lack of space. This includes a more quantitative version of the theory, with notions such as stability degree and weight of an FI-module, allowing for explicit estimates on stable ranges and degrees of character polynomials. Co-FI-modules are useful when one has maps going the wrong way. Also useful are FI-spaces, FI-varieties, and FI-hyperplane arrangements (see [9] for the latter); these give FI-modules by applying the (co)homology functor. Church-Putman [13] have developed the theory of FI-groups in order to prove a kind of relative finite generation theorem in group theory; they apply this in [13] to certain subgroups of Torelli groups. Sam and Snowden have given in [28] a more detailed analysis of the algebraic structure of the category of FI-modules in characteristic 0.

5. Combinatorial statistics for varieties over finite fields

In [9] we exposed a close connection between representation stability in cohomology and the stability of various combinatorial statistics for polynomials over finite fields and for maximal tori in $\mathrm{GL}_n(\mathbb{F}_q)$. We now give a brief sketch of how this works.

5.1. The space of polynomials over $\mathbb{F}_q$. Consider the following basic questions: how many square-free (i.e. having no repeated roots), degree n monic polynomials in $\mathbb{F}_q[T]$ are there? How many linear factors does one expect such a polynomial to have? factors of degree d? What is the variance of this expectation?

If one fixes q and allows n to increase, something interesting happens. A good example of what I'd like to describe is the expected *quadratic excess* of a polynomial in $\mathbb{F}_q[T]$; that is, the expected difference of the number of reducible quadratic factors and the number of irreducible quadratic factors. This number can be computed by adding up the quadratic excess of each degree n, monic square-free polynomial in $\mathbb{F}_q[T]$ and then dividing by the total number $q^n - q^{n-1}$ of such polynomials. Here are some values for small n:

	total:	expectation:
$n=3:$	q^2-q	$\frac{1}{q}$
$n=4:$	q^3-3q^2+2q	$\frac{1}{q}-\frac{2}{q^2}$
$n=5:$	$q^4-4q^3+5q^2-2q$	$\frac{1}{q}-\frac{3}{q^2}+\frac{2}{q^3}$
$n=6:$	$q^5-4q^4+7q^3-7q^2+3q$	$\frac{1}{q}-\frac{3}{q^2}+\frac{4}{q^3}-\frac{3}{q^4}$
$n=7:$	$q^6-4q^5+7q^4-8q^3+8q^2-4q$	$\frac{1}{q}-\frac{3}{q^2}+\frac{4}{q^3}-\frac{4}{q^4}+\frac{4}{q^5}$
$n=8:$	$q^7-4q^6+7q^5-8q^4+9q^3-10q^2+4q$	$\frac{1}{q}-\frac{3}{q^2}+\frac{4}{q^3}-\frac{4}{q^4}+\frac{5}{q^5}-\frac{5}{q^6}$

Notice that in each column in the counts above, the coefficient changes as n increases, until n is sufficiently large, and then this coefficient stabilizes. For example the third column gives coefficients $0, 2, 5, 7, 7, 7, \ldots$ Theorem 5.2 below implies that these formulas must converge term-by-term to a limit. A somewhat involved computation (see below) allowed us in [9] to compute this limit as:

$$q^{n-1}-4q^{n-2}+7q^{n-3}-8q^{n-4}+\cdots \qquad \text{and} \qquad \frac{1}{q}-\frac{3}{q^2}+\frac{4}{q^3}-\frac{4}{q^4}+\cdots \quad (5.1)$$

This numerical stabilization is a reflection of something deeper. To explain, consider the space Z_n of all monic, square-free, degree n polynomials with coefficients in the finite field $\mathbb{F}_q$. Recall that the *discriminant* $\Delta_n \in \mathbb{Z}[x_1, \ldots, x_{n-1}]$ is a polynomial with the property that an arbitrary monic polynomial $f(z) = z^n + a_{n-1}z^{n-1} + \cdots + a_1 z_1 + a_0 \in \mathbb{C}[z]$ is square-free if and only if $\Delta_n(a_0, \ldots a_{n-1}) \neq 0$. Thus Z_n is a complex algebraic variety. For example

$$Z_2 = \{z^2 + bz + c \in \mathbb{C}[z] : b^2 - 4c \neq 0\}$$

and

$$Z_3 = \{z^3 + bz^2 + cz + d \in \mathbb{C}[z] : b^2c^2 - 4c^3 - 4b^3d - 27d^2 + 18bcd \neq 0\}.$$

The complex variety Z_n is also an algebraic variety over the finite field $\mathbb{F}_q$ for any prime power q. The set of $\mathbb{F}_q$-points $Z_n(\mathbb{F}_q)$ is exactly the set of monic, square-free, degree n polynomials in $\mathbb{F}_q[T]$. From this point of view we should think of the original complex algebraic variety as the complex points $Z_n(\mathbb{C})$. There is a remarkable relationship between $Z_n(\mathbb{C})$ and $Z_n(\mathbb{F}_q)$, given by the Grothendieck–Lefschetz fixed point theorem in étale cohomology, which we now explain.

5.2. The Grothendieck-Lefschetz formula. It is a fundamental observation of Weil that for an algebraic variety Z defined over $\mathbb{F}_q$, one can realize $Z(\mathbb{F}_q)$ as the fixed points of a dynamical system, as follows. Denote by $\overline{\mathbb{F}}_q$ the algebraic closure of $\mathbb{F}_q$. The *geometric Frobenius* morphism $\mathrm{Frob}_q\colon Z(\overline{\mathbb{F}}_q) \to Z(\overline{\mathbb{F}}_q)$ acts (in an affine chart) on the coordinates of Z by $x \mapsto x^q$. Fermat's Little Theorem implies that

$$Z(\mathbb{F}_q) = \mathrm{Fix}[(\mathrm{Frob}_q : Z(\overline{\mathbb{F}}_q) \to Z(\overline{\mathbb{F}}_q)].$$

In the case of the varieties Z_n that we are considering, the Grothendieck-Lefschetz fixed point theorem takes the form:

$$|Z_n(\mathbb{F}_q)| = \sum_{f \in \mathrm{Fix}(\mathrm{Frob}_q)} 1 = \sum_i (-1)^i q^{n-i} \dim_{\mathbb{C}} H^i(Z_n(\mathbb{C}); \mathbb{C}) = q^n - q^{n-1} \tag{5.2}$$

where the last equality comes from the theorem of Arnol'd that $H^i(Z_n(\mathbb{C}); \mathbb{C}) = 0$ unless $i = 0, 1$, in which case it is $\mathbb{C}$.

We want to compute more subtle counts than just $|Z_n(\mathbb{F}_q)|$. To this end, we can *weight* the points of $Z_n(\mathbb{F}_q) = \mathrm{Fix}(\mathrm{Frob}_q)$, as follows. For each $f \in \mathrm{Fix}(\mathrm{Frob}_q) = Z_n(\mathbb{F}_q)$ the map Frob_q permutes the set

$$\mathrm{Roots}(f) := \{y \in \overline{\mathbb{F}}_q : f(y) = 0\}$$

giving a conjugacy class σ_f in S_n. Thus $X_i(\sigma_f)$ is well defined. Let $d_i(f)$ denote the number of irreducible (over $\mathbb{F}_q$) degree i factors of f. A crucial observation is that for any $i \geq 1$:

$$X_i(\sigma_f) = d_i(f). \tag{5.3}$$

Any $P \in \mathbb{C}[x_1, \ldots, x_r]$ (here $r \geq 1$ is arbitrary) determines a character polynomial $P(X_1, \ldots, X_r)$ (cf. §4.2 above). The polynomial P gives a way to weight points $f \in Z_n(\mathbb{F}_q)$ via

$$P(f) := P(d_1(f), \ldots, d_r(f)) = P(X_1(\sigma_f), \ldots, X_r(\sigma_f)).$$

So for example $P(f) = d_1(f)$ counts the number of linear factors of f (i.e. the number of roots of f that lie in $\mathbb{F}_q$), and $P(f) = d_2(f) - d_1(f)^2$ counts the quadratic excess of f. In general we call such a P a *polynomial statistic*. The expected value of $P(f)$ for $f \in Z_n(\mathbb{F}_q)$ is then given by $[\sum_{f \in Z_n(\mathbb{F}_q)} P(f)]/(q^n - q^{n-1})$.

$H^i(\mathrm{Conf}_n(\mathbb{C}); \mathbb{C})$ enters the picture. Computing this expectation for a given P is where $H^i(\mathrm{Conf}_n(\mathbb{C}); \mathbb{C})$ comes in. We can identify $Z_n(\mathbb{C})$ with the space $\mathrm{UConf}_n(\mathbb{C}) = \mathrm{Conf}_n(\mathbb{C})/\ S_n$ of unordered n-tuples of distinct points in $\mathbb{C}$ via the bijection that sends $f \in Z_n(\mathbb{C})$ to its set of roots. We thus have a covering $\mathrm{Conf}_n(\mathbb{C}) \to Z_n(\mathbb{C})$ of algebraic varieties, with deck group S_n.

Now, it's something of a long story, and there are a number of technical details to worry about, but the theory of étale cohomology and the twisted Grothendieck-Lefschetz formula, together with work of Lehrer [19], who proved that this machinery can be applied in this case, can be used to give the following theorem of [9]. Let $\langle \phi, \psi \rangle_{S_n} := \sum_{\sigma \in S_n} \phi(\sigma)\overline{\psi(\sigma)}$ be the standard inner product on the space of $\mathbb{C}$-valued functions on S_n.

Theorem 5.1 (Twisted Grothendieck–Lefschetz for Z_n). *For each prime power q, each positive integer n, and each character polynomial P, we have*

$$\sum_{f \,\in\, Z_n(\mathbb{F}_q)} P(f) = \sum_{i=0}^{n} (-1)^i q^{n-i} \left\langle P, \chi_{H^i(\mathrm{Conf}_n(\mathbb{C}); \mathbb{C})} \right\rangle_{S_n}. \tag{5.4}$$

For example, when $P = 1$ the inner product $\langle P, H^i(\mathrm{Conf}_n(\mathbb{C}); \mathbb{C}) \rangle$ is the multiplicity of the trivial S_n-representation in $H^i(\mathrm{Conf}_n(\mathbb{C}); \mathbb{C})$, which by transfer is the dimension of $H^i(Z_n(\mathbb{C}); \mathbb{C})$, giving the formula (5.2) above. Theorem 5.1 tells us that we can compute various weighted point counts on $Z_n(\mathbb{F}_q)$ if we understand the cohomology of the S_n-cover $\mathrm{Conf}_n(\mathbb{C})$ of $Z_n(\mathbb{C})$ as an S_n-representation.

5.3. Representation stability and Grothendieck-Lefschetz. Now we can bring representation stability into the picture. According to Theorem 4.6, for each $i \geq 0$ the character of $H^i(\mathrm{Conf}_n(\mathbb{C}); \mathbb{C})$ is given by a character polynomial for $n \gg 1$ (actually in this case it holds for all $n \geq 1$). The inner product of two character polynomials is, for $n \gg 1$, constant. Keeping track of stable ranges, and defining $\deg P$ as usual but with $\deg x_k = k$, we deduce in [10] the following.

Theorem 5.2 (Stability of polynomial statistics). *For any polynomial $P \in \mathbb{Q}[x_1, x_2, \ldots]$, the limit*

$$\big\langle P, H^i(\mathrm{Conf}_\bullet(\mathbb{C}); \mathbb{C})\big\rangle := \lim_{n\to\infty} \big\langle P, \chi_{H^i(\mathrm{Conf}_n(\mathbb{C}); \mathbb{C})}\big\rangle_{S_n}$$

exists; in fact, this sequence is constant for $n \geq 2i + \deg P$. Furthermore, for each prime power q:

$$\lim_{n\to\infty} q^{-n} \sum_{f \in Z_n(\mathbb{F}_q)} P(f) = \sum_{i=0}^{\infty} (-1)^i \big\langle P, \chi_{H^i(\mathrm{Conf}_\bullet(\mathbb{C}); \mathbb{C})}\big\rangle q^{-i} \tag{5.5}$$

In particular, both the limit on the left and the series on the right in (5.5) *converge, and they converge to the same limit.*

Plugging $P = \binom{X_1}{2} - X_2$ into Theorem 5.2 gives the stable formula (5.1) for quadratic excess of a square-free degree n polynomial in $\mathbb{F}_q[T]$. The limiting values of other polynomial statistics P are computed in [9]; some of these are given in Table 5.1 below. One can actually apply Equation (5.5) of Theorem 5.2 in reverse, using number theory to compute the left-hand side in order to determine the right-hand side, as we do in §4.3 of [9].

The above method is applied in [9] to a different counting problem. Consider the complex algebraic variety of ordered n-frames in $\mathbb{C}^n$:

$$Z_n(\mathbb{C}) = \big\{(L_1, \ldots, L_n) \,\big|\, L_i \text{ a line in } \mathbb{C}^n,\ \ L_1, \ldots, L_n \text{ linearly independent}\big\}.$$

The group S_n acts on $Z_n(\mathbb{C})$ via $\sigma \cdot L_i = L_{\sigma(i)}$. The quotient $Z_n(\mathbb{C})/S_n$ is also an algebraic variety, and its $\mathbb{F}_q$-points parametrize the set of maximal tori in the finite group $\mathrm{GL}_n \mathbb{F}_q$. In analogy with the case of square-free polynomials, each $P \in \mathbb{C}[X_1, \ldots, X_r]$ counts maximal tori in $\mathrm{GL}_n \mathbb{F}_q$ with different weights. Since $H^i(Z_n(\mathbb{C}); \mathbb{C})$ is known to be representation stable (essentially by a theorem of Kraskiewicz-Weyman, Lustig, and Stanley - see §7.1 of [11]), we can apply an analogue of Theorem 5.2 in this context to compute this weighted point count.

Table 5.1 lists some examples of specific asymptotics that are computed in [9] using this method. The formulas in each column are obtained from Theorem 5.2 (and its analogue for $Z_n(\mathbb{C})$) with $P = 1$, $P = X_1$, $P = \binom{X_1}{2} - X_2^2$, the character χ_{sign} of the sign representation, and the characteristic function $\chi_{n\mathrm{cyc}}$ of the n-cycle, respectively. Note that the latter two are not character polynomials.

The formulas for square-free polynomials in Table 5.1 can be proved by direct means, for example using analytic number theory (e.g. weighted L-functions). In contrast, the formulas for maximal tori in $\mathrm{GL}_n \mathbb{F}_q$ may be known but are not so easy to prove. For example, the formula for the number of maximal tori in $\mathrm{GL}_n \mathbb{F}_q$ is a well-known theorem of Steinberg; proofs using the Grothendieck–Lefschetz formula have been given by Lehrer and Srinivasan (see e.g. [30]). Regardless, a central message of [9] is that representation stability provides a single underlying mechanism for all such formulas.

P	Counting theorem for squarefree polys in $\mathbb{F}_q[T]$	Counting theorem for maximal tori in $\mathrm{GL}_n\,\mathbb{F}_q$
1	# of degree n squarefree polynomials $= q^n - q^{n-1}$	# of maximal tori in $\mathrm{GL}_n\,\mathbb{F}_q$ (both split and non-split) $= q^{n^2-n}$
x_1	expected # of linear factors $= 1 - \frac{1}{q} + \frac{1}{q^2} - \frac{1}{q^3} + \cdots \pm \frac{1}{q^{n-2}}$	expected # of eigenvectors in $\mathbb{F}_q^n$ $= 1 + \frac{1}{q} + \frac{1}{q^2} + \cdots + \frac{1}{q^{n-1}}$
$\binom{x_1}{2} - x_2^2$	expected excess of *reducible* vs. *irreducible* quadratic factors $\to \frac{1}{q} - \frac{3}{q^2} + \frac{4}{q^3} - \frac{4}{q^4} + \frac{5}{q^5} - \frac{7}{q^6} + \frac{8}{q^7} - \frac{8}{q^8} + \cdots$ as $n \to \infty$	expected excess of *reducible* vs. *irreducible* dim-2 subtori $\to \frac{1}{q} + \frac{1}{q^2} + \frac{2}{q^3} + \frac{2}{q^4} + \frac{3}{q^5} + \frac{3}{q^6} + \frac{4}{q^7} + \frac{4}{q^8} + \cdots$ as $n \to \infty$
χ_{sign}	discriminant of random squarefree polynomial is equidistributed in $\mathbb{F}_q^\times$ between residues and nonresidues	# of irreducible factors is more likely to be $\equiv n \bmod 2$ than not, with bias $\sqrt{\#\text{ of tori}}$

Table 5.1. Some asymptotics from [9], computed using Theorem 5.2 and its $Z_n(\mathbb{C})$ analogue.

Remark 5.3 (Stable range vs. rate of convergence). The dictionary between representation stability and stability of point-counts goes one level deeper. One can of course ask how quickly the formulas in Table 5.1 converge. As discussed in [9], the speed of convergence of any such formula depends on the stable range of the corresponding representation stability problem. For example, let L denote the limit of each side of Equation (5.5). The fact that $\langle \chi_P, H^i(\mathrm{Conf}_n(\mathbb{C}))\rangle_{S_n}$ is stable with stable range $n \geq 2i + \deg P$ can be used to deduce that

$$q^{-n} \sum_{f(T)\in Z_n(\mathbb{F}_q)} P(f) = L + O(q^{(\deg P - n)/2}) = L + O(q^{-n/2}).$$

We thus have a *power-saving bound* on the error term. See [9] for more details.

6. FI-modules in characteristic p

The Noetherian property for FI-modules was extended from fields of characteristic 0 to arbitrary Noetherian rings by Church-Ellenberg-Farb-Nagpal [10]. The proof is significantly more difficult in this case, and new ideas were needed. Indeed, [10] brought in more categorical and homological methods into the theory, for example with a homological reformulation of finite generation, and a certain shift functor that plays a crucial role. This line of ideas has culminated in the recent theory of FI-homology of Church-Ellenberg [7], which is an

exciting and powerful new tool.

One reason that we care about characteristic $p > 0$ is that in some examples this case contains most of the information. As an example, let K be a number field with ring of integers $\mathcal{O}_K$, and let $\mathfrak{p} \subset \mathcal{O}_K$ be any proper ideal. Define the *congruence subgroup* $\Gamma_n(\mathfrak{p}) \subset \mathrm{GL}_n(\mathcal{O}_k)$ to be

$$\Gamma_n(\mathfrak{p}) := \text{kernel}[\mathrm{GL}_n(\mathcal{O}_k) \to \mathrm{GL}_n(\mathcal{O}_k/\mathfrak{p})].$$

As shown by Charney [5], when one considers coefficients localized at $\mathfrak{p}$ then $\Gamma_n(\mathfrak{p})$ and $\mathrm{GL}_n(\mathcal{O}_K)$ have the same homology. Thus the interesting new information about $\Gamma_n(\mathfrak{p})$ comes via coefficients k with $\mathrm{char}(k) = p > 0$. While $H_i(\Gamma_n(\mathfrak{p}); k)$ is most naturally a representation of $\mathrm{SL}_n(\mathcal{O}_k/\mathfrak{p})$, one can restrict this action to a copy of S_n, and show that $H_i(\Gamma_n(\mathfrak{p}); k)$ is an FI-module. The Noetherian condition is crucial for proving that this FI-module is finitely generated, since the proof uses a spectral sequence argument (see below).

The proof of Theorem 4.4, that for a finitely-generated FI-module V the character χ_{V_n} is a character polynomial for $n \gg 1$, works only over a field k with $\mathrm{char}(k) = 0$. However, for fields k with $\mathrm{char}(k) > 0$, we were still able to prove [10, Theorem B] that there is a polynomial $P \in \mathbb{Q}[T]$ so that $\dim_k(V_n) = P(n)$ for all $n \gg 1$. Following the approach of Putman [26], we were able to apply this to $H_i(\Gamma_n(\mathfrak{p}); k)$, giving the following theorem, first proved by Putman [26] for fields of large characteristic.

Theorem 6.1 (**mod p Betti numbers of congruence subgroups**). *Let K be a number field, $\mathcal{O}_K$ its ring of integers, and $\mathfrak{p} \subsetneq \mathcal{O}_K$ any proper ideal. For any $i \geq 0$ and any field k, there exists a polynomial $P(T) = P_{\mathfrak{p},i,k}(T) \in \mathbb{Q}[T]$ so that for all sufficiently large n,*

$$\dim_k H_i(\Gamma_n(\mathfrak{p}); k) = P(n).$$

The exact numbers $\dim_k H_i(\Gamma_n(\mathfrak{p}); k)$ for $i > 1$ are known in very few cases, even for the simplest case $K = \mathbb{Q}, \mathfrak{p} = (p), k = \mathbb{F}_p$. Frank Calegari [4] has recently determined the rate of growth of the mod p Betti numbers of the level p^d congruence subgroup of $\mathrm{SL}_n(\mathcal{O}_K)$. He proves for example in [4, Lemma 3.5] that for $p \geq 5, d \geq 1$:

$$\dim_{\mathbb{F}_p} H_i(\Gamma_n(p^d); \mathbb{F}_p) = \binom{n^2-1}{i} + O(n^{2i-4}).$$

Calegari's result tells us the leading term of the polynomial guaranteed by Theorem 6.1. It should be noted that Calegari's proof uses (Putman's version of) Theorem 6.1.

Problem 6.2 ([10]). Compute the polynomials $P_{\mathfrak{p},i,k} \in \mathbb{Q}[T]$ given by Theorem 6.1. Do the Brauer characters of $H_i(\Gamma_n(\mathfrak{p}); k)$, or indeed of an arbitrary finitely-generated FI-module over a finite field k with $\mathrm{char}(k) > 0$, exhibit polynomial behavior in n for $n \gg 1$?

The more categorical setup in [10] allowed us to find an inductive description for any finitely generated FI-module.

Theorem 6.3 (**Inductive description of f.g. FI-modules**). *Let V be a finitely-generated FI-module over a Noetherian ring R. Then there exists some $N \geq 0$ such that for all $n \in \mathbb{N}$, there is an isomorphism of S_n-representations:*

$$V_n \approx \varinjlim V(S) \tag{6.1}$$

where the direct limit is taken over the poset of subsets $S \subset \{1, \ldots, n\}$ with $|S| \leq N$.

The condition (6.1) in Theorem 6.3 can be viewed as a reformulation of Putman's central stability condition [26, §1].

Since we proved in [10] that $H_m(\Gamma_n(\mathfrak{p}); k)$ is a finitely generated FI-module, Theorem 6.3 thus gives the following inductive presentation of $H_m(\Gamma_n(\mathfrak{p}); \mathbb{Z})$. Let $\Gamma^{(i)}_{n-1}(\mathfrak{p})$ with $1 \leq i \leq n$ denote the n standard subgroups of $\Gamma_n(\mathfrak{p})$ isomorphic to $\Gamma_{n-1}(\mathfrak{p})$. Let $\Gamma^{(i,j)}_{n-2}(\mathfrak{p}) := \Gamma^{(i)}_{n-1}(\mathfrak{p}) \cap \Gamma^{(j)}_{n-1}(\mathfrak{p})$. As the notation suggests, each $\Gamma^{(i,j)}_{n-2}(\mathfrak{p})$ is isomorphic to $\Gamma_{n-2}(\mathfrak{p})$. As with the Mayer-Vietoris sequence, the difference of the two inclusions gives a map

$$H_m(\Gamma^{(i,j)}_{n-2}(\mathfrak{p})) \to H_m(\Gamma^{(i)}_{n-1}(\mathfrak{p})) \oplus H_m(\Gamma^{(j)}_{n-1}(\mathfrak{p}))$$

whose image vanishes in $H_m(\Gamma_n(\mathfrak{p}))$. A version of the following theorem for coefficients in a sufficiently large finite field was first proved by Putman [26].

Theorem 6.4 (**A presentation for** $H_m(\Gamma_n(\mathfrak{p}); \mathbb{Z})$)**.** *Let K be a number field, let $\mathcal{O}_K$ be its ring of integers, and let $\mathfrak{p}$ be a proper ideal in $\mathcal{O}_K$. Fix $m \geq 0$. Then for all sufficiently large n,*

$$H_m(\Gamma_n(\mathfrak{p}); \mathbb{Z}) \simeq \frac{\bigoplus_{i=1}^{n} H_m(\Gamma^{(i)}_{n-1}(\mathfrak{p}); \mathbb{Z})}{\operatorname{im} \bigoplus_{i<j} H_m(\Gamma^{(i,j)}_{n-2}(\mathfrak{p}); \mathbb{Z})}.$$

We think of Theorem 6.4 as giving a presentation for $H_m(\Gamma_n(\mathfrak{p}); \mathbb{Z})$, with copies of $H_m(\Gamma_{n-1}(\mathfrak{p}); \mathbb{Z})$ as generators and copies of $H_m(\Gamma_{n-2}(\mathfrak{p}); \mathbb{Z})$ as relations. Theorem 6.3 is applied in [10] to give a similar description for $H_m(\mathrm{Conf}_n(M); \mathbb{Z})$ and for graded pieces of diagonal coinvariant algebras. Nagpal [25] has recently extended this point of view considerably, and has applied it to prove that the groups $H_m(\mathrm{UConf}_n(M); \mathbb{F}_p)$ are periodic in n.

7. Representation stability for other sequences of representations

In this paper we focused our attention on sequences V_n of S_n-representations. This is just one of the examples from [11], where we introduced and studied representation stability (and variations) for other families G_n of groups whose representation theory has a consistent naming system. Examples include $G_n = \mathrm{GL}_n \mathbb{Q}$, $\mathrm{Sp}_{2g} \mathbb{Q}$ and the hyperoctahedral groups. We also explored the case of modular representations of algebraic groups over finite fields, where instead of stability we found representation periodicity. The reader is referred to [11] for precise definitions and many examples.

I would like to illustrate here how these kinds of examples arise. For brevity let's stick to the calculation of group homology. Here is the general setup. Let Γ be a group with normal subgroup N and quotient $A := \Gamma/N$. The conjugation action of Γ on N induces a Γ–action on $H_i(N; R)$ for any coefficient ring R. This action factors through an A–action on $H_i(N, R)$, making $H_i(N, R)$ into an A–module.

The structure of $H_i(N, R)$ as an A–module encodes fine information. For example, the transfer isomorphism shows that when A is finite and $R = \mathbb{Q}$, the space $H_i(\Gamma; \mathbb{Q})$ appears precisely as the subspace of A–fixed vectors in $H_i(N; \mathbb{Q})$. But there are typically many other summands, and knowing the representation theory of A (over R) gives us a language with which to access these.

There are many natural examples of families Γ_n of this type, with normal subgroups N_n and quotients A_n. Table 7 summarizes some examples that fit into this framework.

kernel N_n	group Γ_n	acts on	quotient A_n	$H_1(N_n; R)$ for big n
pure braid group P_n	braid group B_n	$\{1, \dots, n\}$	S_n	$\mathrm{Sym}^2 V_n / V_n$
Torelli group $\mathcal{I}_n$	mapping class group Mod_n	$H_1(\Sigma_n, \mathbb{Z})$	$\mathrm{Sp}_{2n}\,\mathbb{Z}$	$\bigwedge^3 V_n / V_n$
$\mathrm{IAut}(F_n)$	$\mathrm{Aut}(F_n)$	$H_1(F_n, \mathbb{Z})$	$\mathrm{GL}_n\,\mathbb{Z}$	$V_n^* \otimes \bigwedge^2 V_n$
congruence subgroup $\Gamma_n(p)$	$\mathrm{SL}_n\,\mathbb{Z}$	$\mathbb{F}_p^n$	$\mathrm{SL}_n\,\mathbb{F}_p$	$\mathfrak{sl}_n\,\mathbb{F}_p$
level p subgroup $\mathrm{Mod}_n(p)$	Mod_n	$H_1(\Sigma_n; \mathbb{F}_p)$	$\mathrm{Sp}_{2n}\,\mathbb{F}_p$	$\bigwedge^3 V_n / V_n \oplus \mathfrak{sp}_{2n}\,\mathbb{F}_p$

Table 7.1. Some natural sequences of representations.

In each case the group N_n arises as the kernel of a natural Γ_n-action. Each example is explained in detail in [11]. Here $R = \mathbb{Q}$ in the first three examples, $R = \mathbb{F}_p$ in the fourth and fifth, and V_n stands in each case for the "standard representation" of A_n. In the last example p is an odd prime.

In each of the examples in Table 7, the groups Γ are known to satisfy classical homological stability. In contrast, the rightmost column of Table 7 shows that none of the groups N satisfies homological stability, even in dimension 1. In fact, except for the example of P_n, very little is known about the A_n–module $H_i(N_n, R)$ for $i > 1$, and indeed it is not clear if there is a nice closed form description of these homology groups. However, the appearance of some kind of stability can already be seen in the rightmost column, as the names of the irreducible composition factors of these A_n–modules are constant for large enough n; this is discussed in detail in [11].

A crucial common property of the examples in Table 7 is that each of the sequences A_n has an inherent stability in the naming of its irreducible algebraic representations over R. For example, an irreducible algebraic representation of $\mathrm{SL}_n\,\mathbb{Q}$ is determined by its highest weight vector, and these vectors can be described uniformly without reference to n. For example, for $\mathrm{SL}_n\,\mathbb{Q}$ the irreducible representation $V(L_1 + L_2 + L_3)$ with highest weight $L_1 + L_2 + L_3$ is isomorphic to $\bigwedge^3 V$ regardless of n, where V is the standard representation of SL_n.

In [11] we defined a notion of representation stability for each of the sequences of groups A_n given in Table 7. We gave some examples, gave some conjectures using this language, and worked out some of the basic theory. The powerful FI-module point of view has only been developed in the special case of $A_n = S_n$. This is completely missing in general.

Problem 7.1 (FI-theory for other sequences of groups). For each of the sequences $A_n = \mathrm{Sp}_{2n}\,\mathbb{Z}, \mathrm{GL}_n\,\mathbb{Z}, \mathrm{SL}_n\,\mathbb{F}_p, \mathrm{Sp}_{2n}\,\mathbb{F}_p$, work out a theory of FI_{A}-modules, where:

(1) Finite generation (perhaps with an additional condition) is equivalent to representation stability for A_n-represntations, as defined in [11].

(2) The theory gives uniform descriptions (uniform in n) of the characters of the examples in Table 7.

(3) FI_{A}-modules satisfy a Noetherian property.

In [34] J. Wilson extended the theory of FI-modules from the case of S_n to the other two sequences of classical Weyl groups (of type B/C and D); this includes the hyperoctahedral groups. New phenomena occur here. For example, character polynomials must be given with two distinct sets $\{X_i\}, \{Y_i\}$ of variables. Wilson applies this theory to a number of examples, including the cohomology of the pure string motion groups (see also [33]), the cohomology of various hyperplane arrangements, and diagonal co-invariant algebras for Weyl groups.

Acknowledgements. The author gratefully acknowledges support from the National Science Foundation. He would also like to thank his collaborators Thomas Church and Jordan Ellenberg, without whom the work discussed herein would not exist. Thanks to them and also to Dan Margalit for making extensive comments on an earlier version of this paper.

Moduli spaces of manifolds

Søren Galatius

Abstract. This article surveys some recent advances in the topology of moduli spaces, with an emphasis on moduli spaces of manifolds.

Mathematics Subject Classification (2010). 57R90, 57R15, 57R56, 55P47.

Keywords. Manifolds, moduli spaces, classifying spaces, infinite loop spaces, surgery theory, diffeomorphism groups.

1. Introduction: Cohomology of $B\mathrm{Diff}(W)$

In this paper I shall survey some recent developments in the topological approach to moduli spaces of manifolds. The moduli spaces in question are classifying spaces $B\mathrm{Diff}(W)$, where $\mathrm{Diff}(W)$ denotes the topological group of diffeomorphisms of a smooth compact manifold W, restricting to the identity near ∂W, and variations thereof. These spaces show up in numerous contexts, but at the most basic level they are classifying spaces for smooth fiber bundles whose fibers are diffeomorphic to W: For a smooth manifold B there is a natural bijection between the set of smooth fiber bundles $\pi : E \to B$ whose fibers are diffeomorphic to W, and the set of homotopy classes of maps $X \to B\mathrm{Diff}(W)$. From this point of view, it is especially interesting to understand the *cohomology* of $B\mathrm{Diff}(W)$, as it is the ring of characteristic classes of such fiber bundles.

A motivating previous result concerns the case where W is an oriented connected 2-manifold, where the theorems of Harer ([25]) and of Madsen and Weiss ([35]) give a complete description of $H^*(B\mathrm{Diff}(W))$ in a range of degrees growing with the genus of W. These results are recalled in Section 1.2 below.

In Section 1.3 we shall state precise analogues of these theorems for $B\mathrm{Diff}(W)$ when W is an (even-dimensional) manifold of higher dimension, leading to a similar understanding of $H^*(B\mathrm{Diff}(W))$, in a range of degrees depending on a suitable analogue of genus. Some calculational aspects, and two interesting examples are discussed in Section 1.4.

1.1. Classification of $2n$-manifolds by tangential n-type. In the classical approach (cf. e.g. [9, 56]) to the classification of (high dimensional) manifolds, the basic homotopy theoretic invariant attached to a manifold M is its homotopy type, and one attempts only to classify manifolds inside one homotopy type at a time: If a space X is fixed, the *structure set* $\mathscr{S}(X)$ parametrizes pairs consisting of a smooth manifold and a homotopy equivalence $M \to X$. In this section we briefly recall another approach to classification, due to Kreck ([32]).

Proceedings of the International Congress of Mathematicians, Seoul, 2014

As the basic homotopy theoretic invariant of a smooth $2n$-manifold W, we shall instead consider the *tangential n-type* defined below (a minor variation of the normal n-type from [32]). Let W be a smooth compact $2n$-dimensional manifold. Writing γ_{2n} for the canonical vector bundle over $BO(2n)$, the space of vector bundle maps $TW \to \gamma_{2n}$ is contractible. Picking an element in this contractible space gives an underlying map $W \to BO(2n)$, and we may form the Moore–Postnikov factorization

$$W \xrightarrow{\ell} X_W \xrightarrow{\theta_W} BO(2n),$$

uniquely characterized up to weak homotopy equivalence by the facts that ℓ is an n-connected cofibration and θ_W is an n-coconnected Serre fibration. (Being n-connected means that the induced map in homotopy groups is surjective for π_n and bijective for $\pi_{<n}$; being n-coconnected means that the induced map in homotopy groups is injective in π_n and bijective in $\pi_{>n}$.)

We shall consider the fiber homotopy equivalence class of the fibration $\theta_W : X_W \to BO(2n)$ a primary homotopy theoretic invariant of W. If W has non-empty boundary $\partial W = P$, we shall consider the factorization $P \to X_W \to BO(2n)$, up to weak equivalence over $BO(2n)$ and under P. (Here, over and under are used in the usual sense: the map is required to commute with the maps to $BO(2n)$ and with the maps from P.)

Definition 1.1. Let $\theta : X \to BO(2n)$ be an n-coconnected Serre fibration. Let $\mathscr{Y}(\theta)$ be the set of diffeomorphism classes of closed manifolds W for which there exists a weak equivalence $X_W \to X$ over $BO(2n)$.

More generally, given a closed $(2n-1)$-manifold P and a bundle map $\ell_P : \varepsilon^1 \oplus TP \to \theta^*\gamma_{2n}$, let $\mathscr{Y}(\theta, P, \ell_P)$ be the set of diffeomorphism classes of compact manifolds W with $\partial W = P$, up to diffeomorphism relative to P, for which there exists a weak equivalence $X_W \to X$ over $BO(2n)$ and under P.

For some purposes it might be cleaner to define a set $\mathscr{Y}'(\theta)$ classifying pairs of a closed manifold W together with a choice of weak equivalence $X_W \to X$ over $BO(2n)$, up to homotopy through such maps. These sets contain essentially the same information, since $\mathscr{Y}(\theta)$ is the set of orbits of the monoid $\mathrm{Aut}(\theta)$ of weak equivalences $X \to X$ over $BO(2n)$ acting on $\mathscr{Y}'(\theta)$ in the obvious way. These sets admit self-maps induced by $[W] \mapsto [W\#(S^n \times S^n)]$, which we shall denote by s, for "stabilization". (Here we are assuming X and hence W is connected, so the diffeomorphism class of $W\#(S^n \times S^n)$ is well defined.) A remarkable theorem of Kreck ([32]) determines the direct limit of sets $\mathscr{Y}'(\theta) \xrightarrow{s} \mathscr{Y}'(\theta) \xrightarrow{s} \dots$ by constructing a bijection to a certain bordism group. Let us recall his result.

The composition $X \xrightarrow{\theta} BO(2n) \subset BO \xrightarrow{-1} BO$ defines a bordism theory $\Omega_*^{-\theta}$ in the usual way, cf. e.g. [51]: representatives are closed manifolds with a lift of their stable normal bundle to X, and these are considered up to bordism with the same structure. By definition, an element in $\mathscr{Y}'(\theta)$ represents an element of $\Omega_{2n}^{-\theta}$, and [32, Theorem C] (when translated from normal n-types to the tangential n-types used here) implies that this induces an bijection

$$\mathrm{colim}\left(\mathscr{Y}'(\theta) \xrightarrow{s'} \mathscr{Y}'(\theta) \xrightarrow{s'} \dots\right) \to \Omega_{2n}^{-\theta}.$$

Thus, a connected closed manifold W with tangential n-type θ is uniquely classified by a single invariant in the orbit set $(\Omega_{2n}^{-\theta})/\mathrm{Aut}(\theta)$, up to *stable diffeomorphism*, i.e. the equivalence

relation generated by $W \sim W'$ if $W \# k(S^n \times S^n)$ is diffeomorphic to $W' \# k(S^n \times S^n)$ for some k.

1.2. Classification of smooth (surface) bundles. The classification problem for manifolds has a parametrized version: for a given manifold B, describe the set of smooth fiber bundles $\pi : E \to B$, say with a fixed diffeomorphism type of the fibers, up to fiberwise diffeomorphism. If the fiber is a closed manifold W, this set is in natural bijection with the set $[B, B\mathrm{Diff}(W)]$ of homotopy classes of maps. If $P = \partial W \neq \emptyset$, the set $[B, B\mathrm{Diff}(W)]$ is in bijection with smooth fiber bundles $\pi : E \to B$ with an identification $\partial E = B \times P$, such that all fibers are diffeomorphic to W relative to P. (Recall that we write $\mathrm{Diff}(W)$ for the diffeomorphisms of W restricting to the identity near ∂W.) Thus the classification theory for smooth fiber bundles amounts to the understanding of the homotopy type of $B\mathrm{Diff}(W)$.

The association of the factorization $W \to X_W \to BO(2n)$ to the manifold W is, when carefully constructed, continuous and functorial in W and gives rise to a continuous map

$$B\mathrm{Diff}(W) \to B\mathrm{Aut}(\theta_W, \partial W), \tag{1.1}$$

where $\mathrm{Aut}(\theta_W, \partial W)$ is the topological monoid of self-homotopy equivalences $\phi : X \to X$ with $\phi \circ \ell|_{\partial W} = \ell|_{\partial W}$ and $\theta \circ \phi = \phi$.

Definition 1.2. For a compact manifold W, let $\theta = \theta_W : X_W \to BO(2n)$ be its tangential n-type, and write

$$B\mathrm{Diff}^{\theta}(W) = \mathrm{hofib}\big(B\mathrm{Diff}(W) \to B\mathrm{Aut}(\theta, \partial W)$$

for the homotopy fiber of the map (1.1).

(Despite the notation, this space is not always the classifying space of a group, and may have several path components.) By construction, the space $B\mathrm{Diff}^{\theta}(W)$ comes with an action of the monoid $\mathrm{Aut}(\theta, \partial W)$ and the ordinary $B\mathrm{Diff}(W)$ can be reconstructed as the homotopy orbit space of that action.

Example 1.3. If $n = 1$ and W is a connected, closed, orientable 2-manifold, the tangential 1-type of W is that of $\theta : BSO(2) \to BO(2)$. In this case, $B\mathrm{Diff}(W)$ is the classifying space of the group of all diffeomorphisms of W, not necessarily preserving orientation. The monoid $\mathrm{Aut}(\theta)$ is homotopy equivalent to the discrete group $\mathbb{Z}^{\times} \cong \mathbb{Z}/2$, and the map $B\mathrm{Diff}(W) \to B\mathrm{Aut}(\theta)$ is induces by the action of $\mathrm{Diff}(W)$ on $H_2(W) \cong \mathbb{Z}$. Therefore, $B\mathrm{Diff}^{\theta}(W)$ is homotopy equivalent to the classifying space of the group of orientation preserving diffeomorphisms.

If $n = 1$ and W is a connected orientable 2-manifold with *non-empty* boundary, the tangential 1-type is still $BSO(2) \to BO(2)$, but now $B\mathrm{Aut}(\theta, \partial W)$ is contractible and hence $B\mathrm{Diff}^{\theta}(W, \partial W) \simeq B\mathrm{Diff}(W, \partial W)$, corresponding to the fact that diffeomorphisms fixing the boundary are automatically orientation preserving.

By the classification theorem for connected oriented compact 2-manifolds, the diffeomorphism type of W is given by two numbers, viz. the genus and the number of boundary components. If $W = W_{g,n}$ has genus g and n boundary components, the moduli space $B\mathrm{Diff}^{\theta}(W_{g,n})$ is known to have several interesting geometric models (at least when excluding the exceptional surfaces of non-negative Euler characteristic), most notably the moduli space $\mathscr{M}_{g,n}$ of isomorphism classes of genus g Riemann surfaces, with n marked points and

a non-zero tangent vector at each point. This space has a wealth of geometric structure, including all the structure which follows from being the complex points of a variety defined over $\mathbb{Z}$ (a mixed Hodge structure on its rational cohomology, and a Galois action on its profinite completion), as well as metric and dynamic aspects related to the Teichmüller and Weil-Petersson metrics. This shall barely be touched upon here, except to note that it would be interesting to better understand the connections between these more geometric aspects of moduli spaces and the homotopy theoretic aspects covered in the present paper. In particular it would be interesting to understand how much, if any, of that geometric structure admits an analogue for moduli spaces of higher dimensional manifolds.

Let us recall two important theorems about the cohomology of this space. A version of the following result was first proved by Harer.

Theorem 1.4. *For any inclusion $j : W \subset W'$ of connected oriented compact 2-dimensional manifolds, the map*

$$H_k(B\mathrm{Diff}^\theta(W)) \to H_k(B\mathrm{Diff}^\theta(W'))$$

induced by extending a diffeomorphism of W by the identity map of $W' \setminus jW$, is an isomorphism for $k \leq (g(W) - 1)/1.5$, where $g(W)$ is the genus of W.

Harer's original paper [25] proved a weaker version of this result where the linear term $g/1.5$ in the range is replaced by $g/3$. Later results [31] improved this to $g/2$ and allowed closed surfaces. The slope $g/1.5$ above is due to Boldsen ([8]), inspired by unpublished ideas of Harer ([27]), and is known to be optimal ([41]).

Determining the cohomology of $B\mathrm{Diff}^\theta(W)$ in the stable range is then equivalent to determining the inverse limit

$$H^*(B\mathrm{Diff}^\theta(W_\infty)) = \varprojlim H^*(B\mathrm{Diff}^\theta(W_{g,1})),$$

where $W_{g,1}$ denotes a genus g surface with one boundary component. The following result is due to Madsen and Weiss.

Theorem 1.5 ([35]). *Let $BSO(2)^{-\theta}$ denote the Thom spectrum of the map $BSO(2) \xrightarrow{\theta} BO(2) \subset BO \xrightarrow{-1} BO$, graded such that the Thom class is in degree -2. There is a map*

$$B\mathrm{Diff}^\theta(W_\infty) \to \Omega^\infty(BSO(2)^{-\theta})$$

which is a homology equivalence (i.e. it induces an isomorphism in singular homology with integral coefficients) after restricting to a map between path connected spaces.

Analogues of the theorems of Harer and of Madsen–Weiss have been established for unoriented surfaces ([47, 53]) and for surfaces with certain tangential structures (cf. e.g. [4, 11, 26], or the comprehensive treatment in [47]). It would be interesting to understand how these results are related to the finite-generation criteria of A. Kupers and J. Miller ([33]). For manifolds of dimension higher than 2, A. Hatcher and N. Wahl ([28]) have proved homological stability for *mapping class groups* of many 3-manifolds.

The theorems of Harer and Madsen–Weiss combine to a formula for the homology of $B\mathrm{Diff}^\theta(W)$ for any orientable 2-manifold W, in the range where homological stability applies. The rational cohomology of a path component of $\Omega^\infty(BSO(2)^{-\theta})$ is easy to calculate, implying that in the stable range, the ring $H^*(B\mathrm{Diff}^\theta(W); \mathbb{Q})$ is polynomial on a sequence of classes κ_i of degree $2i$, $i \geq 1$.

1.3. Bundles of higher dimensional manifolds. Next, I shall discuss analogues for higher-dimensional manifolds of the results of Harer and Madsen–Weiss. To begin with, the following turns out to be useful generalizations of *genus*.

Definition 1.6. Write $W_1 = S^n \times S^n$ and $W_{1,1} = W_1 \setminus \mathrm{int}(D^{2n})$ for some choice of embedding $D^{2n} \to W_1$. The *genus* of a connected compact smooth $2n$-manifold W (with or without boundary) is the maximal number $g(W)$ for which there exist $g(W)$ disjoint embeddings $W_{1,1} \to W$. The *stable genus* is the maximal number $\overline{g}(W)$ such that for some k there exist $k + \overline{g}(W)$ disjoint embeddings $W_{1,1} \to W \# kW_1$.

If $j : W \hookrightarrow W'$ is an embedding of compact connected $2n$-manifolds, then $g(W') \geq g(W)$ and $\overline{g}(W') \geq \overline{g}(W)$. Such an embedding also induces a map of tangential n-types $\theta_W \to \theta_{W'}$, i.e. a map $X_W \to X_{W'}$ over $BO(2n)$. The fibration (1.1) can be made functorial with respect to embeddings and j induces a diagram

$$\begin{array}{ccccc} B\mathrm{Diff}^{\theta_W}(W) & \longrightarrow & B\mathrm{Diff}(W) & \longrightarrow & B\mathrm{Aut}(\theta_W, \partial W) \\ \downarrow & & \downarrow & & \downarrow \\ B\mathrm{Diff}^{\theta_{W'}}(W') & \longrightarrow & B\mathrm{Diff}(W') & \longrightarrow & B\mathrm{Aut}(\theta_{W'}, \partial W') \end{array}$$

whose middle vertical arrow is induced by extending diffeomorphisms of W by the identity on $W' \setminus j(W)$. We shall be especially concerned with embeddings j which induce a weak equivalence of tangential n-types, i.e. where the map $X_W \to X_{W'}$ is a weak equivalence. In this case we can identify θ_W and $\theta_{W'}$ and denote them both by θ. The following generalization of Harer's theorem is proved in joint work with O. Randal-Williams.

Theorem 1.7 ([18, 19]). *Let $j : W \hookrightarrow W'$ be an embedding of compact, connected manifolds of dimension $2n$, inducing an equivalence of tangential n-types. If W is simply connected and $n > 2$, then the map*

$$B\mathrm{Diff}^{\theta}(W) \to B\mathrm{Diff}^{\theta}(W')$$

induces an isomorphism in $H_k(-; \mathbb{Z})$ for $k \leq (\overline{g}(W) - 3)/2$, when restricted to a map between path connected spaces.

If we write $W_g = g(S^n \times S^n)$ for the connected sum of g copies of $S^n \times S^n$, then for any connected manifold W with non-empty boundary we get embeddings $W \hookrightarrow W \# W_1 \hookrightarrow W \# W_2 \hookrightarrow \dots$, by first using a collar of the boundary to embed M into its own interior, then performing the connected sum outside the image of that self-embedding. Each embedding induces an equivalence of tangential n-types, and we will write $B\mathrm{Diff}^{\theta}(W \# W_\infty)$ for the homotopy direct limit of the resulting sequence

$$B\mathrm{Diff}^{\theta}(W \# W_\infty) = \operatorname*{hocolim}_{g \to \infty} B\mathrm{Diff}^{\theta}(W \# W_g). \tag{1.2}$$

The limiting case $g \to \infty$ of Theorem 1.7 holds with weaker assumptions. Let us note that if $j : W \to W'$ is an embedding which maps a chosen disk $D^{2n-1} \approx D \subset \partial W$ into $\partial W'$, then j induces maps $B\mathrm{Diff}(W \# W_g) \to B\mathrm{Diff}(W' \# W_g)$ compatible with the maps in the direct limit (1.2), and similarly for $B\mathrm{Diff}^{\theta}$, provided the connected sum is performed near the chosen disk. Therefore j induces a map $B\mathrm{Diff}^{\theta}(W \# W_\infty) \to B\mathrm{Diff}^{\theta}(W' \# W_\infty)$. The following infinite-genus version of Theorem 1.7 is proved in joint work with O. Randal-Williams.

Addendum 1.8 ([19]). *Let $j : W \hookrightarrow W'$ be an embedding of compact, connected manifolds of dimension $2n > 0$, inducing an equivalence of tangential n-types. If j takes a disk in ∂W to a disk in $\partial W'$ as above, the induced map*

$$B\mathrm{Diff}^{\theta}(W \# W_{\infty}) \to B\mathrm{Diff}^{\theta}(W' \# W_{\infty})$$

is a homology equivalence, when restricting to a map between path connected spaces.

The following generalization of Madsen and Weiss' theorem to higher dimensional manifolds determines the homology in the stable range. It is proved in joint work with O. Randal-Williams.

Theorem 1.9 ([19, 20]). *Let W be any connected manifold of dimension $2n > 0$ with non-empty boundary. There is a map*

$$B\mathrm{Diff}^{\theta}(W \# W_{\infty}) \to \Omega^{\infty} X^{-\theta}$$

which, when restricted to a map between path connected spaces, induces an isomorphism in integral homology.

The map to $\Omega^{\infty} X^{-\theta}$ is defined using the Pontryagin–Thom construction. It exists also for closed manifolds, and can be made functorial under gluing, cf. Section 2 below. When W is simply connected and $n > 2$, the two theorems can be combined to deduce that the map

$$B\mathrm{Diff}^{\theta}(W) \to \Omega^{\infty} X^{-\theta}$$

induces an isomorphism in $H_k(-; \mathbb{Z})$ when $k \leq (\overline{g}(W) - 3)/2$, when restricted to a map between path connected spaces.

If constructed carefully, this map is also equivariant with respect to the action of $\mathrm{Aut}(\theta, \partial W)$ on both sides. The induced map of homotopy orbit spaces (= Borel constructions)

$$B\mathrm{Diff}(W) \to (\Omega^{\infty} X^{-\theta})_{h\mathrm{Aut}(\theta, \partial W)}, \tag{1.3}$$

then also induces an isomorphism in homology of path components in the stable range.

If n is large and W is very complicated, the monoid $\mathrm{Aut}(\theta, \partial W)$ may well be quite complicated too. However, it is always an $(n-1)$-type (i.e. the homotopy groups $\pi_{\geq n}$ all vanish, with all basepoints) and is an $(n-c-2)$-type if the inclusion $\partial W \to W$ is c-connected, since the fibers of θ are all $(n-1)$-types. In many examples of interest, the homotopy type of $B\mathrm{Aut}(\theta, \partial W)$ is easy to understand, and in particular it is contractible if $(W, \partial W)$ is $(n-1)$-connected.

1.4. Explicit calculations. For a given $\theta : X \to BO(2n)$, the integral homology of the infinite loop spaces $\Omega^{\infty} X^{-\theta}$ appearing in Theorem 1.9 is almost certainly very complicated in any interesting example. The rational cohomology is usually easy; in this section we spell out two interesting examples.

The integral cohomology is probably best approached one prime at a time, where several calculations have been carried out in the case $2n = 2$, cf. [16, 17, 46]. It would be useful to get a more concrete hold of the cohomology classes resulting from those calculations (perhaps in the style of [23]). It also seems interesting to investigate the real or complex K-theory, as well as more exotic cohomology theories.

1.4.1. Miller–Morita–Mumford classes. The calculations of the cohomology rings $H^*(B\mathrm{Diff}^\theta(W);\mathbb{Q})$ and $H^*(B\mathrm{Diff}(W);\mathbb{Q})$ in the stable range implied by Theorems 1.7 and 1.9 involve the characteristic classes known as MMM classes, after Miller, Morita and Mumford, who defined these classes in [38, 39, 42] in the case of oriented surfaces. Their definition readily generalizes to higher dimensions.

A smooth fiber bundle $\pi : E \to B$ has a fiberwise tangent bundle $T_\pi E$ which is a vector bundle on E. If the fibers of E are compatibly oriented d-manifolds and $p \in H^{k+2n}(BSO(2n))$, we obtain a class $p(T_\pi E) \in H^{k+2n}(E)$. If the fibers of π are closed, in addition to being oriented, we have a fiber integration map $\pi_! : H^{k+2n}(E) \to H^k(B)$, and we define the MMM class associated to $p \in H^{k+2n}(BSO(2n))$ as

$$\kappa_p(\pi) = \pi_!(T_\pi E) \in H^{*-2n}(B).$$

There are universal classes $\kappa_p \in H^*(B\mathrm{Diff}^+(W))$ for any closed oriented manifold W, where $\mathrm{Diff}^+(W)$ denotes the group of orientation preserving diffeomorphisms.

These characteristic classes and their variants appear in applications of Theorems 1.7 and 1.9, as well as multiple other contexts (cf. [12, 13, 24, 30] and others).

1.4.2. Connected sums of products of spheres. An interesting special case concerns the manifold $W_g^{2n} = g(S^n \times S^n)$, which could perhaps be regarded as a higher-dimensional analogue of the genus g surfaces. This manifold is $(n-1)$-connected and $W_g \to BO(2n)$ induces the trivial map in π_n, so in this case the Moore–Postnikov factorization $X \to BO(2n)$ is the n-connected cover of $BO(2n)$, denoted $\theta^n : BO(2n)\langle n\rangle \to BO(2n)$ in [20] (the notation $BO(2n)\langle n+1\rangle$ is sometimes used for the same thing). The inclusion $D^{2n} \hookrightarrow W_g$ is $(n-1)$-connected, so $B\mathrm{Aut}(\theta, D^{2n})$ is contractible and Theorem 1.9 asserts that the map

$$B\mathrm{Diff}(W_g^{2n}, D^{2n}) \to \Omega^\infty(BO(2n)\langle n\rangle^{-\gamma})$$

induces an isomorphism in homology (onto a path component of the target) in the range $* \le (g-3)/2$.

The rational cohomology of $\Omega^\infty(BO(2n)\langle n\rangle^{-\gamma})$ corresponds to certain MMM-classes in the cohomology of $B\mathrm{Diff}(W_g^{2n}, D^{2n})$ and $B\mathrm{Diff}^\theta(W_g^{2n})$, namely those corresponding to the subring $H^*(BO(2n)\langle n\rangle;\mathbb{Q}) \subset H^*(BSO(2n);\mathbb{Q})$. To obtain $B\mathrm{Diff}^+(W_g)$ from $B\mathrm{Diff}^\theta(W_g)$ we take homotopy orbit space by the monoid of fiber homotopy equivalences of the fibration $BO(2n)\langle n\rangle \to BSO(2n)$, whose classifying space is weakly equivalent to $BO[0,n]$. This leads to the following consequence of Theorems 1.7 and 1.9.

Theorem 1.10 ([18–20]). *Let $\mathcal{B} \subset H^*(BSO(2n))$ be the set of monomials in the classes $\{e, p_i | \frac{n+1}{4} \le i \le n-1\}$ of total degree more than $2n$ and let $\mathcal{B}' = \mathcal{B} \cup \{ep_i | 1 \le i \le \frac{n}{4}\}$. Then the natural maps*

$$\mathbb{Q}[\kappa_c | c \in \mathcal{B}] \to H^*(B\mathrm{Diff}^\theta(W_g);\mathbb{Q}) \to H^*(B\mathrm{Diff}(W_g, D^{2n});\mathbb{Q})$$

and

$$\mathbb{Q}[\kappa_c | c \in \mathcal{B}'] \to H^*(B\mathrm{Diff}^+(W_g);\mathbb{Q})$$

are all isomorphisms in degrees $* \le (g-3)/2$.

1.4.3. Complete intersections. Theorems 1.7 and 1.9 are most useful when applied to manifolds for which the genus is easily estimated. As in [32], an interesting class of such examples arises from the Lefschetz hyperplane theorem. I will briefly outline the simplest non-trivial example.

Let $V_d \subset \mathbb{C}P^4$ denote the variety defined by a homogeneous polynomial of degree d (a section of the line bundle $\mathcal{O}(d)$). For generically chosen polynomial, V_d is a smooth manifold whose diffeomorphism type is independent of the polynomial. By [55], the genus of V_d is half the third Betti number, and an easy Chern class calculation then proves that $g(V_d) = (d^4 - 5d^3 + 10d^2 - 10d + 4)/2$, allowing for a calculation of cohomology in a range of degree growing as $d^4/4$.

The embedding $V_d \subset \mathbb{C}P^4$ classifies a natural complex line bundle over V_d which we shall denote L_d, and $c_1(L_d)$ is a generator of $H_2(V_d;\mathbb{Z}) \cong \mathbb{Z}$. We consider the group $\mathrm{Diff}(V_d, L_d)$ consisting of pairs of a diffeomorphism $\phi : V_d \to V_d$ and a (specified) isomorphism $L_d \to \phi^* L_d$. The classifying space $B\mathrm{Diff}(V_d, L_d)$ classifies smooth fiber bundles $\pi : E \to B$ with fibers diffeomorphic to V_d, together with a complex line bundle $L \to E$ such that the class $x = c_1(L) \in H_2(E;\mathbb{Z})$ restricts to a generator of H^2 of each fiber. For such bundles, the relevant characteristic classes are defined as follows. For each monomial $p = p_1^i p_2^j e^k \in H^*(BSO(6))$ and each $n \in \mathbb{Z}_{\geq 0}$, we have the class $x^n p(T_\pi E) \in H^{2n+4i+8j+6k}(E)$ and may define the corresponding MMM class

$$\kappa_{x^n p}(\pi) = \pi_!(x^n p(T_\pi E)) \in H^{2n+4i+8j+6k-6}(B)$$

with a universal class $\kappa_{x^n p} \in H^*(B\mathrm{Diff}(V_d, L_d))$. The space $B\mathrm{Diff}(V_d, L_d)$ is rationally equivalent to the space $B\mathrm{Diff}^\theta(V_d)$ of Theorems 1.7 and 1.9, so we may use those theorems to calculate the rational cohomology.

Theorem 1.11 ([19]). *Let $\mathcal{B} \subset H^*(BSO(6))$ denote the set of monomials in p_1, p_2 and e. The natural map*

$$\mathbb{Q}[\kappa_{x^n p} | p \in \mathcal{B}, 2n + |p| > 6] \to H^*(B\mathrm{Diff}(V_d, L_d); \mathbb{Q})$$

is an isomorphism in degrees $* \leq (d^4 - 5d^3 + 10d^2 - 10d - 2)/4$.

The forgetful map $B\mathrm{Diff}(V_d, L_d) \to B\mathrm{Diff}^+(V_d)$ can also be analyzed in cohomology. Up to homotopy, it is a principal $K(\mathbb{Z}, 2)$-bundle, and the restriction of the action map to $\mathbb{C}P^1 \subset \mathbb{C}P^\infty = K(\mathbb{Z}, 2)$ gives rise to a homomorphism

$$D : H^*(B\mathrm{Diff}(V_d, L_d); \mathbb{Q}) \to H^{*-2}(B\mathrm{Diff}(V_d, L_d); \mathbb{Q}), \tag{1.4}$$

encoding the differential in the Serre spectral sequence for the fibration associated to the action of $K(\mathbb{Z}, 2)$. That spectral sequence can then be used to deduce the following result from Theorem 1.11.

Corollary 1.12. *In the stable range, the homomorphism*

$$H^*(B\mathrm{Diff}^+(V_d); \mathbb{Q}) \to H^*(B\mathrm{Diff}(V_d, L_d); \mathbb{Q})$$

is injective and its image is precisely the kernel of the homomorphism D in (1.4). The homomorphism D is a derivation with respect to cup product, and in the stable range it is explicitly determined by the formula $D(\kappa_{x^n p}) = n\kappa_{x^{n-1} p}$.

Three of the MMM classes, namely κ_{x^3}, κ_{xp_1} and κ_e, have degree 0 and are really characteristic *numbers* of the fiber V_d, depending only on the number d. These appear in the formula for three of the classes $D(\kappa_{x^n p})$ in Theorem 1.11, leading to a numerically somewhat complicated formula for the subring $H^*(B\mathrm{Diff}^+(V_d);\mathbb{Q}) \subset \mathbb{Q}[\kappa_{x^n p}]$ in the stable range.

The space $B\mathrm{Diff}(V_d, L_d)$ admits a map from an algebraic counterpart, defined as follows. Let $\Gamma(\mathcal{O}(d))$ be the algebraic sections of the line bundle $\mathcal{O}(d)$ on $\mathbb{P}^4$. The open set $U \subset \mathbb{P}(\Gamma(\mathcal{O}(d)))$ consisting of homogeneous polynomials defining a smooth variety $V_d \subset \mathbb{P}^4$ admits an action of the group $\mathrm{Aut}(\mathbb{P}^4) = \mathrm{PGL}(5)$. The quotient stack $U/\!\!/\mathrm{Aut}(\mathbb{P}^4)$ is a moduli space of complete intersections, whose complex points map in a natural way to $B\mathrm{Diff}(V_d, L_d)$. It would be interesting to understand more about that map and its variations.

2. Moduli spaces and bordism categories

In this section we wish to explain the role played by bordism categories in the proof of Theorem 1.9.

Theorem 1.9 concerns a very particular *gluing* of manifolds, namely the iterated gluing $S^n \times S^n$ to W near the boundary of W, but it has long been realized (cf. [22, 35, 52]) that more general gluing constructions are important. A convenient encoding of such gluing is through *bordism categories*, whose objects are closed $(2n-1)$-dimensional manifolds, morphisms are $2n$-dimensional bordisms, and composition defined by gluing of bordisms.

2.1. Higher and lower categories. Categories of bordisms have appeared in many other contexts, and in many variations. The cobordism categories of [51] are mainly used to keep track of transitivity of the bordism relation. The category theoretical aspects play an important role in Atiyah's and Segal's definition of topological quantum field theory ([1, 50]), defined as functors from a category of bordisms to the category of vector spaces, subject to certain axioms. More recently, the most mathematically popular field theories have been the *extended* field theories, defined as functors out of a higher category of bordisms, bordisms between bordisms, etc. Much of the recent interest has been inspired by the classification theorem for field theories announced by Lurie ([34]). Giving the right definitions has proved delicate, and popular approaches, e.g. the Θ_n-spaces of [49] or the iterated complete Segal spaces of [2], have only recently been proved equivalent ([3, 7]).

For the purpose of calculating cohomology of $B\mathrm{Diff}(W)$ or $B\mathrm{Diff}^\theta(W)$, it is not desirable to involve any higher categories of bordisms, and in this document we shall work entirely with simplicial categories whose objects are closed manifolds. On the contrary, the full bordism category of all compact bordisms between closed manifolds is already too large. For example, in the oriented 2-dimensional case Theorem 1.9 concerns *connected* surfaces of high genus, and it is not desirable to have bordisms which have many path components of low genus. In fact, an important step (going back to [52]) in the proof is to reduce to a subcategory where morphisms are highly connected relative to one end.

2.2. A bordism category. We define a simplicial version of a category of bordisms, useful for proving Theorems 1.7 and 1.9, after explaining some conventions.

Remark 2.1 (Conventions on simplicial sets). In the following we shall often consider sim-

plicial sets whose p-simplices are certain *families* of objects, parametrized by the extended simplices $\Delta^p_e = \{t \in \mathbb{R}^{p+1} | \sum t_i = 1\}$. The families are certain maps $\pi : E \to \Delta^p_e$ and the simplicial structure is given by pull-back along face inclusion $\Delta^{p-1}_e \to \Delta^p_e$. There are well known ways to deal with the inherent set-theoretical problems involved in this type of definition, cf. e.g. [45, §1.1] or [35, §2.1], as follows. Choose once and for all a set Ω and insist that E is *equal* to a subset of $\Delta^p_e \times \Omega$ and that $\pi : E \to \Delta^p_e$ is equal to the composition $E \subset (\Delta^p_e \times \Omega) \to \Delta^p_e$, where the second map is the projection. When the cardinality of Ω is sufficiently large, the homotopy type of the resulting simplicial set will not depend on Ω. This requirement shall be imposed without further mention in all the following definitions, whenever a map $\pi : E \to \Delta^p_e$ or $\theta : X \to \Delta^p_e$ appears. When a pair of maps $(\pi, f) : E \to \Delta^p_e \times \mathbb{R}$ appears, we shall instead assume that $E \subset (\Delta^p \times \mathbb{R}) \times \Omega$ and that (π, f) is equal to the projection.

Remark 2.2 (Conventions on boundaries). We shall consider various moduli spaces of manifolds with boundary. However, we shall generally eschew actual boundries, replacing them instead by germs of open manifolds containing them. For example, instead of a compact bordism W with incoming boundary P_0 and outgoing boundary P_1, we will consider a triple (t, E, f), where $t \geq 0$, E is a smooth manifold without boundary, $f : E \to \mathbb{R}$ is a smooth map which has 0 and t as regular values and such that $W = f^{-1}([0, t]) \subset E$ is compact. Such triples will be considered up to the equivalence relation generated by identifying (t, E, f) with $(t, E', f|'_E)$ whenever $E' \subset E$ is an open subset containing W. Instead of taking the actual incoming boundary $P = f^{-1}(0) \subset W$, we would consider (E, f) up to the coarser equivalence relation generated by being equal near P.

This convention has various technical advantages. For example, we will only ever need to discuss tangential structures on manifolds of the same dimension. More importantly, the germs give a well defined gluing of manifolds: a diffeomorphism $\partial W \cong \partial W'$ does not quite induce a well defined smooth structure on the topological manifold $W \cup_\partial W'$.

We shall need a simplicial category of bordisms equipped with tangential structures. Since the entire definition is rather long, we first define a category of bordisms without structure.

Definition 2.3. Let $\mathscr{C}'$ be the simplicial category where $N_q\mathscr{C}'_p$ is the set of equivalence classes of triples (t, π, f), where $t : \Delta^p_e \to (\mathbb{R}_{\geq 0})^q$ is a smooth function, $\pi : E \to \Delta^p_e$ is a submersion from a smooth manifold E of dimension $p + 2n$, and $f : E \to \mathbb{R}$ is a smooth function. Writing $a_i = \sum_{j=1}^i t_j$, this data is subject to the requirement that the functions $(\pi, f - a_i \circ \pi) : E \to \Delta^p_e \times \mathbb{R}$ are transverse to the submanifold $\Delta^p_e \times \{0\}$ for all $i = 0, \dots, q$. Writing $E_{ij} \subset E$ for the submanifold $(f - a_i \circ \pi)^{-1}(\mathbb{R}_{\geq 0}) \cap (f - a_j \circ \pi)^{-1}(\mathbb{R}_{\leq 0})$, we require that the restriction $\pi|_{E_{0q}} : E_{0q} \to \Delta^p_e$ is a proper map. Finally, the data is subject to the equivalence relation generated by replacing (π, f) by their restriction to an open subset $E' \subset E$ containing E_{0q}.

The face maps in the p-direction are defined in the obvious way, pulling all the data back along a face map $\Delta^{p-1}_e \to \Delta^p_e$. The face map $d_i : N_q\mathscr{C}'_p \to N_{q-1}\mathscr{C}'_p$ replaces $(t_1, \dots, t_q)$ by $(t_1, \dots, t_i + t_{i+1}, \dots, t_q)$ if $0 < i < q$. If $i = q$ it forgets t_q, and if $i = 0$ it forgets t_1 and additionally replaces $(\pi, f) : E \to \Delta^p_e \times \mathbb{R}$ by its pullback along the map $(x, s) \mapsto (x, s - t_1 \circ \pi(x))$.

With appropriate set-theoretic conventions, cf. Remark 2.1, the simplicial space $[q] \mapsto N_q\mathscr{C}'$ is the nerve of a simplicial category $\mathscr{C}'$. Informally, the morphisms are (Δ^p_e-parameter

families of) compact $2n$-dimensional bordisms E_{01}, and composition is defined by gluing; the germ of a thickening $E \supset E_{01}$ could be thought of as a technical detail.

Definition 2.4. Let $\mathscr{C}$ be the simplicial category where $N_q\mathscr{C}_p$ is the set of (t, π, f, x) where $(t, \pi, f) \in N_q\mathscr{C}'_p$ is as before, and $x = (c, \theta, \ell)$ consists of the following bundle data. Writing $T_\pi E$ for the fiberwise tangent bundle of π, $c : E \to BO(2n)$ is a map covered by a vector bundle map $\bar{c} : T_\pi E \to \gamma_{2n}$. θ is an n-coconnected Serre fibration $\theta : X \to \Delta^p_e \times BO(2n)$ such that X is weakly equivalent to a CW complex with finite n-skeleton. Finally, $\ell : E \to X$ is a map with $\theta \circ \ell = (\pi, c)$.

If we fix an n-coconnected Serre fibration $\theta_0 : X_0 \to BO(2n)$, the simplicial subcategory of $\mathscr{C}$ where $\theta : X \to \Delta^p_e \times BO(2n)$ is equal to $\mathrm{id} \times \theta_0 : \Delta^p_e \times X_0 \to \Delta^p_e \times BO(2n)$ shall be denoted $\mathscr{C}_{\theta_0}$.

Remark 2.5. The simplicial category $\mathscr{C}_\theta$ is a simplicial model for the topological category denoted $\mathscr{C}_\theta$ in [22]. Allowing θ to vary as in the above definition of $\mathscr{C}$ models the functoriality of $\theta \mapsto \mathscr{C}_\theta$. In fact, we can let $\mathscr{H}_p$ be the category whose objects are the n-coconnected Serre fibrations $\theta : X \to \Delta^p_e \times BO(2n)$ such that X is weakly equivalent to a CW complex with finite n-skeleton, and morphisms $\mathscr{H}_p(\theta, \theta')$ the set of maps $\phi : X \to X'$ with $\theta' \circ \phi = \theta$. This defines a simplicial category $\mathscr{H}$ and there is an obvious forgetful functor $\mathscr{C} \to \mathscr{H}$ which could perhaps be viewed as modelling $\mathscr{C}$ as a homotopy colimit of a functor $\theta \mapsto \mathscr{C}_\theta$ from $\mathscr{H}$ to the self-enriched category of small simplicial categories.

Let us write $B\mathscr{C}_\theta$ for the classifying space of the simplicial category $\mathscr{C}_\theta$, i.e. the topological space obtained by realizing in both directions. The following result, obtained in joint work with I. Madsen, U. Tillmann, and M. Weiss, determines the homotopy type of this classifying space.

Theorem 2.6 ([22]). *Let $\theta : X \to BO(d)$ and write $X^{-\theta}$ for the Thom space of the inverse of the bundle classified by θ (graded so that the Thom class is in degree $-d$). There is a weak equivalence*

$$B\mathscr{C}_\theta \simeq \Omega^{\infty-1} X^{-\theta}. \tag{2.1}$$

Using this result, the connection between $B\mathrm{Diff}^\theta(W)$ and $\Omega^\infty X^{-\theta}$ expressed in Theorems 1.7 and 1.9 goes via the based loop space $\Omega B\mathscr{C}_\theta$, or more precisely a space of paths in $B\mathscr{C}_\theta$ with fixed endpoints.

2.3. The moduli spaces. Let us explain how the bordism categories $\mathscr{C}$ and $\mathscr{C}_\theta$ are related to the moduli spaces $B\mathrm{Diff}^\theta(W)$ from Section 1.

The unique zero-simplex of $N_0\mathscr{C}_\theta$ with empty underlying manifold shall be denoted simply by $\emptyset$. If $P \in N_0\mathscr{C}_\theta$ is some other zero-simplex, the morphism space $\mathscr{C}_\theta(P, \emptyset)$ is quite closely related to the spaces $B\mathrm{Diff}^\theta(W)$. Indeed, the space $\mathscr{C}_\theta(P, \emptyset)$ is the "moduli space of null bordisms" of P. Ignoring the distinction between closed $(2n-1)$-dimensional manifolds and germs of $2n$-dimensional thickenings, $\mathscr{C}(P, \emptyset)$ is the space of compact $2n$-manifolds W with $\partial W = P$, equipped with a lift of the classifying map $TW : W \to BO(2n)$ over the fixed $\theta_0 : X_0 \to BO(2n)$, extending a given lift over P. Let us define the following subspaces.

Definition 2.7. For a zero-simplex $P \in N_0\mathscr{C}_\theta$, define

$$\mathscr{N}(P) \subset \mathscr{C}(P, \emptyset)$$

as the subspace defined by the requirement that, in the notation of Definition 2.4, the map $\ell : E \to X$ is n-connected.

The space $\mathscr{N}(P)$ is then the moduli space of null bordisms W of P, equipped with lifts to X_0 of a classifying map for their tangent bundle, extending a specified lift over $P = \partial W$, subject to the requirement that $W \to X$ be n-connected. The bundle condition is then nothing but an identification, up to homotopy equivalence, of the factorization $W \to X \to BO(2n)$ with the Moore–Postnikov factorization of $W \to BO(2n)$. From these considerations a weak equivalence

$$\mathscr{N}(P) \simeq \coprod_W B\mathrm{Diff}^\theta(W), \tag{2.2}$$

may be deduced, where the disjoint union is over representatives W for the set $\mathscr{Y}(P)$ from Definition 1.1.

Unfortunately $\mathscr{N}(-)$ is not a subfunctor of the representable functor $\mathscr{C}(-, \emptyset)$, because pre-composing with a morphism does not always preserve the connectivity conditions imposed in $\mathscr{N}$. Motivated by this observation, we consider the following subcategories.

Definition 2.8. Define subcategories $\mathscr{C}^i_\theta, \mathscr{C}^o_\theta \subset \mathscr{C}_\theta$, with the same objects as $\mathscr{C}_\theta$, in the following way. A morphism $f \in \mathscr{C}_\theta(P_0, P_1)$ is in $\mathscr{C}^o_\theta(P_0, P_1)$ provided the underlying bordism satisfies that the inclusion of the outgoing boundary be $(n-1)$-connected (in the notation of Definition 2.4, the inclusion $(f - \pi \circ t)^{-1}(0) \hookrightarrow E$ should be $(n-1)$-connected). To be in $\mathscr{C}^i_\theta$ we instead require that the inclusion of the incoming boundary be $(n-1)$-connected.

In the special case $n = 1$ the categories $\mathscr{C}^i_\theta$ and $\mathscr{C}^o_\theta$ are sometimes called *positive boundary* subcategories. In this case the condition is simply that every path component of a bordism is required to have non-empty incoming boundary, respectively non-empty outgoing boundary.

2.4. Group completion and stable homology. The association $P \mapsto \mathscr{N}(P) \subset \mathscr{C}_\theta(P, \emptyset)$ defines a functor from $\mathscr{C}^o_\theta$ to simplicial sets. Using the weak equivalences (2.1) and (2.2), we can now explain the map appearing in Theorem 1.9, which arises from a special case of a very general principle. If C is a simplicial category and $F : C \to \mathrm{sSet}$ is a simplicially enriched functor, there is a simplicial category $C \wr F$ and a functor $C \wr F \to C$. The fiber of the induced map $B(C \wr F) \to BC$ over a point $c \in N_0 C \subset C$ is $F(c)$, and the inclusion into the homotopy fiber gives a map $F(c) \to \mathrm{hofib}_c(B(C \wr F) \to BC)$. This homotopy fiber is weakly equivalent to ΩBC provided $B(C \wr F)$ contractible, which is the case if for example F is representable, or even just homotopy ind-representable (i.e. a filtered homotopy colimit of representable functors). Given any inverse system $k = (P_0 \xleftarrow{K_1} P_1 \xleftarrow{K_2} \dots)$ in $\mathscr{C}_\theta$ we therefore obtain a map

$$\mathscr{C}_\theta(k, \emptyset) \to \Omega B \mathscr{C}_\theta,$$

where $\mathscr{C}_\theta(k, -)$ denotes the ind-representable functor $Q \mapsto \mathrm{hocolim}\, \mathscr{C}_\theta(P_i, Q)$. If the morphisms in the inverse system are in the subcategory $\mathscr{C}^i_\theta$ we likewise obtain a map

$$\mathscr{C}^i_\theta(k, \emptyset) \to \Omega B \mathscr{C}^i_\theta. \tag{2.3}$$

We may restrict to the subspace $\mathscr{N}(k) = \mathrm{hocolim}\, \mathscr{N}(P_i) \subset \mathscr{C}_\theta(k, \emptyset)$ to obtain a map

$$\mathscr{N}(k) \to \Omega B \mathscr{C}_\theta.$$

By Theorem 2.6, the right hand side is a model for $\Omega^\infty X^{-\theta}$, and by the equivalence (2.2), the left hand side is the disjoint union of direct limits of spaces of the form $B\mathrm{Diff}^\theta(W)$. If we choose an appropriate inverse system k, these direct limits become $B\mathrm{Diff}^\theta(W\#W_\infty)$. More precisely, we may for each object $P \in \mathscr{C}_\theta$ choose an endomorphism $t_P \in \mathscr{C}_\theta(P,P)$ whose underlying bordism is diffeomorphic to $([0,1]\times P)\#(S^n\times S^n)$ and form the direct system $t_P^{-1} = (P \xleftarrow{t_P} P \xleftarrow{t_P} \dots)$. Then taking direct limit of the weak equivalence (2.2) gives a weak equivalence

$$\begin{aligned}\mathscr{N}(t_P^{-1}) &\simeq \mathrm{hocolim}\left(\coprod_W B\mathrm{Diff}^\theta(W) \xrightarrow{s} \coprod_W B\mathrm{Diff}^\theta(W) \xrightarrow{s} \dots\right)\\ &\simeq \mathbb{Z}\times\coprod_W B\mathrm{Diff}^\theta(W\#W_\infty),\end{aligned}$$

where s again denotes the map which forms connected sum with $S^n\times S^n$, the first disjoint union is over $[W]\in\mathscr{Y}_\theta$, and the second is over the quotient of $\mathscr{Y}_\theta$ by the equivalence relation generated by $[W]\sim[W\#(S^n\times S^n)]$.

With this notation, the following result is a strengthening of Theorem 1.9. The implied bijection on π_0 is essentially equivalent to [32, Theorem C], as discussed in Section 1.1 above.

Theorem 2.9. *For connected X and any non-empty object $P\in\mathscr{C}_\theta$, the map $\mathscr{N}(t_P^{-1})\to\Omega B\mathscr{C}_\theta$ induces an isomorphism in integral homology.*

Notes on the proof. Most of the proof is in [20], but the result claimed here is slightly stronger. We explain the two main ingredients in the proof, full details will appear in [19].

The first ingredient is the infinite-genus homological stability theorem stated as Addendum 1.8 above. As stated there, nothing is said about π_0, but a slightly modified version of the statement, also proved in [19], asserts that an appropriate disjoint union of the maps in Addendum 1.8 is a homology equivalence (not just after restricting to a map between path connected spaces). It implies that for certain inverse systems $k = (P_0 \xleftarrow{K_0} P_1 \xleftarrow{K_1} \dots)$, the ind-representable functor $Q\mapsto\mathscr{C}_\theta^i(k,Q)$ sends all morphisms in $\mathscr{C}_\theta^i$ to homology equivalences. By a general result of [36], used in a similar way as in [52], this implies that the map $\mathscr{C}_\theta^i(k,\emptyset)\to\Omega B\mathscr{C}_\theta^i$ from (2.3) is a homology equivalence as well.

The requirement on the direct system $k = (P_0 \xleftarrow{K_0} P_1 \xleftarrow{K_1} \dots)$ is that it must be a "universal θ-end", in the language of [20], which will be the case if the morphisms K_i are in both $\mathscr{C}_\theta^o$ and $\mathscr{C}_\theta^i$ and the map $K_i\to X$ underlying the tangential structure is n-connected for all i. That condition also implies that $\mathscr{N}(k)\simeq\mathscr{C}^i(k,\emptyset)$. The homological stability results of [19] is then used again to produce homology equivalences $\mathscr{N}(t_P^{-1})\to\mathscr{N}(k)$ for any non-empty object P. This combines to a homology equivalence $\mathscr{N}(t_P^{-1})\to\Omega B\mathscr{C}_\theta^i$ for any non-empty object P.

The second ingredient is a theorem of [20] (and in the case $n=1$, also [21] and [22]) asserting that the inclusion $B\mathscr{C}_\theta^i\to B\mathscr{C}_\theta$ is a weak equivalence. □

3. Other approaches to $B\mathrm{Diff}(W)$

A well established approach to understanding $B\mathrm{Diff}(W)$ goes via the *block* diffeomorphism group $\widetilde{\mathrm{Diff}}(W)$ and the corresponding moduli space $B\widetilde{\mathrm{Diff}}(W)$. It seems quite different

from the theory presented here, and a deeper understanding of their relationship seems worthwhile.

For a fixed dimension d, there is a simplicial set Man^d whose p-simplices are the maps $\pi : E \to \Delta^p_e$ where E is a smooth $(d+p)$-manifold without boundary and π is a smooth map which is proper (i.e. the inverse image of a compact set is compact) and a submersion. Its homotopy type is the disjoint union of $B\mathrm{Diff}(W)$ over all closed smooth d-manifolds W, one in each diffeomorphism class.

There is a larger space $\widetilde{\mathrm{Man}}^d$ defined in the same way, except that the condition on π is weakened to requiring only that for all morphisms $\theta : [q] \to [p]$ in Δ, the map $\pi : E \to \Delta^p_e$ is transverse to $\Delta^q_e \to \Delta^p_e$, and the resulting square

$$\begin{array}{ccc} \theta^* E & \longrightarrow & E \\ \downarrow & & \downarrow \pi \\ \Delta^q & \xrightarrow{\theta} & \Delta^p \end{array}$$

is homotopy cartesian (i.e. the top horizontal map is a homotopy equivalence). Thus the 0-simplices are the same for the two spaces, essentially the set of all closed d-manifolds, whereas the 1-simplices of $\widetilde{\mathrm{Man}}^d$ are essentially the h-cobordisms, etc.

The path component of Man^d containing a 0-simplex W is a model for the space $B\mathrm{Diff}(W)$, and the path component of $\widetilde{\mathrm{Man}}^d$ containing W is a model for $B\widetilde{\mathrm{Diff}}(W)$. F. Quinn's thesis [45] established a homotopy fiber sequence

$$G(W)/\widetilde{\mathrm{Diff}}(W) \to \mathrm{Map}(W, G/O) \to \Omega^{\infty+d} L(\pi_1(W)),$$

where $G(W)$ denotes the monoid of self-homotopy equivalences of W, $G(W)/\widetilde{\mathrm{Diff}}(W)$ denotes the homotopy fiber of a map $B\widetilde{\mathrm{Diff}}(W) \to BG(W)$, G/O denotes the homotopy fiber of the stable J-homomorphism $BO \to BG$, and $L(\pi_1 W)$ is the quadratic L-theory spectrum. (More precisely, $G(W)/\widetilde{\mathrm{Diff}}(W)$ is one of the path components of the fiber, which in general need not be path connected.) The latter is defined purely algebraically and is well understood, at least when W is simply connected. The space $\mathrm{Map}(W, G/O)$ is a purely homotopy theoretic object, although in general quite a difficult one to understand explicitly. This in principle pins down the homotopy type of the space $B\widetilde{\mathrm{Diff}}(W)$, as the homotopy orbit space of $G(W)$ acting on $G(W)/\widetilde{\mathrm{Diff}}(W)$ whose homotopy type is in turn described by Quinn's fibration sequence. In practice, the homotopy types of G/O and $G(W)$ are quite complicated themselves, but for instance in rational homotopy one can sometimes say a great deal about $B\widetilde{\mathrm{Diff}}(W)$ this way, cf. e.g. [5].

To obtain information about the more geometric object $B\mathrm{Diff}(W)$ by this method, the second step is to understand $\widetilde{\mathrm{Diff}}(W)/\mathrm{Diff}(W)$, the homotopy fiber of $B\mathrm{Diff}(W) \to B\widetilde{\mathrm{Diff}}(W)$. This is done via algebraic K-theory, in the form of Waldhausen's functor $A(W)$. M. Weiss and B. Williams ([57]) constructed a highly connected map

$$\widetilde{\mathrm{Diff}}(W)/\mathrm{Diff}(W) \to \Omega^\infty(\Sigma^{-1}\mathrm{Wh}^{\mathrm{Diff}}(W)_{hC_2}), \tag{3.1}$$

where $\mathrm{Wh}^{\mathrm{Diff}}(W)$ is the Whitehead spectrum of W, in turn described by the splitting $A(W) \simeq Q(W_+) \times \mathrm{Wh}^{\mathrm{Diff}}(W)$ (cf. [54] and Rognes' article in these proceedings), and

the subscript hC_2 denotes the homotopy orbit spectrum. The connectivity of the map (3.1) depends on the *concordance stable range* which is known [29] to be $\gtrsim \dim(M)/3$.

This two-step approach to $B\mathrm{Diff}(W)$ has an analogue for topological manifolds, describing $B\mathrm{Top}(W)$, where $\mathrm{Top}(W)$ denotes the topological group of homeomorphisms of W. There are block version $B\widetilde{\mathrm{Top}}(W)$ and $G(W)/\widetilde{\mathrm{Top}}(W)$, whose homotopy type is understood by an analogue of the fibration sequence (3.1); the homotopy fiber $\widetilde{\mathrm{Top}}(W)/\mathrm{Top}(W)$ of a map $B\mathrm{Top}(W) \to B\widetilde{\mathrm{Top}}(W)$ is again described in a concordance stable range via algebraic K-theory, cf. [54] and [57]. The two-step approach via block homeomorphisms can also be combined into one, cf. [58].

In comparison with the approach to $B\mathrm{Diff}(W)$ outlined in Section 1.3, the following are some of the main conceptual differences.

- Theorems 1.7 and 1.9 are fundamentally homological, and at best determines the homotopy type of $B\mathrm{Diff}(W)^+$ (or $B\mathrm{Diff}^\theta(W)^+$), where the plus denotes Quillen's plus construction. In particular, it would be very difficult to deduce much about the diffeomorphism group itself from this formula. In contrast, the approach via $B\widetilde{\mathrm{Diff}}(W)$ is homotopical, and the homotopy theoretic approximation to $B\mathrm{Diff}(W)$ it provides may be looped to an approximation of $\mathrm{Diff}(W)$.
- Both approaches describe $B\mathrm{Diff}(W)$ only below a certain stable range. In theorems 1.7 and 1.9 the range depends on the *genus* of W, whereas in the approach via $B\widetilde{\mathrm{Diff}}(W)$ the stable range depends on the *dimension* of W.
- The homotopy theoretic calculations involved are somewhat different. For example, the approach via $B\widetilde{\mathrm{Diff}}(W)$ involves the monoid $G(W)$ of all homotopy equivalences of W, whereas the approach via Theorem 1.9 instead involves the monoid $\mathrm{Aut}(\theta)$.

4. Unstable cohomology

Let me briefly discuss what is known about about the cohomology of moduli spaces of manifold outside the stable range, focusing on the case $W = W_g = g(S^n \times S^n)$. In the notation of Section 1.4, we consider the ring homomorphisms

$$\mathbb{Q}[\kappa_c | c \in \mathcal{B}] \to H^*(B\mathrm{Diff}(W_g, D^{2n}); \mathbb{Q}) \tag{4.1}$$

and

$$\mathbb{Q}[\kappa_c | c \in \mathcal{B}'] \to H^*(B\mathrm{Diff}^+(W_g); \mathbb{Q}) \tag{4.2}$$

which are isomorphisms in the stable range, known to be at least $* \leq (g-1)/2$ for $n \geq 3$ and $* \leq (g-1)/1.5$ for $n = 1$. However, the homomorphisms (4.1) and (4.2) are still defined outside this stable range and one may ask for an estimate of how non-trivial they are. We shall call the image of either map the *tautological subring* of cohomology, following established terminology in the case $n = 1$. The kernel is the ideal consisting of the relations satisfied universally by these classes.

Even for $n = 1$, the cokernel is still largely mysterious: various constructions are known to produce non-zero elements in the cokernel, but no pattern (even conjecturally) is known. By contrast, much effort by many people has gone into understanding the kernel of these maps when $n = 1$, leading to a complete understanding of the tautological subring for $g \leq 23$, as well as a conjectural description for all g, cf. e.g. [14, 15, 44].

For larger n, I. Grigoriev has devised a method for producing relations among the tautological classes for finite g, at least when $n = \dim(W_g)/2$ is odd. His method generalizes [40] and [48], and puts a lower bound on the size of the kernels of (4.1) and (4.2).

Theorem 4.1 ([24]). *For $n = (\dim(W_g))/2$ odd, the images of the ring maps* (4.1) *and* (4.2) *are finitely generated $\mathbb{Q}$-algebras. The kernel is non-trivial in degree $6g + 6$ if $n \equiv 1 \mod 4$ and in degree $2g + 2$ if $n \equiv 3 \mod 4$.*

The non-triviality of the kernel in particular shows that if the bound $* \leq (g - 3)/2$ in Theorem 1.7 can be improved to $* \leq ag + b$, then a is at most 2, at least if $n \equiv 3 \mod 4$. Hence the optimal such a is somewhere in the interval $[.5, 2]$.

Recent joint work between Grigoriev, Randal-Williams and myself has addressed the question of whether the tautological ring might in fact be finite dimensional as a *vector space* over $\mathbb{Q}$. We prove the following result.

Theorem 4.2. *Let $n = \dim(W_g)/2$ be an odd number and let $g \geq 2$. Then the image of the ring map* (4.1) *is a finite dimensional $\mathbb{Q}$-vector space and the image of the ring map* (4.2) *has Krull dimension precisely $(n - 1)$.*

In particular, the space $B\mathrm{Diff}^+(W_g)$ is not rationally equivalent to a finite CW complex except when $n = 1$. It seems unlikely that $B\mathrm{Diff}(W_g, D^{2n})$ could be homotopy equivalent to a finite dimensional CW complex for any $n > 1$.

5. Further moduli spaces

The theory presented in this survey is most well developed for smooth manifolds of even dimension. I now wish to briefly discuss moduli spaces of other objects, which seem sufficiently similar to $B\mathrm{Diff}(W)$ that one might expect that some or all of the theory will have an analogue for those moduli spaces.

5.1. Embedded manifolds. The group $\mathrm{Diff}(W)$ acts freely on the space of embeddings of W into any other manifold. The orbit space $\mathrm{Emb}(W, M)/\mathrm{Diff}(W)$ is the space of submanifolds of M diffeomorphic to W. When $M = \mathbb{R}^\infty$, the quotient space $\mathrm{Emb}(W, \mathbb{R}^\infty)/\mathrm{Diff}(W)$ is a convenient model for $B\mathrm{Diff}(W)$. It is also interesting to study $\mathrm{Emb}(W, M)/\mathrm{Diff}(W)$ for $M = \mathbb{R}^k$ for finite k, or for even more general manifolds M. In the case where W is an oriented 2-manifold, F. Cantero and O. Randal-Williams ([10]) have proved a homological stability result very similar to Harer's, provided $\dim M \geq 5$, and described the stable homology in terms of a space of compactly supported sections of a certain fibration over M.

5.2. Discretized diffeomorphism groups. The moduli spaces from Section 1.4.2 are classifying spaces of $\mathrm{Diff}(W_g^{2n}, D^{2n})$ considered as a topological group in the C^∞ topology. However, it makes perfect sense to consider also the underlying group with the discrete topology. Thus we write $\mathrm{Diff}^\delta(W_g, D)$ for the discrete group of diffeomorphisms of W_g which restrict to the identity on a neighborhood of D. S. Nariman has proved an analogue of Theorem 1.7 for these: There is a natural group homomorphism $\mathrm{Diff}^\delta(W_g, D) \to \mathrm{Diff}^\delta(W_{g+1}, D)$, induced by forming connected sum with $S^n \times S^n$ and extending by the identity diffeomorphism. Up to conjugation, this homomorphism is independent of choices, and [43] shows that the induced map in group homology is an isomorphism in a stable range.

The stable homology is expressed in terms of classifying spaces for foliations.

5.3. Odd dimensions. As proved by Meyer ([37]), any manifold which fibres over an odd dimensional manifold must have vanishing signature. Another proof was given by Ebert ([12]), who also pointed out that this implies that any analogue of Theorem 1.9 for odd dimensional manifolds must differ significantly from the even dimensional case.

Consider for example the manifolds $W_g^{2n+1} = g(S^n \times S^{2n+1})$ and choose some embedded disk $D^{2n+1} \subset W_g^{2n+1}$. Writing $\mathrm{Diff}(W_g^{2n+1}, D^{2n+1})$ for the topological group of diffeomorphisms fixing the disk pointwise, the Pontryagin–Thom construction can be used to define a map

$$B\mathrm{Diff}(W_g^{2n+1}, D^{2n+1}) \to \Omega^\infty(BO(2n+1)\langle n\rangle^{-\theta^*\gamma})$$

where $\theta : BO(2n+1)\langle n\rangle \to BO(2n+1)$ denotes the n-connected cover. It seems tempting to conjecture that the induced map in homology be an isomorphism in some stable range. As pointed out in [12] this cannot be true, even rationally: there are non-trivial classes in the rational cohomology of the codomain (viz. the MMM classes associated to the $\mathcal{L}$-classes in Hirzebruch's signature formula) which pull back to the zero class in $B\mathrm{Diff}(W_g^{2n+1}, D^{2n+1})$, for all large g.

One would expect that the limiting homology is described by some infinite loop space, but it is an open question which one it is. For $n = 1$, A. Hatcher has announced a proof that it is $Q(BSO(4)_+)$.

5.4. Other categories of manifolds. It is an interesting question whether the methods discussed in this survey may be applied in the setting of topological manifolds, or piecewise linear manifolds.

In a related direction, I. Madsen and A. Berglund ([6], [5]) have studied the case where $\mathrm{Diff}(W)$ is replaced by the monoid $G(W)$ consisting of self-homotopy equivalences of W (restricting to the identity near ∂W). Making extensive use of rational homotopy theory, they prove homological stability for $G(W_{g,1})$ and find a formula for the rational stable cohomology which intriguingly involves the *unstable* rational cohomology of automorphism groups of free groups.

Acknowledgements. S. Galatius was partially supported by NSF grant DMS-1105058. It is a pleasure to thank my long-term collaborator Oscar Randal-Williams, with whom many of the results presented here are obtained. I also wish to acknowledge the lasting impact of the work by Ib Madsen, Ulrike Tillmann and Michael Weiss, which has greatly influenced the work presented here.

On the non-existence of elements of Kervaire invariant one

Michael A. Hill, Michael J. Hopkins, and Douglas C. Ravenel

Abstract. We sketch a proof of our solution to the Kervaire invariant one problem, showing that there are Kervaire invariant one manifolds only in dimensions 2, 6, 14, 30, 62, and possibly 126. This resolves a long-standing problem in algebraic and differential topology.

Mathematics Subject Classification (2010). Primary 55Q45; Secondary 57R60.

Keywords. Kervaire invariant, algebraic topology, equivariant homotopy, bordism, slice filtration.

1. Introduction

At the 1936 ICM in Oslo, Norway, Lefschetz presented on behalf of Pontryagin the following result:

Pontryagin's Theorem. *The second stable homotopy group of spheres is trivial.*

His approached this computation via geometry, establishing a perfect dictionary between geometric information, in this case the bordism classes of framed manifolds, and algebraic topology, here the homotopy groups of spheres. He deduced his theorem from the classification of surfaces, using his newly developed technique of framed surgery to reduce the genus of a framed surface until he had a framed sphere. Unfortunately, Pontryagin made a subtle mistake: it is not always possible to reduce the genus of a framed manifold by framed surgery. In fact, there is a quadratic obstruction to performing framed surgery, and this obstruction is non-trivial on, say, the 2-torus with the framing induced by the Lie multiplication.

Pontryagin's techniques have remained influential in algebraic topology, and his approach to bordism via surgery is still a very powerful tool. The obstruction to surgery is our primary object of study, the Kervaire invariant.

The early 1960s saw the topology community rocked by two related theorems. Milnor showed that there are smooth manifolds homeomorphic to the 7 sphere but not diffeomorphic to it [34]. Kervaire then showed that there are topological (really piecewise-linear), framed 10-manifolds that do not admit any smooth structure [24]. Kervaire did this by defining a quadratic form μ_f associated to a framing f on M:

$$\mu_f \colon H_5(M; \mathbb{Z}/2) \to \mathbb{Z}/2$$

Proceedings of the International Congress of Mathematicians, Seoul, 2014

which refines the intersection form $- \cap -$ in the sense that

$$\mu(x+y) = \mu(x) + \mu(y) + x \cap y.$$

The distinguishing feature of quadratic forms with values in $\mathbb{Z}/2$ is their Arf invariant, and Kervaire showed that for smooth manifolds M, the Arf invariant of μ_f vanishes for every f. He then produced a topological manifold and framing for which μ_f had nontrivial Arf invariant, proving the result. Kervaire's quadratic form is exactly the obstruction encountered by Pontryagin, just in dimension 10.

These results set the stage for Kervaire-Milnor's treatment of smooth structures on spheres [25]. They first observed that the set of smooth structures on the n-sphere is finite if $n > 4$, and that the diffeomorphism classes of n-spheres forms a group Θ_n under connected sum. Kervaire and Milnor observed that any exotic smooth structure on an n-sphere still produces an n-sphere, and hence is a framed manifold. They used this to produce a map

$$\psi_n \colon \Theta_n \to \pi_n S^0 / Im(J),$$

where $Im(J)$ is the subgroup of $\pi_n S^0$ consisting of all possible framings on the standard n-sphere. This uses Pontryagin's dictionary, as $\pi_n S^0$ is the same as the bordism classes of framed n-manifolds.

The kernel of ψ_n is, by definition, the collection of exotic spheres which bound frameable manifolds, and Kervaire-Milnor call this group bp_n. This group is cyclic, and

$$|bp_n| = \begin{cases} 1 & n \equiv 0 \mod 2 \\ 1 \text{ or } 2 & n \equiv 1 \mod 4 \\ 2^{2k-2}(2^{2k-1}-1)num\left(\frac{4B_k}{k}\right) & n = 4k-1 > 3, \end{cases}$$

where B_k is the k^{th} Bernoulli number. If n is not congruent to 2 modulo 4, then Kervaire and Milnor showed that ψ_n is surjective. When n is congruent to 2 modulo 4, there is a longer exact sequence

$$0 \to bp_n \to \Theta_n \xrightarrow{\Psi_n} \pi_n^s / Im(J) \xrightarrow{\Phi_n} \mathbb{Z}/2 \to \Theta_{n-1}^{bp} \to 0.$$

The map Φ_n is *exactly* the Kervaire invariant, so this allows us to describe our problem.

Problem. *For which n is there a manifold of Kervaire invariant 1?*

Equivalently, for which n are there smooth manifolds *not* framed bordant to an exotic sphere?

Browder greatly reduced the problem, tethering it to the fate of elements in the Adams spectral sequence. To describe this, we need a small amount of background.

Adams introduced his eponymous spectral sequence to solve the Hopf invariant one problem (and thereby to also determine which vector spaces $\mathbb{R}^n$ admit a division algebra structure) [1]. The spectral sequence starts by considering mod 2 cohomology together with its ring of natural endomorphisms $\mathcal{A}$, the Steenrod algebra. For Y of finite type, the Adams spectral sequence has the form

$$E_2^{s,t} = \operatorname{Ext}_{\mathcal{A}}^{s,t}\left(H^*(Y), \mathbb{Z}/2\right) \Rightarrow \pi_{t-s}(Y) \otimes \mathbb{Z}_2.$$

The most interesting cases for us is $Y = S^0$, where we are computing the derived $\mathcal{A}$-module endomorphisms of $\mathbb{Z}/2$. This is a bi-graded commutative algebra, the values of which for small s have been completely determined.

Adem showed that

$$\mathrm{Ext}_{\mathcal{A}}^{1,t}(\mathbb{Z}/2, \mathbb{Z}/2) = \begin{cases} \mathbb{Z}/2 \cdot h_j & t = 2^j \\ 0 & \text{otherwise.} \end{cases}$$

These elements have geometric content: the survival of h_j in the Adams spectral sequence is equivalent to the existence of an element of Hopf invariant one.

Adams showed that these elements generate Ext for small values of s. In particular

$$\mathrm{Ext}_{\mathcal{A}}^{2,?} = \{h_i h_j | |i - j| \neq 1\}.$$

Moreover, he produced a differential

$$d_2(h_j) = h_0 h_{j-1}^2$$

for $j \geq 4$.

Browder's reformulation of the Kervaire invariant one problem also uses the Adams spectral sequence.

Theorem (Browder [10]). *There can only be elements of Kervaire invariant one in dimensions of the form $2^k - 2$. Any element of Kervaire invariant one is detected in the Adams spectral sequence by h_{k-1}^2.*

Since h_1, h_2, and h_3 are themselves permanent cycles (corresponding to the framings on S^1, S^3, and S^7 coming from viewing them as the units in a division ring), so their squares are. These manifolds were known to be Kervaire invariant one manifolds, the first being the obstruction into which Kervaire ran.

Barratt and Mahowald showed the next case.

Theorem. *There is a 30 manifold of Kervaire invariant one.*

Jones produced the manifold. He began with a genus 5 surface Σ. Arranging 4 of the holes at the points of a square and placing the fifth at the center shows that there is a free action of the dihedral group of order 8, D_8 on this surface. Jones then produced a framing on

$$\Sigma \times_{D_8} (S^7)^4,$$

where D_8 acts on $(S^7)^4$ via a coinducing up the antipodal action.

Barratt-Jones-Mahowald then showed the next case.

Theorem (Barratt-Jones-Mahowald [8]). *The class h_5^2 survives the Adams spectral sequence.*

To date, there is no explicit construction of this manifold.

Our theorem resolves all but one remaining case, showing that h_j^2 is not a permanent cycle for $j \geq 7$ [20].

Main Theorem. *There are manifolds of Kervaire invariant one only in dimensions 2, 6, 14, 30, 62, and maybe 126.*

The proof follows from four smaller theorems concerning a C_8-equivariant spectrum Ω and its basic properties. This spectrum is by construction periodic in the same way that K-theory is periodic, and we use this natural self-symmetry to simplify the problem.

At this point, the appearance of equivariance might be surprising. The problem, as stated, is one of manifolds with no equivariance. Our method has an important antecedent, Ravenel's proof for primes larger than 3 of the analogous result [38].

1.1. Ravenel's proof for very odd primes and the Adams-Novikov Spectral Sequence. The first step in our argument is to lift the computation to a more universal example. At this point, we can no longer avoid spectra. A more detailed description will be given below when we discuss equivariant homotopy; we use them here mainly for expository flavor.

The Adams spectral sequence is really a recipe. Given any (ring) spectrum R, we can form an Adams tower which, if R has nice homological properties (like the R-homology of R itself is flat as an R_*-module), then we can identify the E_2 term of the spectral sequence. If R is moreover commutative, then we can describe this as a kind of descent spectral sequence approximating a spectrum X by R-module spectra via the Amitsur complex. As a bit of jargon, when used without any modifiers, the phrase "Adams spectral sequence" refers to the one described above, built out of the mod 2 Eilenberg-MacLane spectrum.

While $H\mathbb{F}_2$ is a beautiful commutative ring spectrum, it has the disadvantage that any algebra R over $H\mathbb{F}_2$ is again Eilenberg-MacLane. This means that the Adams spectral sequence based on an $H\mathbb{F}_2$-algebra R is *isomorphic* to the classical Adams spectral sequence. In some sense, that makes this spectral sequence terminal. There are no Adams spectral sequences which receive a map from the classical one that are not isomorphic to it.

Novikov observed that if instead we use the bordism theory of (almost) complex manifolds, MU, then we have an Adams spectral sequence, here called the Adams-Novikov spectral sequence, which maps to the classical Adams spectral sequence. The homotopy groups of MU were computed by Milnor to be a polynomial ring with one generator in every positive, even degree [35], and the MU-homology of MU is also polynomial:

$$MU_*MU \cong MU_*[b_1, \dots].$$

Quillen showed that this is closely related to formal group laws, as MU_* is the Lazard ring classifying formal group laws and MU_*MU classifies the universal isomorphism [37]. The descent formulation of the Adams spectral sequence then identifies the E_2-term of the Adams-Novikov spectral sequence with a descent spectral sequence on the moduli stack of formal groups. This algebro-geometric perspective has been deeply influential in algebraic topology for the last 50 years.

We need very little of the algebraic geometry here. However, the myriad spectra which receive ring maps from MU provide a host of other Adams spectral sequences in which we can detect elements. In particular, we will produce a theory (Ω) which sees the Kervaire classes at 2. We must first lift these elements.

Since we have a map of spectral sequences

$$ANSS \to ASS,$$

any element in the Adams-Novikov spectral sequence which detects the Kervaire classes must have filtration at most 2. The zero line of the Adams-Novikov E_2 term is simple: it is a copy of $\mathbb{Z}$ in dimension zero corresponding to the MU-Hurewicz image. Thus we cannot

see the Kervaire classes here. The one line, at all primes, is the image of J, $Im(J)$, which showed up in the Kervaire-Milnor result. This was computed up to a factor of 2 by Adams [2], and the ambiguity was resolved by Quillen and Mahowald [36], [29]. In particular, the Kervaire classes are not detected in $Im(J)$, and hence not on the one line. Thus if the Kervaire classes exist, then they are detected on the two line of the Adams-Novikov spectral sequence. Here work of Miller-Ravenel-Wilson, described in Ravenel's ICM talk, allows us to identify exactly what we see [33, 39]. For $p = 2$, the reader is also directed to work of Shimomura [41].

Theorem (Miller-Ravenel-Wilson [33]).

(1) *At odd primes, the* 2*-line is generated by elements* $\beta_{i/j,k}$.

(2) *At two, the* 2*-line is generated by elements* $\beta_{i/j,k}$ *and* $\alpha_1\alpha_j$*, where* α_i *are the generators on the* 1*-line.*

(3) *The elements* $\beta_{i/j,k}$ *and* α_i *are all readily and algebraically described using short exact sequences of* Ext *groups.*

Since we are mapping the two line of the Adams-Novikov spectral sequence to the two line of the Adams spectral sequence, this can be directly computed.

Theorem. *If* x *is an element on the Adams-Novikov* 2 *line maps to* h_j^2*, then*

$$x = \beta_{2^j/2^j,1} + (\textit{sum of monomials not involving} \beta_{2^j/2^j,1}).$$

In other words, any lift of h_j^2 to the Adams-Novikov spectral sequence involves $\beta_{2^j/2^j,1}$.

Ravenel considered the analogous problem for primes greater than 3 (sometimes called "very odd primes") [38].

Theorem (Ravenel [38]). *For primes* $p > 3$ *and for any* $j > 0$*, the classes*

$$\beta_{p^j/p^j,1}$$

are not permanent cycles in the Adams-Novikov spectral sequence.

Ravenel's strategy was to chose an appropriately simplified cohomology theory into which the classes $\beta_{p^j/p^j,1}$ map non-trivially and in which the images of these classes support differentials. The modern language of the higher real K-theories of Hopkins and Miller make this more transparent.

Theorem (Hopkins-Miller [40]). *There is a* C_p*-equivariant spectrum* E *such that*

(1) $\beta_{p^i/p^i,1}$ *maps to a non-trivial element in the Adams-Novikov spectral sequence for* E^{hC_p}.

(2) *The Adams-Novikov* E_2*-term is given by the group cohomology* $H^*(C_p; \pi_* E)$.

(3) *The image of* $\beta_{p^i/p^i,1}$ *supports a differential.*

We copy this argument at $p = 2$. Here, we need to use a larger group than C_2 to distinguish between the Kervaire elements; we use C_8.

1.2. Outline of the proof of the main theorem. We first need that out of Ω, we can build a spectrum which detects the Kervaire classes. In this case, we can mirror a refinement of an odd-primary argument of Ravenel and look in the homotopy fixed points of Ω.

Detection Theorem. *If there is a manifold of Kervaire invariant one, then the corresponding homotopy class is non-zero in the homotopy groups of homotopy fixed points of* Ω*:* Ω^{hC_8}.

This reduces the problem to studying the homotopy groups of the homotopy fixed points Ω^{hC_8}. This is still a tall order, so we approach an *a priori* harder computation and determine the actual fixed points.

Gap Theorem. *The group* $\pi_{-2}\Omega^{C_8}$ *is zero.*

The periodicity of Ω now also comes into play, as does the connection between the fixed and homotopy fixed points.

Periodicity Theorem. *The homotopy groups of* Ω^{hC_8} *are* 256*-periodic:*

$$\pi_{k+256}\Omega^{hC_8} = \pi_k\Omega^{hC_8}.$$

Homotopy Fixed Points Theorem. *The natural map*

$$\Omega^{C_8} \to \Omega^{hC_8}$$

is a weak equivalence, and hence the homotopy groups of the fixed and homotopy fixed points are the same.

The proof of the detection theorem is essentially identical to Ravenel's argument for primes bigger than 3, and so we will not sketch a proof here. We will provide a sketch of the remaining theorems below.

2. Equivariant homotopy, real K-theory, and real bordism

2.1. Equivariant homotopy. Equivariant homotopy theory is homotopy theory for spaces with an action of a fixed group G. For our purposes, G will be a finite group. Group actions on spaces are always assumed to be continuous. Excellent introductions are found in the books of tom Dieck [42, 43].

2.1.1. G-Spaces. There is a category of G-spaces. In $\mathcal{T}op^G$, the objects are G-spaces and the morphisms are equivariant maps, maps which commute with the G-action. This category is enriched in topological spaces, in that there is a space of maps between any two objects. It is also tensored and cotensored over space.

For any subgroup $H \subset G$, we have an obvious forgetful functor

$$i_H^* \colon \mathcal{T}op^G \to \mathcal{T}op^H,$$

and this functor has both adjoints. The left adjoint, induction, is given by the balanced product:

$$X \mapsto G \times_H X.$$

We should think of this as taking the disjoint union (the coproduct in $\mathcal{T}op^G$) of G/H copies of X and letting the group act by permuting the coordinates. The right adjoint, coinduction, is given by the mapping space

$$X \mapsto \mathrm{Map}_H(G, X),$$

where $\mathrm{Map}_H(-,-)$ is the space of H-equivariant maps. Here H and G both act on G on different sides. We think of this as the product of G/H copies of X, letting the group act by permuting the coordinates.

The values of induction and coinduction on the image of the restriction have other descriptions. We have natural homeomorphisms

$$G \times_H i_H^* X \cong G/H \times X \text{ and } \mathrm{Map}_H(G, i_H^* X) \cong \mathrm{Map}(G/H, X),$$

where G acts diagonally on $G/H \times X$ and where the final Map is the G-space of all continuous maps G/H to X, with the conjugation action.

Any G-space can be approximated by a G-CW complex. The definition is essentially identical to that of an ordinary CW-complex: we built our space by iterative forming mapping cones out of a distinguished collection of spaces, spaces of the form $T \times S^n$, where T is a discrete G-set and $n \geq 0$.

As is standard, in both spaces and spectra, we will let $[X, Y]^G$ denote the set of G-homotopy classes of equivariant maps from X to Y. When there is no ambiguity, we will suppress the G from the notation.

2.1.2. *G*-Spectra. We need the stable version of this. We actually work in the rigid, point-set category of orthogonal G-spectra, but for expository purposes, we describe Lewis-May-Steinberger spectra [27]. Adams gives a beautiful treatment of the classical approach to stabilizing the category of finite G-CW complexes [4], and this gives intuition for us. Adams also gives a nice general introduction to spectra and their connection to cohomology [3].

Classically, a spectrum is a sequence of spaces $\ldots, X_0, X_1, \ldots$ together with structure maps

$$\Sigma X_i \to X_{i+1}$$

whose adjoints are equivalences. Brown Representability [11] provides a dictionary linking cohomology theories and spectra via

$$E^n(X) \cong [X, E_n].$$

In the equivariant context, we grade on a larger set: the set of (isomorphism classes of) finite dimensional representations of G. These form a category, which we will denote by $\mathcal{S}p^G$. There is an obvious forgetful functor

$$i_H^* \colon \mathcal{S}p^G \to \mathcal{S}p^H,$$

and this again has both adjoints: $G_+ \wedge_H (-)$ and $\mathrm{Map}_H(G_+, -)$.

The key benefit of grading on all finite dimensional representations is the Wirthmüller isomorphism:

Theorem 2.1 (Wirthmüller [47]). *If X is a G-spectrum, then we have a natural equivalence*

$$G_+ \wedge_H X \simeq \mathrm{Map}_H(G_+, X).$$

This means that maps into

$$G/H_+ \cong G_+ \wedge_H S^0 \simeq \mathrm{Map}_H(G_+, S^0)$$

is nontrivial. In fact, the Wirthmüller isomorphism makes finite G-sets stably self-dual. In many ways, this is the defining feature of the "genuine" equivariant stable homotopy, as it endows G-spectra and their homotopy groups with much richer structure. The homotopy classes of maps between two G-spectra has a richer structure than classically: they are Mackey functors in the sense of Dress [12]. For expository reasons, we use a slight refinement of Dress's original definition [42].

Definition 2.2. Let $\mathcal{A}$ denote the Burnside category. The objects are finite G-sets, and the morphisms are given by the group completion of the monoid isomorphism classes of finite G-sets which map to $S \times T$ together with disjoint union. The composition is given by pullback.

This category is obviously isomorphic to its dual, and disjoint union is both the product and coproduct. The canonical isomorphisms $T \to T \times *$ and $T \to * \times T$ give distinguished elements in $\mathcal{A}(T, *)$ and $\mathcal{A}(*, T)$. We call the former the "transfer" and the latter the "restriction". The action of the automorphisms of T is the "Weyl action".

Definition 2.3. A Mackey functor is an additive functor

$$\underline{M} \colon \mathcal{A} \to \mathcal{A}b.$$

Example 2.4. The most important Mackey functors we will consider are "fixed point" Mackey functors. If M is a $\mathbb{Z}[G]$-module, then the assignment

$$T \mapsto \mathrm{Map}_G(T, M)$$

defines a Mackey functor, the value at G/H of which is just M^H. The restrictions are the natural inclusions, while the transfers are "summing over cosets". We will denote this $\underline{M}$. If $M = \mathbb{Z}$ with the trivial action, then we get the "constant Mackey functor $\underline{\mathbb{Z}}$". Here, the value at G/H is $\mathbb{Z}$ for all subgroups H, the Weyl action is trivial, the restriction maps are the identity, and the transfer from H to K is the index.

Theorem 2.5 (Tom Dieck). *The assignment*

$$T \mapsto \Sigma^\infty T_+$$

extends to a fully-faithful embedding of $\mathcal{A}$ into the homotopy category of G-spectra.

Corollary 2.6. *If $n \in \mathbb{Z}$, then we have a Mackey functor*

$$\underline{\pi}_n(X)(T) := [T_+ \wedge S^n, X]^G.$$

When evaluating on a G-set of the form G/H, we will often denote this by

$$\pi_n^H(X) := \underline{\pi}_n(X)(G/H).$$

On the G-set G/H, this gives us the n^{th} homotopy group of the H-fixed points of X:

$$\underline{\pi}_n(X)(G/H) \cong \pi_n(X^H).$$

However, we have a huge warning here: the fixed points of a G-spectrum are not what one would immediately think! For example, tom Dieck showed that the fixed points of the sphere spectrum S^0 split as a wedge of classifying spaces of Weyl groups of conjugacy classes of subgroups. This is the topological underpinning of the theorem cited above.

2.1.3. Bredon homology. Associated to any Mackey functor $\underline{M}$ is an Eilenberg-MacLane spectrum $H\underline{M}$. This is the homotopy type defined by the property

$$\underline{\pi}_n H\underline{M} = \begin{cases} \underline{M} & n = 0 \\ 0 & \text{otherwise.} \end{cases}$$

Just as in the classical case, the Eilenberg-MacLane spectra represent ordinary homology. In this case, the homology theory was described by Bredon [9]. We will use a slight refinement: our version of Bredon homology is actually Mackey functor valued and uses a chain complex of Mackey functors. Bredon's original treatment handled a slightly more general type of coefficients for spaces.

By definition, we have

$$\underline{H}_k(X; \underline{M}) \cong \underline{\pi}_k(X \wedge H\underline{M}). \tag{2.1}$$

In particular, we know immediately the homology of spheres, and more generally, of induced spheres:

$$\underline{H}_k(G/H_+ \wedge S^n; \underline{M}) \cong \begin{cases} \underline{M}_{G/H} & k = n \\ 0 & \text{otherwise,} \end{cases}$$

where $\underline{M}_{G/H}(T) = \underline{M}(G/H \times T)$. Now if X is a finite G-CW complex, then as above, X has a filtration $X^{[n]}$ such that each $X^{[n]}$ is a homotopy cofiber

$$T_{n+} \wedge S^{n-1} \xrightarrow{e_n} X^{[n-1]} \xrightarrow{\partial_n} X^{[n]}.$$

Our cellular chain complex arises from the obvious Mayer-Vietoris sequence for this, using the dimension axiom. As an aside, we assume here that T_n is finite (otherwise, we take the colimit). The boundary map in the complex comes from

$$T_{n+} \wedge S^{n-1} \to X^{[n-1]} \to T_{(n-1)+} \wedge S^{n-1},$$

This is an element in

$$[T_{n+} \wedge S^{n-1}, T_{(n-1)+} \wedge S^{n-1}] \cong [\Sigma^\infty T_{n+}, \Sigma^\infty T_{(n-1)+}] \cong \mathcal{A}(T_n, T_{n-1}),$$

and by functoriality, we know exactly how to evaluate a Mackey functor on this! This is the cellular differential. We summarize this into a proposition.

Proposition 2.7. *The Bredon cellular chain complex for a G-CW complex X is the chain complex $C_*^{cell}(X; \underline{M})$ with*

$$C_n^{cell}(X; \underline{M}) = \underline{M}_{T_n},$$

and boundary induced by the composite

$$\underline{M}\big((T_n \to T_{(n-1)}) \times -\big).$$

The Bredon cochain complex is the Bredon chain complex on the Spanier-Whitehead dual of X.

We now restrict attention to $G = C_{2^n}$, $\underline{M} = \underline{\mathbb{Z}}$, and X a representation or dual representation sphere. Proposition 2.7 says we need only find convenient G-CW models for representation spheres.

For this, we need to list the irreducible representations.

Definition 2.8.

(1) Let λ_n denote the 1-dimensional complex representation of C_{2^n} arising from the inclusion of the $2^{n\text{th}}$ roots of unity into $\mathbb{C}^\times$.

(2) Let $\lambda_n(k)$ denote the k^{th} complex tensor power of λ_n.

(3) Let σ_n denote the sign representation of C_{2^n}

(4) Let ρ_n denote the regular representation of C_{2^n}, and let $\bar{\rho}_n$ denote the quotient of the regular representation by the trivial subrepresentation.

We implicitly work 2-locally, and in this context, it is not difficult to see that if the 2-adic valuations of k and ℓ are equal, then

$$S^{\lambda_n(k)} \simeq S^{\lambda_n(\ell)}.$$

This lets us restrict attention to those k which are powers of 2. These representations are also more easily described as the composite

$$C_{2^n} \to C_{2^n}/C_{2^k} \cong C_{2^{n-k}} \to \mathbb{C}^\times.$$

In other words, we pull the representation λ_{n-k} back along the canonical quotient. The cell-structure then also pulls back in the obvious way (recognizing that $C_{2^{n-k}}/H \cong C_{2^n}/H'$ for the subgroup H' that projects to H). Similarly, the sign representation comes from

$$C_{2^n} \to C_2 \to \mathbb{R}^\times.$$

We therefore need only describe the cell structure for S^{λ_n} and S^{σ_1}, as all others follow from this.

For the former, we have a single S^0 for our zero cells: the point at infinity and the origin. We have a copy of $C_{2^n+} \wedge e^1$ for the one cells: the rays from the origin to the point at infinity and passing through the various roots of unity. We then have a single 2-cell: $C_{2^n+} \wedge e^2$ filling in the wedges between the rays. In particular, the boundary of our two cell comes in as the difference $1 - \gamma$ of 1 and a fixed generator γ. This gives the following picture:

$$S^{\lambda_n} = S^0 \cup C_{2^n+} \wedge e^1 \cup_{1-\gamma} C_{2^n+} \wedge e^2. \tag{2.2}$$

Again, the map labeled $1 - \gamma$ describes the cellular attaching map. The unlabeled attaching map is the canonical projection $C_{2^n+} \to S^0$.

The sign representation is even easier:

$$S^{\sigma_n} = S^0 \cup C_{2+} \wedge e^1.$$

We can view this as the unit sphere in the complex numbers together with complex conjugation.

Again, for $\lambda_n(2^k)$, we replace all instances of C_{2^n} with C_{2^n}/C_{2^k} and similarly for σ_n, we replace C_2 with $C_{2^n}/C_{2^{n-1}}$.

This is actually sufficient to build any other representation sphere. First note that if $\ell \geq k$, then

$$C_{2^n}/C_{2^k+} \wedge S^{\lambda_n(2^\ell)} \cong C_{2^n+} \wedge_{C_{2^k}} S^{\downarrow \lambda_n(2^\ell)} \cong C_{2^n+} \wedge_{C_{2^k}} S^2 \cong C_{2^n}/C_{2^k+} \wedge S^2. \tag{2.3}$$

In other words, from the point of view of cells induced up from C_{2^k} for $k \leq \ell$, the $S^{\lambda_n(2^\ell)}$ sphere is trivial. An easy induction argument then shows the following.

Proposition 2.9. *If V is a representation of C_{2^n} such that $V^{C_{2^k}} = V$, then for any $j \leq k$, there is a cell structure on $S^{V+\lambda_n(2^j)}$ of the form*

$$S^V \cup C_{2^n}/C_{2^j+} \wedge e^{\dim V+1} \cup C_{2^n}/C_{2^j+} \wedge e^{\dim V+2}.$$

If V is orientable (arising from a map $C_{2^n} \to SO(V)$), then the top cellular boundary map is again $1-\gamma$.

Proof. Smash S^V with the cell structure given by Equation 2.2. The isomorphisms given by Equation 2.3 then prove the first part of the proposition. The second part follows from observing that any oriented representation of C_{2^n} arises from a representation of S^1, and the map $1-\gamma$ is the map in the cell structure for S^1 as a C_{2^n}-space. □

We close with two computations. Choose once and for all an orientation of S^2. This gives an orientation for all other even spheres.

Proposition 2.10. *If V is orientable, then*

$$\underline{H}_{\dim V}(S^V; \underline{\mathbb{Z}}) \cong \underline{\mathbb{Z}}.$$

Proof. This follows immediately from Proposition 2.9 once we understand the base case of $V = \lambda_n(2^k)$. Here our Bredon cellular chain complex is

$$\underline{\mathbb{Z}} \leftarrow \underline{\mathbb{Z}}_{C_{2^n}/C_{2^k}} \xleftarrow{1-\gamma} \underline{\mathbb{Z}}_{C_{2^n}/C_{2^k}}.$$

An elementary-but-illuminating computation shows that the kernel of $1-\gamma$ is exactly $\underline{\mathbb{Z}}$. □

Remark 2.11. The bottom boundary map is non-trivial. It is the covariant map associated to the canonical quotient $C_{2^n}/C_{2^k} \to *$, and that is the transfer. Thus the differential is a Mackey functor lift of the transfer. The dual version, giving the Bredon cohomology is therefore a Mackey functor lift of the restriction map. This is the key ingredient in Theorem 2.16 below.

Definition 2.12. Let u_V be the generator of $\underline{H}_2(S^V; \underline{\mathbb{Z}})(G/G)$ which restricts to the fixed orientation of $S^{\dim V}$.

For the rest of the homology groups, we need Euler classes in the homotopy groups of spheres.

Definition 2.13. Let V be a representation of a finite group G. If V is such that $V^G = \{0\}$, then let

$$a_V \colon S^0 \to S^V$$

denote the inclusion of the origin and the point at infinity into S^V. This is an element in

$$\underline{\pi}_0 S^V(G/G).$$

The Hurewicz map provides for us elements in $H_0(S^V)$, and we will also denote these by a_V. Then we have the following relations connecting the orientation classes u_V and the Euler classes a_W.

Proposition 2.14. *For $G = C_{2^n}$, we have*

(1) $a_{V+W} = a_V a_W$ *and if* V *and* W *are oriented, then* $u_{V+W} = u_V u_W$.

(2) *If* $H \subset G$ *has* $V^H \neq \{0\}$, *then* $|G/H| a_V = 0$.

(3) *If* $k \leq \ell$, *then*

$$a_{\lambda_n(2^\ell)} u_{\lambda_n(2^k)} = 2^{\ell-k} a_{\lambda_n(2^k)} u_{\lambda_n(2^\ell)}.$$

Only the relation involving swapping the subscripts on a and u is any work, and this is a direct computation [21].

With this, we can completely determine a portion of the homology of representation spheres. Since $H\underline{\mathbb{Z}}$ is a ring spectrum, we have a natural map

$$(S^V \wedge H\underline{\mathbb{Z}}) \wedge (S^W \wedge H\underline{\mathbb{Z}}) \to S^{V+W} \wedge H\underline{\mathbb{Z}}.$$

This means that the collection of all groups

$$\underline{\pi}_*(S^\star \wedge H\underline{\mathbb{Z}})(G/G),$$

where $* \in \mathbb{Z}$ and where $\star$ runs over all isomorphism classes of representations, forms a ring. Proposition 2.14 completely determines this ring, and this in turn gives the homology of any representation sphere.

Theorem 2.15. *The ring* $\underline{\pi}_*(S^\star \wedge H\underline{\mathbb{Z}})(G/G)$ *is isomorphic to*

$$\mathbb{Z}[a_\sigma, a_{\lambda_n(2^k)}, u_{\lambda_n(2^j)} | 0 \leq k \leq n-2, 0 \leq j \leq n-1]/(rels)$$

where $(rels)$ *is the ideal*

$$(rels) = (2a_\sigma, 2^{n-k} a_{\lambda_n(2^k)}, a_{\lambda_n(2^\ell)} u_{\lambda_n(2^k)} = 2^{\ell-k} a_{\lambda_n(2^k)} u_{\lambda_n(2^\ell)}).$$

For the Gap Theorem, we need a small number of Bredon cohomology groups. In particular, we need

$$\underline{H}^2(S^{k\rho_n}; \underline{\mathbb{Z}})(G/G) = \underline{H}_{-2}(S^{-k\rho_n}; \underline{\mathbb{Z}})(G/G).$$

Theorem 2.16. *For all* $n \neq 0$ *and for all* $k \in \mathbb{Z}$, *the group*

$$\underline{H}_{-2}(S^{k\rho_n}; \mathbb{Z})(G/G)$$

is zero.

Proof. If $k \geq 0$, then $S^{k\rho_n}$ is a space, and hence it has no negative homology. Similarly, if $k \leq -3$, then $S^{k\rho_n}$ is (-2)-coconnected, and again, we have no

$$\underline{\pi}_{-2}(S^{k\rho_n} \wedge H\underline{\mathbb{Z}}) = \underline{H}{-2}(S^{k\rho_n}; \mathbb{Z}).$$

We need only consider the cell structure for S^{ρ_n} and $S^{2\rho_n}$. If $n = 1$, then the argument is left as an exercise. Otherwise, we have the following cell structures from Proposition 2.9, using the fact that the trivial representation is stabilized by everything and the index 2 subgroup stabilizes only 1 and σ_n:

$$S^{\rho_n} : S^1 \cup C_{2^n}/C_{2^{n-1}+} \wedge e^2 \cup C_{2^n}/C_{2^{n-2}} \wedge e^3 \cup \dots$$

and

$$S^{2\rho_2} : S^2 \cup C_{2^n}/C_{2^{n-1}+} \wedge e^3 \cup_{1-\gamma} C_{2^n}/C_{2^{n-1}+} \wedge e^4 \dots.$$

Spanier-Whitehead duality swaps all the signs and the arrows. Thus for the first, the relevant cochain complex is

$$\underline{\mathbb{Z}} \to \mathbb{Z}_{C_{2^n}/C_{2^{n-1}}} \to \mathbb{Z}_{C_{2^n}/C_{2^{n-2}}} \cdots$$

and

$$\underline{\mathbb{Z}} \to \mathbb{Z}_{C_{2^n}/C_{2^{n-1}}} \xrightarrow{1-\gamma} \mathbb{Z}_{C_{2^n}/C_{2^{n-1}}} \cdots.$$

The unlabeled map is the restriction map, by Remark 2.11, which is an isomorphism here! This lets us determine the homology in the second position in the first sequence and that in the first position in the second, getting zero. □

2.2. Real theories.

2.2.1. Real K-theory. Just as the heart of the Kervaire invariant one problem is about bordism classes of manifolds, the heart of our proof is a bordism theory: the bordism theory of Real manifolds. Real (always with a capital "R" to distinguish them from unReal ones) theories arose from work of Atiyah on K-theory [7]. Atiyah defined a $C_2 = Gal(\mathbb{C}/\mathbb{R})$-equivariant version of K-theory, Real K-theory $K_{\mathbb{R}}$ which records Galois descent for vector bundles.

If a space X has a trivial action, then there is a canonical real bundle associated to any Real bundle on X, namely the fixed points of the Real bundle. This identifies the fixed points of $K_{\mathbb{R}}$ with ordinary real K-theory:

$$K_{\mathbb{R}}^{C_2} = KO.$$

Similarly, if X has a free C_2-action, then the Real structure provides an identification of the fibers over a point x and those over its translates under the group action. This identifies the underlying spectrum of $K_{\mathbb{R}}$ with complex K-theory:

$$i_e^* K_{\mathbb{R}} = KU.$$

Atiyah also determined the relationship between the fixed and homotopy fixed points of $K_{\mathbb{R}}$. Using the nilpotence of η, he showed that the fixed and homotopy fixed points coincide:

$$KO = K_{\mathbb{R}}^{C_2} = K_{\mathbb{R}}^{hC_2}.$$

Real K-theory provides a model for the entire argument that follows. We have a Gap Theorem ($\pi_{-2}KO = 0$ by work of Bott), Atiyah proved the Homotopy Fixed Points theorem (and gave a model for how to prove such things in general), and he also showed how one can deduce the 8-fold periodicity of KO (giving another proof of Bott periodicity). We will produce the same sort of argument, but for a more complicated equivariant spectrum.

2.2.2. Real bordism. Building on Atiyah's work, Landweber and Araki considered a Real version of bordism, $MU_{\mathbb{R}}$ [6, 26]. This is the bordism theory of C_2-manifolds with a Real structure on their stable normal bundle.

First Araki and then Hu-Kriz extensively studied the fixed points of the spectrum $MU_{\mathbb{R}}$, determining the homotopy groups and showing that the fixed and homotopy fixed points agree [5, 23]. Similarly, essentially by construction, the underlying spectrum is the ordinary complex bordism spectrum MU. One of the most important features is that the homotopy groups indexed by regular representations are especially nice:

$$\pi_{*\rho_2} MU_{\mathbb{R}} \cong \pi_{2*} MU,$$

and by a celebrated theorem of Quillen, this is the Lazard ring classifying formal group laws [37].

This is related to a Real version of formal groups and formal group laws, and just as in the classical case, the spectrum $MU_{\mathbb{R}}$ classifies Real oriented spectra. This allows us to use classical techniques and approaches. We use this to help determine the homotopy groups of related spectra, but a key starting point is the determination of the homotopy type of the smash square of $MU_{\mathbb{R}}$:

$$MU_{\mathbb{R}} \wedge MU_{\mathbb{R}} \simeq MU_{\mathbb{R}}[\bar{b}_1, \bar{b}_2, \dots],$$

where $|\bar{b}_i| = i\rho_2$. This in particular applies to all higher smash powers of $MU_{\mathbb{R}}$, letting us completely determine the homotopy groups in multiples of ρ_2:

$$\pi_{*\rho_2}\big(MU_{\mathbb{R}}^{\wedge k}\big) \cong \big(\pi_{2*}MU\big)^{\otimes k}. \tag{2.4}$$

While $MU_{\mathbb{R}}$ has a very satisfying story, it is not sufficient to detect the Kervaire classes. For this, we need to study a larger group. Experience with the techniques similar to Ravenel's results for $p > 3$ show that C_8 is the smallest group which detects the Kervaire classes appropriately. For this, we need to produce a new ring spectrum which is a C_8 analogue of $MU_{\mathbb{R}}$. Additive induction is insufficient: the C_8-equivariant homotopy theory of that is essentially the same as the C_2-equivariant theory of $MU_{\mathbb{R}}$ by the Wirthmüller isomorphism. Instead, we use the norm functor provides a way to do this.

2.3. The norm. Equivariant spectra are a bisymmetric monoidal category. The wedge provides the sum in the category, while the smash product provides a multiplication. The norm functor is a multiplicative kind of induction. It is the rigid, spectral version of the Evens' transfer in group cohomology [14], which was imported into stable homotopy by Greenlees-May, [16].

Theorem 2.17. *There is a strong symmetric monoidal functor*

$$N_H^G \colon \mathcal{S}p^H \to \mathcal{S}p^G$$

which commutes with certain colimits and for which

$$N_H^G S^V \cong S^{\mathrm{Ind}_H^G V}$$

for every representation V of H.

The way we should think of $N_H^G(X)$ is "smashing together G/H copies of X", and letting the group act by permuting the factors as well. This describes a functor from spectra with an H-action to spectra with a G-action, and showing that it is homotopically meaningful is one of the most difficult parts of the proof.

2.3.1. Relation to commutative rings. Since the smash product is the coproduct on commutative ring spectra, the norm is the corresponding "induction" functor.

Theorem 2.18. *The norm lifts to the left adjoint to the forgetful functor i_H^*:*

$$N_H^G \colon \mathcal{C}omm^H \rightleftarrows \mathcal{C}omm^G \colon i_H^*.$$

This means that commutative ring maps out of the a norm are easy to compute, as they are determined by the underlying H-equivariant maps. Since the norm is the left adjoint to the forgetful funtor, for any G-eqivaraint commutative ring R, we have a natural map of G-equivariant commutative rings

$$N_H^G i_H^* R \to R.$$

In particular, this allows us to define several kinds of internal norms on the cohomology theory given by R.

Definition 2.19. If $x \in \left(i_H^* R\right)^0(X)$, then let $N_H^G(x) \in R^0(N_H^G X)$ also denote the composite

$$N_H^G X \xrightarrow{N_H^G x} N_H^G i_H^* R \to R,$$

where the last map is the counit to the adjunction.

Since the sphere is a commutative ring spectrum, we have norms of the Euler classes, and since $H\underline{\mathbb{Z}}$ is a commutative ring spectrum as well, we have norms of orientation classes.

Proposition 2.20. *If V is a representation of H of dimension d (orientable for the second line), we have*

$$N_H^G a_V = a_{\mathrm{Ind}_H^G V}$$
$$u_{d\,\mathrm{Ind}_H^G 1} N_H^G u_V = u_{\mathrm{Ind}_H^G V}.$$

With the machinery aside, we can move towards defining Ω.

Definition 2.21. Let $MU^{((G))}$ be the commutative G-equivariant ring spectrum

$$MU^{((G))} = N_{C_2}^G MU_{\mathbb{R}}.$$

Our spectrum Ω is a localization of this, the exact form of which is forced by the Detection, Periodicity, and Homotopy Fixed Points Theorems. We will return to this as we delve into their proofs.

3. Slice filtration and the Gap Theorem

The main computational tool we use is the "slice filtration". This generalizes groundbreaking work of Dugger [13], where he describes the C_2-equivariant version. The filtration and name are motivated by the motivic slice filtration of Voevodsky, especially as applied by Hopkins-Morel in their study of the motivic bordism spectrum MGL [44–46].

The idea behind the slice filtration is to mirror the construction of the Postnikov tower. Classically, we form the Postnikov tower by considering the localization functors $P^n(-)$ whose acyclics are exactly the n-connected spectra or spaces. The category of n-connected spectra is a localizing category in the sense of Farjoun [15]. We build a different collection of localizing subcategories, using non-trivial representation spheres as our basic ingredients [18]. This gives us a tower of equivariant spectra and an associated spectral sequence. For simplicity, we only describe what is seen for $MU^{((G))}$.

3.1. The slice filtration of norms of $MU_{\mathbb{R}}$. For the spectra $MU^{((G))}$, for G a cyclic 2-group, the slice tower is beautifully simple. To describe it, we need to use Equation 2.4 to produce enough homotopy elements.

Theorem 3.1. *Let $G = C_{2^n}$ be a cyclic 2-group, generated by an element γ. Then there are elements $\bar{r}_i \in \pi_{i\rho_2} MU^{((G))}$ such that*

$$\{\bar{r}_1, \dots, \gamma^{2^{n-1}-1}\bar{r}_1, \bar{r}_2, \dots\}$$

is a set of polynomial generators for

$$\pi_{*\rho_1} MU^{((G))} \cong \left(\pi_{*\rho_1} MU_{\mathbb{R}}\right)^{\otimes 2^{n-1}}.$$

If we need to consider multiple groups G, then we will add them as superscripts: $\bar{r}_i^G$.

This is a refinement of Equation 2.4. The restriction to C_2 of $MU^{((G))}$ is the $|G|/2$-fold smash power of $MU_{\mathbb{R}}$. This classifies a $|G|/2$-tuple of Real formal group laws, and the group G acts by permuting these formal groups. The elements $\bar{r}_i$ are then essentially the coefficients of the universal isomorphism between a chosen first formal group and γ on it.

Definition 3.2. Let $\mathcal{P}$ be the set of monic monomials in $\pi_{*\rho_1} MU^{((G))}$ with the generators $\bar{r}_j$.

If $\bar{p} \in \mathcal{P}$, let $H_{\bar{p}}$ denote the stabilizer of the reduction modulo 2 of $\bar{p}$.

If $\bar{p} \in \mathcal{P}$ is in $\pi_{k\rho_1} MU^{((G))}$, then let

$$|p| = 2k \text{ and } |\bar{p}| = \tfrac{2k}{|H_{\bar{p}}|}\rho_{H_{\bar{p}}}.$$

Then the heart of our identification of the slice tower is the following proposition (which follows formally from properties of the norm).

Proposition 3.3. *The spectrum*

$$A = \bigvee_{\bar{p}\in\mathcal{P}} S^{|\bar{p}|} = \bigvee_{\bar{p}\in\mathcal{P}/G} G_+ \wedge_{H_{\bar{p}}} S^{|\bar{p}|}$$

is an associative ring spectrum and the maps

$$\bar{r}_i \colon S^{i\rho_1} \to i_{C_2}^* MU^{((G))}$$

give a G-equivariant associative algebra map $A \to MU^{((G))}$.

This has an obvious monomial filtration by degree, so let

$$I_k = \bigvee_{p\in\mathcal{P}_n/G, |p|\geq 2k} G_+ \wedge_{H_{\bar{p}}} S^{|\bar{p}|}.$$

Then each I_k is an A-A-bimodule, and I_k/I_{k+1} is a wedge of induced regular representations spheres.

This filtration of A by bimodules induces a filtration on any other A-module, so in particular, on $MU^{((G))}$. This is one of our main theorems.

Theorem 3.4. *We have an equivalence*

$$MU^{((G))} \wedge_A S^0 = H\underline{\mathbb{Z}}$$

and the filtration of $MU^{((G))}$ by the ideals I_k has associated graded

$$A \wedge H\underline{\mathbb{Z}} = \bigvee_{p \in \mathcal{P}_n/G} G_+ \wedge_{H_{\bar{p}}} S^{|\bar{p}|} \wedge H\underline{\mathbb{Z}}.$$

This is the slice filtration of $MU^{((G))}$.

The proof of the second part follows from the first immediately. The first is quite difficult and lengthy, and we will not provide a proof here. There are several approaches that can be taken, all of which are underlain by simple geometry. In fact, this theorem can be proved by computing appropriate characteristic numbers for certain C_{2^n}-equivariant manifolds. Determining these manifolds is non-trivial.

Corollary 3.5 (Slice Spectral Sequence). *For any virtual representation V of G, there is a spectral sequence*

$$E_2^{s,t} = \bigoplus_{p \in \mathcal{P}_n/G} \pi_{t-s}^G\big(G_+ \wedge_{H_{\bar{p}}} S^{|\bar{p}|} \wedge S^V \wedge H\underline{\mathbb{Z}}\big) \Rightarrow \pi_{t-s-V} MU^{((G))}.$$

The differentials are Adams type differentials.

The t in $E_2^{s,t}$ records the degree of p and is suppressed in this formulation.

Thus to understand the slice E_2-term, we need only determine

$$\pi_*^G\big(G_+ \wedge_H S^{k\rho_H} \wedge S^V \wedge H\underline{\mathbb{Z}}\big) = H_*^H\big(S^{k\rho_H} \wedge S^V; \underline{\mathbb{Z}}\big),$$

but this was computed in Theorem 2.15.

3.2. The Gap Theorem. We can now prove the Gap Theorem. We give a slightly stronger form, as this subsumes the case of interest.

Gap Theorem. *If $G = C_{2^n}$, and $\bar{D} \in \pi_{m\rho_G}^G MU^{((G))}$ then the group*

$$\pi_{-2}^G\big(\bar{D}^{-1} MU^{((G))}\big)$$

is zero.

Proof. Consider the slice spectral sequence computing

$$\pi_*^G \Sigma^{mk\rho_G} MU^{((G))} = \pi_{*-mk\rho_G}^G MU^{((G))}.$$

By Corollary 3.5, the portion of the E_2 term contributing to π_{-2} is

$$\bigoplus_{p \in \mathcal{P}_n/G} H_2^{H_{\bar{p}}}\big(S^{|\bar{p}|} \wedge S^{\downarrow mk\rho_G}; \underline{\mathbb{Z}}\big).$$

Since the restriction of $mk\rho_G$ to $H(p)$ is of the $mk[G : H(p)]\rho_{H(p)}$, we see by Theorem 2.16 that all of these groups are zero. Thus

$$\pi_{-2} \Sigma^{mk\rho_G} MU^{((G))} = 0.$$

Since inverting an element in dimension $m\rho_G$ is given by a directed colimit of spectra of the form $\Sigma^{mk\rho_G} MU^{((G))}$ and since homotopy groups commute with directed colimits, we conclude that $\pi_{-2} \bar{D}^{-1} MU^{((G))} = 0$. □

4. Geometric fixed points and the homotopy fixed points and periodicity theorems

The Periodicity and Homotopy Fixed Points Theorems are two sides of the same coin, and we will see that the proofs are closely intertwined. Both rely on an argument like Atiyah's: we show that certain classes vanish, which given the equality between fixed and homotopy fixed points, and the reason these classes vanish is because of certain differentials. The vanishing of these classes causes other classes to be permanent cycles, and this gives the Periodicity Theorem. Both rely on the geometric fixed points.

4.1. Geometric fixed points and the norm. When discussing $MU_{\mathbb{R}}$, at no point did we discuss the fixed points of the Thom spaces making up the spectrum. In fact, in contrast to the case of $K_{\mathbb{R}}$, the fixed points of $MU_{\mathbb{R}}$ seem to not have geometric content. The connection back to the geometry is provided by the "geometric fixed points". This is a second kind of fixed points that is actually the one most people would guess when confronted with fixed points.

Theorem. *There is a functor*

$$\Phi^G \colon \mathcal{S}p^G \to \mathcal{S}p$$

that commutes with most homotopy colimits and which has the following properties:

(1) *If X has only cells induced up from proper subgroups, then $\Phi^G(X)$ is contractible.*
(2) *If $X = \Sigma^\infty Y$, then $\Phi^G(X) \simeq \Sigma^\infty Y^G$.*
(3) *For G-CW spectra X and Y, $\Phi^G(X \wedge Y) \simeq \Phi^G(X) \wedge \Phi^G(Y)$.*

Thus the geometric fixed points functor has all of the properties that we would expect a fixed point functor to have, thinking only of what we learn from spaces.

Since it commutes with smash products and essentially interacts nicely with suspensions, it is no surprise that it plays nicely with the norm functor.

Theorem 4.1. *The diagonal map induces a weak equivalence*

$$\Phi^H(X) \simeq \Phi^G N_H^G X.$$

Finally, generalizing the connection to suspension spectra, the geometric fixed points functor has the expected, geometric content for Thom spectra.

Theorem 4.2. *The geometric fixed points of $MU_{\mathbb{R}}$ is MO.*

To describe the geometric fixed points, we introduce the isotropy separation sequence. Let $\mathcal{P}$ denote the family of proper subgroups of G. If $G = C_{2^n}$, then let $E\mathcal{P}$ be the space

$$E\mathcal{P} \simeq \lim_{\to} S(n\sigma),$$

where $S(V)$ is the unit sphere in an orthogonal representation V. This has the property that

$$(E\mathcal{P}_+)^H \simeq \begin{cases} S^0 & H \subsetneq G \\ * & \text{otherwise.} \end{cases}$$

We have an obvious map $E\mathcal{P}_+ \to S^0$. Let $\tilde{E}\mathcal{P}$ denote the homotopy cofiber. In our case, this can be taken to be the infinite sign sphere:

$$\tilde{E}\mathcal{P} \simeq \lim_{\to} S^{n\sigma}.$$

The maps in the direct system are all multiplication by a_σ, so $\tilde{E}\mathcal{P}$ amounts to inverting a_σ.

Definition 4.3. Given a G-CW spectrum X, define the geometric fixed points by

$$\Phi^G(X) = \left(\tilde{E}\mathcal{P} \wedge X\right)^G.$$

The isotropy separation sequence is

$$E\mathcal{P}_+ \wedge X \to X \to \tilde{E}\mathcal{P} \wedge X.$$

The isotropy separation sequence has a purely algebraic description. Since $\tilde{E}\mathcal{P}$ is the infinite sign sphere, the map

$$X \to \tilde{E}\mathcal{P} \wedge X$$

is the map

$$X \to X[a_\sigma^{-1}].$$

This map also inverts all of the other Euler classes a_V; there are classes in the $RO(G)$-graded homotopy groups of S^0 of the form a_σ^k/a_V.

The geometric fixed points are the final tool we need. In particular, the nilpotence of any of the Euler classes results in a contractible geometric fixed point spectrum. We will use our understanding that the geometric fixed points of $MU^{((G))}$ is MO to produce differentials in the slice spectral sequence hitting multiples of powers of a_σ. Inverting the multiples will then produce contractible geometric fixed points.

4.2. A differential in the slice spectral sequence. First, a quick simplification from the observation that smashing with $\tilde{E}\mathcal{P}$ is the nullification of induced cells. For notation, let

$$\bar{n}_i = N_{C_2}^{C_{2^n}} \bar{r}_i,$$

let $\mathcal{N}$ denote the set of monic monomials in

$$\mathbb{Z}[\bar{n}_1, \bar{n}_2, \dots],$$

and let

$$|\bar{n}_i| = i\rho_{2^n}.$$

Theorem 4.4. *The inclusion*

$$\bigvee_{n \in \mathcal{N}} S^{|n|} \to A$$

induces an equivalence after smashing with $\tilde{E}\mathcal{P}$.

Moreover, since smashing with $\tilde{E}\mathcal{P}$ inverts all Euler classes, the regular representation spheres which appear are also simplified.

Proposition 4.5. *The inclusion*

$$a_{i\bar{\rho}}\colon S^i \to S^{i\rho}$$

induces an equivalences after smashing with $\tilde{E}\mathcal{P}$.

In light of this, let f_i denote the composite

$$S^i \xrightarrow{a_{i\bar{\rho}}} S^{i\rho} \xrightarrow{\bar{n}_i} MU^{((G))}.$$

This is detected in the slice spectral sequence by the eponymous element of filtration $i(|G|-1)$.

We want to compute the homotopy groups of the localization $a_\sigma^{-1}MU^{((G))}$. We know, since this gives the homotopy groups of the geometric fixed points, the answer: these are just the homotopy groups of MO! They are packaged in a non-trivial way, and we see a single pattern of differentials which achieves this.

The computational content of Theorem 4.4 is given in the following theorem about the $RO(G)$-graded slice spectral sequence. In particular, it says that only a very narrow collection of elements can contribute to the spectral sequence computing the homotopy of MO.

Theorem 4.6. *The inclusion*

$$\mathbb{Z}[u_{2\sigma}, f_1, f_2, \dots, a_\sigma, \dots]/2a_\sigma, \cdots \to E_2^{*,\star}$$

induces an isomorphism upon inverting a_σ. (Here the dots after a_σ stands for all of the other Euler classes, and the ones after the relation $2a_\sigma$ stand for the truncation of the other Euler classes.)

The classes a_V are all in the Hurewicz image, so they are necessarily permanent cycles. The classes f_i are explicit homotopy classes in $\pi_i^G MU^{((G))}$. Thus the only class that is not a permanent cycle in the algebra listed in Theorem 4.6 is $u_{2\sigma}$. Since the homotopy groups of MO are polynomial on classes in ever dimension not of the form 2^k-1, we have a single pattern of differentials which achieves this.

Theorem 4.7. *There are differentials*

$$d_{2^{k+1}+(2^{k+1}-1)(2^n-1)}(u_{2\sigma}^{2^k}) = a_\sigma^{2^{k+1}} f_{2^{k+1}-1}.$$

Remark 4.8. Theorem 4.6 also shows that the differential on $u_{2\sigma}^{2^k}$ is also the last possible, as the target is on the vanishing line for the slice spectral sequence.

This gives us an immediate corollary.

Corollary 4.9. *In the slice spectral sequence for $\bar{n}_{2^k-1}^{-1}MU^{((G))}$, the element $u_{2\sigma}^{2^k}$ is a permanent cycle.*

Corollary 4.10. *The geometric fixed points of $\bar{n}_{2^k-1}^{-1}MU^{((G))}$ are contractible.*

This is the essential step in both the Periodicity and Homotopy Fixed Points theorem. It is also the key step in proving Atiyah's result for Real K-theory! We include a picture of the slice spectral sequence for $K_{\mathbb{R}}$ as Figure 4.1. This was exactly the impetus for Dugger, and our Figure is essentially the same as his [13].

The element $\bar{v}_1$ is our $\bar{r}_1$ for C_2. The differential on $\bar{v}_1^2 u_{2\sigma}$ is the differential from Theorem 4.7:

$$\bar{v}_1^2 u_{2\sigma} \mapsto \bar{v}_1^3 a_\sigma^3.$$

We see that there is a horizontal vanishing line in the spectral sequence at filtration 3. The differentials on $u_{2\sigma}^2$ and higher are d_7 or longer, and hence these are permanent cycles.

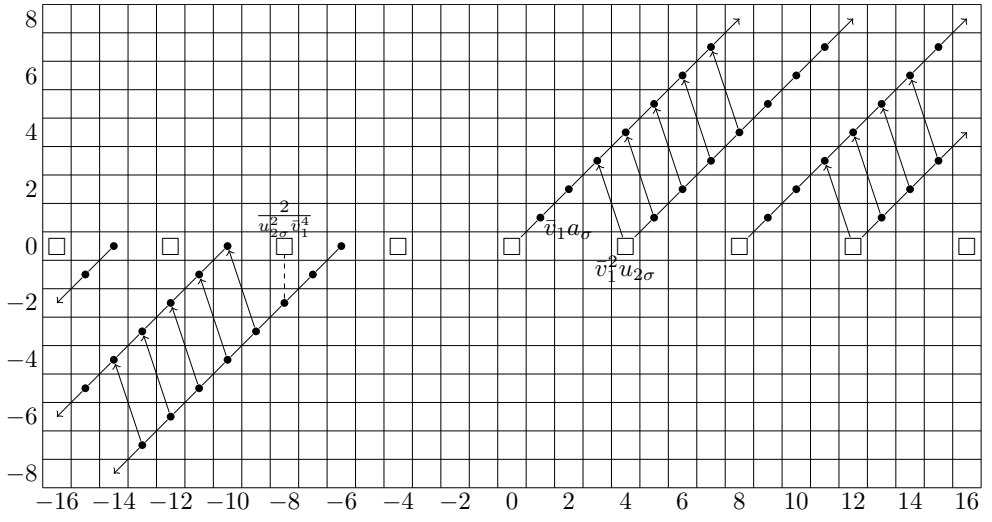

Figure 4.1. The slice spectral sequence for $K_{\mathbb{R}}$.

4.3. Periodicity and homotopy fixed points theorems. We first need a general result linking contractibility of geometric fixed points to the equivalence of fixed and homotopy fixed points.

Lemma 4.11. *Let R be a G-equivariant ring spectrum. If for all non-trivial H, the spectrum $\Phi^H(R)$ is contractible, then*

$$R \to F(EG_+, R)$$

is an equivalence.

Lemma 4.12. *Let M be an $MU^{((G))}$-module. If u_V is a permanent cycle in the slice spectral sequence for M, then u_V induces an equivalence*

$$\Sigma^{\dim V} M^{hG} \simeq (\Sigma^{\dim V} M)^{hG} \to (\Sigma^V M)^{hG}.$$

Proof. Since u_V survives the slice spectral sequence, it gives rise to an equivariant map

$$\Sigma^{\dim V} \bar{D}^{-1} MU^{((G))} \to \Sigma^V \bar{D}^{-1} MU^{((G))}.$$

Any map detected by u_V in the slice spectral sequence has the property that the underlying map is a weak equivalence. However, an equivariant map underlain by a weak equivalence induces a weak equivalence on homotopy fixed points, giving the result. □

If a class $\bar{D}$ we invert is a norm, then the resulting spectrum $\bar{D}^{-1}MU^{((G))}$ is again a commutative ring spectrum [19]. This means we can take the internal norms, which, on classes of the form u_V, were determined by Proposition 2.20.

We now have all of the ingredients. Corollary 4.10 provides a way to show that various geometric fixed point spectra are contractible, while Corollary 4.9 shows that classes $u_{2\sigma}^{2^k}$ are permanent cycles. This plays into the Periodicity Theorem, as the classes u_V are all orientation classes.

Definition 4.13. Let

$$\bar{D} = N_{C_2}^{C_8} \bar{r}_{1,3} N_{C_2}^{C_8} \bar{r}_{3,2} N_{C_2}^{C_8} \bar{r}_{15,1} \colon S^{19\rho_8} \to MU^{((C_8))}.$$

Let

$$\Omega = \bar{D}^{-1} MU^{((C_8))}.$$

Periodicity Theorem. *The homotopy groups of Ω^{hC_8} are 256-periodic.*

Homotopy Fixed Points Theorem. *The natural map*

$$\Omega^{C_8} \to \Omega^{hC_8}$$

is a weak equivalence.

We prove both simultaneously.

Proof. Since for any homotopy class x and for any groups $H \subset K \subset G$, the element $N_H^K(x)$ divides $i_K^* N_H^G(x)$, we know that inverting $\bar{D}$ inverts $N_{C_2}^{C_4} \bar{r}_{3,2}$ and $\bar{r}_{15,1}$. Thus $i_{C_4}^* \Omega$ is a module over $N_{C_2}^{C_4} \bar{r}_{3,2}^{-1} MU^{((C_4))}$ and similarly for $i_{C_2}^* \Omega$. Since by Corollary 4.10 each of these rings has contractible geometric fixed points, we conclude that for all nontrivial H, $\Phi^H \Omega$ is contractible. Lemma 4.11 then gives the desired equivalence.

By Corollary 4.9, we then conclude that $u_{2\sigma_8}^2$, $u_{2\sigma_4}^4$, and $u_{2\sigma_2}^{16}$ are permanent cycles. Combining the parts of Proposition 2.20 then shows that $u_{32\rho_8}$ is a permanent cycle in the slice spectral sequence for Ω.

Inverting $\bar{D}$ automatically makes the homotopy groups of Ω ρ_8-periodic. Combining this with Lemma 4.12 then shows that the homotopy groups of Ω^{hC_8} are 256-periodic. □

Heegaard splittings of 3-manifolds

Tao Li

Abstract. Heegaard splitting is one of the most basic and useful topological structures of 3-manifolds. In the past few years, much progress has been made on Heegaard splittings and several long-standing questions have been answered. In this paper, we review some recent progress in studying Heegaard splittings and discuss related open problems.

Mathematics Subject Classification (2010). Primary 57N10, 57M50; Secondary 57M25.

Keywords. Heegaard splitting, 3-manifold.

1. Introduction

A (3-dimensional) *handlebody* is a compact orientable 3–manifold with boundary that is homeomorphic to a closed regular neighborhood of a graph in $\mathbb{R}^3$. A *Heegaard splitting* of a closed orientable 3–manifold M is a decomposition of M into two handlebodies along an embedded surface called *Heegaard surface*. A Heegaard splitting can also be naturally associated to a Morse function $f\colon M \to \mathbb{R}$. The idea of Heegaard splitting was introduced by Poul Heegaard in his 1898 thesis [15] in which Heegaard constructed a counterexample to an early version of Poincaré's duality theorem. Heegaard splitting has been extensively studied by many mathematicians, such as Haken and Waldhausen in the 1960s and 70s, and it was a major tool in their efforts to prove the Poincaré Conjecture. In the 1980s, Casson and Gordon introduced an extremely powerful new concept called strongly irreducible Heegaard splitting, and this totally changed the study of Heegaard splittings. In particular, it leads to the resolution of several long-standing conjectures, e.g. [24, 25, 28, 30].

The definition of Heegaard splitting can be extended to 3-manifolds with boundary by replacing handlebody with compression body. A compression body can be viewed as the manifold obtained from a handlebody by removing a regular neighborhood of a portion of its core graph. A handlebody can be viewed as a special compression body. It follows from a theorem of Bing and Moise [2, 35] that every orientable 3–manifold has a Heegaard splitting.

Three–manifolds have some very nice topological and geometric structures. For example, a 3–manifold has a canonical prime decomposition along essential 2–spheres; see [16, 18, 21, 34]. A 3–manifold that contains no essential 2–sphere is said to be irreducible. An irreducible 3–manifold can be canonically decomposed into simpler pieces along essential tori, which is called a JSJ decomposition; see [19, 20]. Heegaard splittings also have close connections with these decompositions. Note that Thurston's geometrization, proved by Perelman, says that each closed 3–manifold with trivial prime and JSJ decompositions has one of eight geometries [42–44, 58].

Proceedings of the International Congress of Mathematicians, Seoul, 2014

Definition 1.1. Let $M = V \cup_S W$ be a Heegaard splitting of a 3–manifold M, where V and W are compression bodies and S is the Heegaard surface. The Heegaard splitting is *reducible* if there is a nontrivial simple loop in S that bounds disks in both V and W, otherwise the splitting is said to be *irreducible*. The Heegaard splitting is *weakly reducible* if there are disks $D_V \subset V$ and $D_W \subset W$ such that ∂D_V and ∂D_W are a pair of disjoint nontrivial loops in S. The Heegaard splitting is *strongly irreducible* if it is not weakly reducible.

Irreducible and strongly irreducible Heegaard splittings give tremendous information about the 3-manifolds. For example, by Haken's lemma [5, 10], a Heegaard splitting of a reducible 3–manifold is always reducible. If the 3–manifold contains an incompressible torus, then the distance (see section 3) of any Heegaard splitting is at most 2.

In their seminal work [5], Casson and Gordon showed that if a 3–manifold admits an irreducible but weakly reducible Heegaard splitting, then the manifold must be a Haken 3–manifold. The theorem of Casson and Gordon implies that an irreducible non-Haken 3–manifold always has a strongly irreducible Heegaard splitting. For Haken manifolds, Scharlemann and Thompson [49] gave a natural construction called untelescoping of a Heegaard splitting, which is a decomposition of the Haken 3–manifold into several "blocks" along incompressible surfaces, such that there is a strongly irreducible Heegaard splitting in each block and the original Heegaard splitting can be recovered by amalgamating these strongly irreducible Heegaard splittings along the incompressible surfaces (see [51] for a more detailed description).

Strongly irreducible Heegaard splittings have many remarkable properties. In the next few sections, we will discuss some of these properties and recent progress in studying Heegaard splittings.

2. Normal surfaces and branched surfaces

A Heegaard splitting $M = U \cup_S V$ can be viewed as a sweepout $H : S \times (I, \partial I) \to (M, \Sigma_U \cup \Sigma_V)$, where $I = [0, 1]$, Σ_U and Σ_V are the cores of the compression bodies U and V respectively, and $H|_{S\times(0,1)}$ is an embedding. If one considers the intersection of the sweepout of a strongly irreducible Heegaard splitting with another object (e.g. a surface), then being strongly irreducible puts some great restrains on the intersection patterns. This leads to many remarkable properties of strongly irreducible Heegaard surfaces. For example, by studying how the sweepout meets the 2–skeleton of a triangulation of the 3–manifold, Rubinstein [48] (also see [56]) discovered that a strongly irreducible Heegaard surface can be isotoped into a nice position with respect to any given triangulation. A surface in such a position is called an almost normal surface, which is a slight generalization of the classical normal surface theory studied by Kneser and Haken [9, 21]. A surface is normal with respect to a triangulation if its intersection with every tetrahedron is a collection of normal disks (i.e. triangles or quadrilaterals that meet each edge in at most one point and meet each face of the tetrahedron in at most one edge). A surface is almost normal if its intersection with the tetrahedra consists of normal disks and exactly one almost normal piece, where an almost normal piece in a tetrahedron is either an octagon or an annulus obtained by connecting two normal disks by an unknotted tube; see [56] for details.

Theorem 2.1 (Rubinstein [48], Stocking [56]). *Given a triangulation of a compact orientable 3–manifold M, any strongly irreducible Heegaard surface is isotopic to a normal or*

an almost normal surface with respect to the triangulation.

The idea of sweepout and thin position used in Theorem 2.1 is very powerful in solving some decision problems in 3–manifold topology. In particular, Rubinstein and Thompson proved:

Theorem 2.2 (Rubinstein [48], Thompson [57]). *There is an algorithm to decide whether a closed 3–manifold is S^3.*

There is a natural connection between normal surfaces and branched surfaces. A branched surface can be viewed as a 2-dimensional analogue of a train track; see [23, 24, 28] for a discussion. A useful property of normal and almost normal surfaces is that these surfaces have only a finite number of different types of pieces in each tetrahedron. By identifying the normal disks of the same type, we obtain a branched surface. This implies that there is a finite collection of branched surfaces such that, after isotopy, every strongly irreducible Heegaard surface is carried by a branched surface in this collection. Using branched surfaces and measured laminations, we proved the so-called generalized Waldhausen Conjecture [24].

Theorem 2.3 ([24]). *A closed, orientable, irreducible and atoroidal 3–manifold has only finitely many Heegaard splittings in each genus, up to isotopy.*

A modified proof of Theorem 2.3 gives an algorithm to determine the Heegaard genus of a 3–manifold [28].

Theorem 2.4 ([28]). *There is an algorithm to determine the Heegaard genus of a closed orientable 3–manifold.*

A famous example of Casson and Gordon [6] shows that a 3–manifold can have an infinite family of strongly irreducible Heegaard splittings with different genera. This is constructed by "spinning" a Heegaard surface around an incompressible surface, and in particular, the 3–manifold is Haken. In [25], we used branched surfaces and laminations to study Heegaard surfaces and showed that this phenomenon happens only if there is an incompressible surface in the 3–manifold (i.e. the manifold is Haken); see Theorem 2.5. The proof is a limiting argument: Suppose a 3–manifold M contains an infinite family of strongly irreducible Heegaard splittings. Since all strongly irreducible Heegaard surfaces are isotopic to normal or almost normal surfaces, there is a branched surface carrying infinitely many strongly irreducible Heegaard surfaces. Thus, a subsequence of these Heegaard surfaces has a limit in the projective measured lamination space. By exploring some properties of strongly irreducible Heegaard splittings, we were able to show in [25] that this limit measured lamination is an essential lamination, which implies that the branched surface carries an incompressible surface and hence the manifold is Haken.

Theorem 2.5 ([25]). *A closed orientable non-Haken 3–manifold has only finitely many irreducible Heegaard splittings, up to isotopy.*

In the construction of Casson and Gordon [6], the sequence of strongly irreducible Heegaard surfaces $\{S_n\}$ can be expressed as $S_n = S + nF$, where S is a Heegaard surface, F is a closed incompressible surface and the sum is similar to the Haken sum for normal surfaces. Theorem 2.5 says that if a 3–manifold contains infinitely many strongly irreducible Heegaard surfaces, then the manifold must contain an incompressible surface. However, the limiting argument in the proof does not give a satisfactory picture. The following is an interesting open question. This question was also studied in [39].

Question 2.6. *Suppose a closed orientable 3–manifold M contains infinitely many pairwise nonisotopic strongly irreducible Heegaard surfaces. Does M always contain a sequence of strongly irreducible Heegaard surfaces $\{S_n\}$ that can be expressed as $S_n = S + nF$, where S is a Heegaard surface and F is an incompressible surface?*

In a certain sense, normal surface can be viewed as a combinatorial analogue of minimal surface. This is particularly true for incompressible surfaces and strongly irreducible Heegaard surfaces. For example, using the idea of sweepout, Pitts and Rubinstein proved the following theorem. This theorem provides a useful tool to study Heegaard surfaces using geometry.

Theorem 2.7 (Pitts-Rubinstein). *Let S be a strongly irreducible Heegaard surface in a closed 3–manifold. Then there is a minimal surface F such that S is either isotopic to F or to the surface obtained from the boundary of a regular neighborhood of F by attaching a 1–handle.*

3. Curve complex and Hempel distance

Let S be a closed orientable surface of genus at least 2. The curve complex of S, introduced by Harvey [13], is the complex whose vertices are the isotopy classes of essential simple closed curves in S, and $k+1$ vertices determine a k–simplex if they are represented by pairwise disjoint curves. We denote the curve complex of S by $\mathcal{C}(S)$. The curve complex of a torus is defined similarly, and $\mathcal{C}(T^2)$ is the same as the Farey graph. For any two vertices in $\mathcal{C}(S)$, the distance $d(x,y)$ is the minimal number of 1–simplices in a simplicial path jointing x to y.

Curve complex has been an important ingredient in the solutions of several important questions in low-dimensional geometry and topology, e.g. [30, 32, 33]. In [17], Hempel used the curve complex to define a certain complexity for Heegaard splittings: Given a Heegaard splitting $M = H_1 \cup_S H_2$. Let $\mathcal{H}_i$ $(i = 1, 2)$ be the set of vertices in $\mathcal{C}(S)$ represented by curves bounding disks in H_i. The distance $d(S)$ is defined to be the distance between $\mathcal{H}_1$ and $\mathcal{H}_2$ in the curve complex $\mathcal{C}(S)$. Clearly, the Heegaard splitting is reducible if and only if $d(S) = 0$, and if $g(S) \geq 2$, the Heegaard splitting is strongly irreducible if and only if $d(S) \geq 2$.

Hartshorn first observed that the Hempel distance of a Heegaard splitting is related to the genus of an incompressible surface [12]. Later, Scharlemann and Tomova showed that the same is true for strongly irreducible surfaces and in a much more general setting [50] (see [26] for another proof).

Theorem 3.1 (Hartshorn [12]). *Let $M = H_1 \cup_S H_2$ be a Heegaard splitting of a compact 3–manifold M. Suppose M contains a closed orientable incompressible surface P. Then $d(S) \leq 2g(P)$.*

Theorem 3.2 (Scharlemann-Tomova [50]). *Let $M = H_1 \cup_S H_2$ be a Heegaard splitting of a compact 3–manifold M. Suppose M contains a closed strongly irreducible surface P. Then $d(S) \leq 2g(P)$.*

Theorem 3.1 and Theorem 3.2 imply that if the Hempel distance of a Heegaard splitting is large, then the 3–manifold M contains no other small-genus Heegaard surface, and in

particular, this Heegaard splitting is the unique minimal-genus Heegaard splitting of the 3–manifold.

In [29], Hempel distance is generalized to measure the complexity of an amalgamation of any two compact 3-manifolds; see also [27]. Let F be a closed orientable surface embedded in a closed orientable 3–manifold M, and suppose F divides M into two submanifolds U_1 and U_2 with $\partial U_1 = \partial U_2 = F$. We may view $M = U_1 \cup_F U_2$ as an amalgamation of U_1 and U_2. Let $\mathcal{U}_i$ $(i = 1, 2)$ be the set of vertices in $\mathcal{C}(F)$ represented by boundary curves of properly embedded essential surfaces in U_i with maximal Euler characteristic. The amalgamation distance can be defined as $d(M) = d(\mathcal{U}_1, \mathcal{U}_2)$ in the curve complex $\mathcal{C}(F)$. For example, if F is compressible in U_i, then $\mathcal{U}_i$ consists of vertices represented by curves bounding disks in U_i. So the amalgamation distance is the same as the Hempel distance if F is a Heegaard surface. In [29], we proved the following theorem.

Theorem 3.3 ([29]). *Let $M = U_1 \cup_F U_2$ as above. If the amalgamation distance $d(M)$ is sufficiently large, then all small-genus Heegaard surfaces are standard.*

Theorem 3.3 is a fundamental tool used in answering the rank versus genus conjecture for closed hyperbolic 3-manifolds, which we will discuss in the next section.

4. Rank and Heegaard genus

Given a Heegaard splitting $M = U \cup_S V$ of a compact orientable 3-manifold M, if U is a handlebody, then the Heegaard splitting gives a natural presentation of the fundamental group of M: the core graph of U give a set of generators and a set of compressing disks in the compression body V gives a set of relators.

The Heegaard genus of a 3–manifold M, denoted by $g(M)$, is defined as the minimal genus of all the Heegaard surfaces of M, and we define the *rank* of M to be the minimal number of elements needed to generate $\pi_1(M)$. Suppose M is either closed or has connected boundary. Then every Heegaard splitting of M contains a handlebody, hence giving a presentation of $\pi_1(M)$. Thus we have $r(M) \leq g(M)$.

In the 1960s, Waldhausen asked whether $r(M) = g(M)$ for all M; see [11, 59]. This was called the generalized Poincaré Conjecture in [11], as the case $r(M) = 0$ is the Poincaré conjecture. In fact, many 3-manifolds satisfy this conjecture; e.g. if M is a small Seifert fibered space, then $r(M) = g(M)$. However, this conjecture is not true in general. In [4], Boileau and Zieschang found a Seifert fiber space with $r(M) = 2$ and $g(M) = 3$. Later, many other Seifert fiber spaces and graph manifolds have been found with similar properties; see e.g. [52]. A crucial ingredient in all these examples is that the fundamental group of a Seifert fiber space has a nontrivial center and, for a certain class of Seifert fiber spaces, one can use this property to find a smaller generating set of $\pi_1(M)$ than the one prescribed by a Heegaard splitting. However, these examples are very special. The fundamental group of a closed hyperbolic 3-manifold does not contain such commuting elements, so the modernized version of this old conjecture is whether $r(M) = g(M)$ holds for hyperbolic 3-manifolds; see [53, Conjecture 1.1]. This conjecture is sometimes called the Rank versus Genus Conjecture or the Rank Conjecture, as $r(M)$ can be viewed as the algebraic rank, and $g(M)$ can be regarded as the geometric rank of M. This conjecture is also related to the Fixed Price Conjecture in topological dynamics [1].

Some progress on this conjecture was made in the past few years. In [55], Souto proved

$r(M) = g(M)$ for any fiber bundle whose monodromy is a high power of a pseudo-Anosov map. In [41], Namazi and Souto showed that rank equals genus if the gluing map of a Heegaard splitting is a high power of a generic pseudo-Anosov map. This means that, in some sense, a sufficiently complicated hyperbolic 3-manifold satisfies this conjecture. On the other hand, many simple hyperbolic 3-manifolds also satisfy the conjecture; e.g., if $g(M) = 2$ then $\pi_1(M)$ cannot be cyclic and hence $r(M) = g(M) = 2$. In [30], we gave a negative answer to this conjecture.

Theorem 4.1 ([30]). *There is a closed orientable hyperbolic 3-manifold with rank of its fundamental group smaller than its Heegaard genus. Moreover, the discrepancy between its rank and Heegaard genus can be arbitrarily large.*

A basic idea of proving Theorem 4.1 is an observation based on the curve complex and Theorem 3.3: if there is a 3–manifold M such that ∂M is connected and $r(M) < g(M)$, then one can construct a closed 3–manifold $\hat{M}$ with $r(\hat{M}) < g(\hat{M})$ by capping off ∂M using a handlebody, via a complicated gluing map. This means that it suffices to construct such a 3–manifold M with connected boundary. The construction in [30] is an annulus sum of three pieces according to how generators of their fundamental groups are conjugate to each other.

Although rank and Heegaard genus are among the most basic invariants of 3-manifolds, they are surprisingly not well-studied. Theorem 4.1 says that they are not the same for hyperbolic 3-manifolds, but their relation is still not clear.

Question 4.2. *Is there a function $f(x)$, such that $g(M) \leq f(r(M))$ for any closed hyperbolic 3–manifold M.*

Another closely related but more difficult question is whether the function in Question 4.2 is linear.

Question 4.3. *Is there a number $\delta > 0$, such that $\frac{r(M)}{g(M)} > \delta$ for every closed hyperbolic 3–manifold M?*

Note that Biringer and Souto [3] made significant progress toward solving Question 4.2. They showed that, given any $\epsilon > 0$, there is a function f, such that for any closed hyperbolic 3–manifold M with injectivity radius bigger than ϵ, $g(M) \leq f(r(M))$.

The examples constructed in [30] are Haken manifolds. In a certain sense, non-Haken manifolds are more rigid than Haken manifolds; see e.g. [24, 25]. So it is interesting to know whether rank equals genus for non-Haken manifolds.

Question 4.4. *Is there a non-Haken 3-manifold M with $r(M) < g(M)$?*

Knot group has been an important topic in low-dimensional topology. Ever since 1960s (see [11]), people have been trying to answer the question of rank versus genus for knot exteriors, but this question remains open:

Question 4.5. *Is there a knot k in S^3 such that $r(S^3 - N(k)) < g(S^3 - N(k))$? How about a prime knot k?*

It is conceivable that one can use the methods in [30] to produce a composite knot k in S^3 whose exterior has rank smaller than Heegaard genus. But it is much harder to find a prime-knot example.

The examples in [30] are very complicated. It would be interesting to know what is the simplest hyperbolic 3–manifold with rank smaller than genus. For Seifert fibered spaces, the simplest such examples were discovered first, and the more complicated examples are, in a sense, built on these simple examples; see e.g. [4, 52]. It would be interesting to know whether there is a simpler hyperbolic example, or a simple local structure, such that the examples in [30] can be viewed as an extension of this simpler example or structure.

Question 4.6. *Among all hyperbolic 3-manifolds M with $r(M) < g(M)$, what is the minimal value for $r(M)$?*

Another interesting question related to Question 4.6 is whether the minimal value for $r(M)$ is 2 for hyperbolic 3-manifolds.

Question 4.7. *Let M be a hyperbolic 3-manifold with $r(M) = 2$. Is $g(M) = 2$?*

A fundamental tool in the construction of [30] is Theorem 3.3, which gives a nice formula to compute the Heegaard genus of an amalgamated 3–manifold. It is conceivable that a similar formula also holds for rank.

Question 4.8. *Is there an analogue of Theorem 3.3 for the rank of fundamental group?*

The following question is more specific.

Question 4.9. *Let M_1 and M_2 be compact 3-manifolds with connected boundary and $\partial M_1 \cong \partial M_2$. Let $\phi\colon \partial M_1 \to \partial M_2$ be a homeomorphism and let M be the closed manifold obtained by gluing M_1 to M_2 via ϕ. If ϕ is sufficiently complicated, then is it true that $r(M) = r(M_1) + r(M_2) - g(\partial M_i)$?*

Question 4.9 is true if both M_1 and M_2 are handlebodies and ϕ is a high power of a pseudo-Anosov map [41]. However, the question is unknown if only one of the two manifolds is a handlebody, and it is not even known in the case of Dehn filling, i.e., M_2 is a solid torus.

Theorem 4.1 says that the discrepancy $g(M) - r(M)$ can be arbitrarily large for hyperbolic 3-manifolds. However, the 3-manifolds constructed in [30] have the same ratio $\frac{r(M)}{g(M)}$. Thus the following is a natural question and is a slight variation of Question 4.3.

Question 4.10. *How small can the ratio $\frac{r(M)}{g(M)}$ be? Can the infimum of the ratio $\frac{r(M)}{g(M)}$ be zero for 3-manifolds?*

A map between two topological spaces is one of the most fundamental objects in topology. Degree-one maps are a particularly important class of maps. For 3-manifolds, such maps have a close relation with Thurston's geometrization of 3-manifolds (see [14, 54, 60]). It has been known for a long time that maps of nonzero degree between surfaces are standard [7]. However, many important questions remain open for maps between 3-manifolds. One of the most basic questions about degree-one maps between two 3-manifolds is the relation between their Heegaard genera.

Conjecture 4.11. *Let M and N be closed orientable 3-manifolds and suppose there is a degree-one map $f\colon M \to N$. Then $g(M) \geq g(N)$.*

Conjecture 4.11 is an old and difficult question in 3–manifold topology. It implies the Poincaré Conjecture: If a closed 3–manifold X is homotopy equivalent to S^3, since a homotopy equivalence is a degree-one map, Conjecture 4.11 implies that $g(X) = g(S^3) = 0$ and X must be S^3.

If $f\colon M \to N$ is a degree-one map, then $f_*\colon \pi_1(M) \to \pi_1(N)$ is a surjection and hence $r(M) \geq r(N)$. Thus, a counterexample to Conjecture 4.11 also gives a 3–manifold N with $g(N) > r(N)$. This suggests that Conjecture 4.11 is closely related to the rank versus genus question. In particular, one approach to constructing a counterexample to Conjecture 4.11 is to start with the examples in Theorem 4.1.

5. Dehn surgery on knots

One of the most useful constructions in low-dimensional topology is Dehn surgery. Let K be a nontrivial knot in the 3–sphere S^3 and let $E(K) = S^3 - N(K)$, where $N(K)$ is an open tubular neighborhood of K. Let $g(E(K))$ be the Heegaard genus of the knot exterior $E(K)$. Let $K(s)$ ($s \in \mathbb{Q} \cup \{\infty\}$) be the closed 3–manifold obtained by performing a Dehn surgery on K along slope s. An important question in 3–manifold topology is to determine the Heegaard genus of $K(s)$.

Theorem 5.1 (Gordon-Luecke [8]). *Let K be a nontrivial knot in S^3. If $g(K(s)) = 0$ (i.e. $K(s) = S^3$), then the Dehn surgery must be a trivial surgery, i.e. $s = \infty$.*

Theorem 5.1 concludes that there is no other way to obtain S^3 by performing Dehn surgery on a nontrivial knot in S^3. However, Dehn surgery on many knots can produce lens spaces. Berge observed that if a knot K lies on a genus-2 Heegaard surface of S^3 and K is primitive in each of the two handlebodies, then the genus-2 Heegaard splitting becomes a genus-1 splitting after a Dehn surgery, and hence the Dehn surgery yields a lens space. Such knots are called doubly primitive knots or Berge knots. A difficult question is whether the converse is true:

Conjecture 5.2 (Berge Conjecture). *Let K be a nontrivial knot in S^3. If $K(s)$ is a lens space (i.e. $g(K(s)) = 1$), then K must be a doubly primitive knot.*

When discussing Heegaard genus of knot exterior, sometimes it is more convenient to use another invariant called *tunnel number*. For any knot K is S^3, there is always a collection of disjoint and embedded arcs $\tau_1, \dots, \tau_t$ in S^3, such that $\tau_i \cap K = \partial\tau_i$ for each i, and $H = S^3 - N((\cup_{i=1}^t \tau_i) \cup K)$ is a handlebody. This means that ∂H is a Heegaard surface of $E(K)$. These arcs $\tau_1, \dots, \tau_t$ are called unknotting tunnels of K, and we say that they form a tunnel system for K. The tunnel number of K, denoted by $t(K)$, is the minimal number of arcs in a tunnel system for K. Clearly $g(E(K)) = t(K) + 1$.

By considering $E(K)$ as a submanifold of $K(s)$, it is easy to see that any Heegaard surface of $E(K)$ is a Heegaard surface of $K(s)$. Thus $g(K(s)) \leq g(E(K))$. Moreover, it is known that if the surgery slope s is "complicated", then a minimal-genus Heegaard surface in $E(K)$ remains a minimal-genus Heegaard surface of $K(s)$, in particular $g(K(s)) = g(E(K))$. Moriah and Rubinstein [38] first proved this for hyperbolic knots; Rieck and Sedgwick [45–47] gave a topological proof that works for all knots. This has also been generalized to handlebody surgery; see [29].

Theorem 5.3 (Moriah-Rubinstein [38]; Rieck-Sedgwick [45–47]). *Let K and $K(s)$ be as above. Then there is a finite set of slopes $\mathcal{N}$ and a finite set of lines of slopes $\mathcal{H}$, so that if $s \notin \mathcal{N} \cup \mathcal{H}$, then $g(K(s)) = g(E(K))$.*

In fact, they proved something stronger. They showed that, except for finitely many slopes, $g(K(s)) \geq g(E(K)) - 1$. Note that the theorems of Moriah-Rubinstein and Rieck-Sedgwick are for all 3-manifolds with torus boundary. If we only consider knots in S^3, it seems that this inequality always holds except for the trivial surgery:

Conjecture 5.4. *Let K be a nontrivial knot in S^3. Then $g(K(s)) \geq g(E(K)) - 1$ unless the Dehn surgery is a trivial surgery, i.e. $s = \infty$.*

There is an easy picture to see how Heegaard genus may drop after Dehn surgery. Given a minimal-genus Heegaard splitting $E(K) = H \cup_S W$ of the knot exterior $E(K)$, where H is a handlebody and W is a compression body. The Heegaard splitting is said to be s-primitive if there is a compressing disk D in H and an annulus A properly embedded in W, such that

1. one boundary circle of A lies in the Heegaard surface S and the other boundary circle is a circle of slope s in the boundary torus $\partial E(K)$, and
2. $\partial D \cap \partial A$ is a single point in S.

If the Heegaard splitting is s-primitive, then the annulus A extends to a disk in $K(s)$, which means that the corresponding Heegaard splitting in $K(s)$ is stabilized. Since the splitting $E(K) = H \cup_S W$ is a minimal-genus splitting, this means that $g(K(s)) < g(E(K))$. However, the converse of this phenomenon is not true: it is possible that a minimal-genus Heegaard splitting is not s-primitive in $E(K)$ but becomes stabilized in $K(s)$. Nonetheless, it is conceivable that, in this case, one can modify the Heegaard splitting into a new s-primitive Heegaard splitting of the same genus. The following conjecture says that if the Heegaard genus drops after an integer surgery, then the picture described above always occurs.

Conjecture 5.5. *Let K be a nontrivial knot in S^3. Suppose $g(K(s)) < g(E(K))$ for some integer s. Then $E(K)$ admits a minimal-genus and s-primitive Heegaard splitting.*

If s is an integer and $E(K)$ has an s-primitive genus-2 Heegaard splitting, then the knot K is doubly primitive. Hence Conjecture 5.5 implies the Berge Conjecture for knots with Heegaard genus 2 (i.e. tunnel number one knots).

If a Heegaard splitting of $E(K)$ is s-primitive and s is the meridian, then the splitting is called meridionally primitive or μ-primitive. A knot K is said to be meridionally primitive or μ-primitive, if $E(K)$ has a minimal-genus Heegaard splitting that is meridionally primitive.

Although we are focused on knots in S^3, the concept of s-primitive Heegaard splittings can be extended to all knot manifolds. Let K' be the core curve of the solid torus in the Dehn filling. We may view K' as a knot in $K(s)$. If $E(K)$ has a minimal-genus and s-primitive Heegaard splitting, then the knot K' is meridionally primitive in $K(s)$. Thus one way to understand Conjecture 5.5 is to study meridionally primitive knots in a 3–manifold. This approach seems particularly useful in attacking the Berge Conjecture, as lens spaces are among the best understood 3-manifolds.

Meridionally primitive knots have some very interesting properties. For example, if a knot K in S^3 is meridionally primitive, then for any other knot K', $g(E(K\#K')) <$

$g(E(K)) + g(E(K'))$; in other words, $t((K\#K') \leq t(K) + t(K')$; see [31] for an explanation. In [40], Morimoto proved a converse of this fact for small knots (a knot is small if its exterior contains no nonperipheral incompressible surface). He showed that if both K and K' are small knots, then $t((K\#K') \leq t(K) + t(K')$ only if one of K and K' is meridionally primitive. Morimoto and Moriah conjectured that the converse is always true [36, 40]. Kobayashi and Rieck [22] first gave a counterexample of which the two factors are both composite knots. Since composite knots are special, the conjecture was modified for prime knots; see [37, Conjecture 7.14]). Recently, this conjecture was also shown to be false [31]. In fact, we proved a much more general theorem:

Theorem 5.6 ([31]). *For any integer $n \geq 3$, there is a prime knot K such that*

1 *K is not meridionally primitive, and*

2 *for every m-bridge knot K' with $m \leq n$, the tunnel numbers satisfy $t(K\#K') \leq t(K)$.*

In light of Theorem 5.6, the following question was raised in [31].

Conjecture 5.7. *For any two knots K and K' in S^3, $t(K\#K') \geq t(K)$.*

Note that there is a degree-one map from $E(K\#K')$ to $E(K)$. Thus a counterexample to Conjecture 5.7 also gives a counterexample to Conjecture 4.11.

Algebraic K-theory of strict ring spectra

John Rognes

Abstract. We view strict ring spectra as generalized rings. The study of their algebraic K-theory is motivated by its applications to the automorphism groups of compact manifolds. Partial calculations of algebraic K-theory for the sphere spectrum are available at regular primes, but we seek more conceptual answers in terms of localization and descent properties. Calculations for ring spectra related to topological K-theory suggest the existence of a motivic cohomology theory for strictly commutative ring spectra, and we present evidence for arithmetic duality in this theory. To tie motivic cohomology to Galois cohomology we wish to spectrally realize ramified extensions, which is only possible after mild forms of localization. One such mild localization is provided by the theory of logarithmic ring spectra, and we outline recent developments in this area.

Mathematics Subject Classification (2010). Primary 19D10, 55P43; Secondary 19F27, 57R50.

Keywords. Arithmetic duality, automorphisms of manifolds, brave new rings, étale descent, logarithmic ring spectrum, logarithmic topological André–Quillen homology, logarithmic topological Hochschild homology, motivic truncation, replete bar construction, sphere spectrum, tame ramification, topological K-theory.

1. Strict ring spectra

First, let R be an abelian group. Ordinary singular cohomology with coefficients in R is a contravariant homotopy functor that associates to each based space X a graded cohomology group $\tilde{H}^*(X;R)$. It is stable, in the sense that there is a natural isomorphism $\tilde{H}^*(X;R) \cong \tilde{H}^{*+1}(\Sigma X;R)$, and this implies that it extends from the category of based spaces to the category of spectra. The latter is a category of space-like objects, where the suspension is invertible up to homotopy equivalence, and which has all colimits and limits. The extended cohomology functor becomes representable, meaning that there is a spectrum HR, called the Eilenberg–Mac Lane spectrum of R, and a natural isomorphism $\tilde{H}^*(X;R) \cong [X, HR]_{-*}$, where $[X, HR]_{-n}$ is the group of homotopy classes of morphisms $X \to \Sigma^n HR$.

Next, let R be a ring. Then the cohomology theory is multiplicative, meaning that there is a bilinear cup product $\tilde{H}^*(X;R) \times \tilde{H}^*(X;R) \to \tilde{H}^*(X;R)$. This is also representable in the category of spectra, by a morphism $\mu\colon HR \wedge HR \to HR$, where $\wedge$ denotes the smash product of spectra. With the modern models for the category of spectra [26, 40, 48] we may arrange that μ is strictly unital and associative, so that HR is a *strict ring spectrum*. Equivalent terms are A_∞ ring spectrum, S-algebra, symmetric ring spectrum and orthogonal ring spectrum.

If R is commutative, then the cup product is graded commutative, which at the representing level means that $\mu\tau \simeq \mu$, where $\tau\colon HR \wedge HR \to HR \wedge HR$ denotes the twist iso-

Proceedings of International Congress of Mathematicians, 2014, Seoul

morphism. In fact, we may arrange that μ is strictly commutative, in the sense that $\mu\tau = \mu$ as morphisms of spectra, so that HR is a *strictly commutative ring spectrum*. Equivalent phrases are E_∞ ring spectrum, commutative S-algebra, commutative symmetric ring spectrum and commutative orthogonal ring spectrum. This leads to a compatible sequence of Σ_k-equivariant morphisms $E\Sigma_{k+} \wedge HR^{\wedge k} \to HR$ for $k \geq 0$. At the represented level these morphisms give rise to power operations in cohomology, including Steenrod's operations Sq^i for $R = \mathbb{F}_2$ and $\beta^\epsilon P^i$ for $R = \mathbb{F}_p$.

One now realizes that the Eilenberg–Mac Lane ring spectra HR exist as special cases within a much wider class of ring spectra. Each spectrum B represents a generalized cohomology theory $X \mapsto \tilde{B}^*(X) = [X, B]_{-*}$ and a generalized homology theory $X \mapsto \tilde{B}_*(X) = \pi_*(B \wedge X)$. Examples of early interest include the spectrum KU that represents complex topological K-theory, $KU^*(X) = [X_+, KU]_{-*}$, and the spectrum MU that represents complex bordism, $MU_*(X) = \pi_*(MU \wedge X_+)$. A fundamental example is given by the sphere spectrum S, which is the image of the based space S^0 under the stabilization functor from spaces to spectra. It represents stable cohomotopy $\pi^*_S(X) = \tilde{S}^*(X)$ and stable homotopy $\pi^S_*(X) = \tilde{S}_*(X)$. Each of these three examples, KU, MU and S, is naturally a strictly commutative ring spectrum, representing a multiplicative cohomology theory with power operations, etc. Furthermore, there are interesting multiplicative morphisms connecting these ring spectra to the Eilenberg–Mac Lane ring spectra previously considered, as in the diagram

$$\begin{array}{ccccccc} & & & & KU & \longrightarrow & H\mathbb{Q} \\ & & & & \uparrow & & \uparrow \\ S & \longrightarrow & MU & \longrightarrow & ku & \longrightarrow & H\mathbb{Z}, \end{array}$$

where $ku = KU[0, \infty)$ denotes the connective cover of KU.

By placing the class of traditional rings inside the wider realm of all strict ring spectra, a new world of possibilities opens up. Following Waldhausen [47, p. xiii] we may refer to strict ring spectra as "brave new rings". If we think in algebro-geometric terms, where commutative rings appear as the rings of functions on pieces of geometric objects, then strictly commutative ring spectra are the functions on affine pieces of brave new geometries, more general than those realized by ordinary schemes.

How vast is this generalization? In the case of connective ring spectra B, i.e., those with $\pi_i(B) = 0$ for i negative, there is a natural ring spectrum morphism $B \to H\pi_0(B)$ that induces an isomorphism on π_0. This behaves for many purposes like a topologically nilpotent extension, and in geometric terms, B can be viewed as the ring spectrum of functions on an infinitesimal thickening of $\operatorname{Spec} \pi_0(B)$.

This infinitesimal thickening can be quite effectively controlled in terms of diagrams of Eilenberg–Mac Lane spectra associated with simplicial rings. The Hurewicz map $B \cong S \wedge B \to H\mathbb{Z} \wedge B$ is 1-connected, and there is an equivalence $H\mathbb{Z} \wedge B \simeq HR_\bullet$ for some simplicial ring $R_\bullet$. The square

$$\begin{array}{ccc} S \wedge S \wedge B & \longrightarrow & H\mathbb{Z} \wedge S \wedge B \\ \downarrow & & \downarrow \\ S \wedge H\mathbb{Z} \wedge B & \longrightarrow & H\mathbb{Z} \wedge H\mathbb{Z} \wedge B \end{array}$$

induces a 2-connected map from $B \cong S \wedge S \wedge B$ to the homotopy pullback. More generally, for each $n \geq 1$ there is an n-dimensional cubical diagram that induces an n-connected map

from the initial vertex B to the homotopy limit of the remainder of the cube, and the terms in that remainder have the form $HR_\bullet$ for varying simplicial rings $R_\bullet$. Dundas [24] used a clever strengthening of this statement to prove that relative algebraic K-theory is p-adically equivalent to relative topological cyclic homology for morphisms $A \to B$ of connective strict ring spectra, under the assumption that $\pi_0(A) \to \pi_0(B)$ is a surjection with nilpotent kernel. He achieved this by reducing to the analogous statement for homomorphisms $R_\bullet \to T_\bullet$ of simplicial rings, which had been established earlier by McCarthy [49]. This confirmed a conjecture of Goodwillie [33], motivated by a similar result for rational K-theory and (negative) cyclic homology [32].

How about the case of non-connective ring spectra? Those that arise as homotopy fixed points $B^{hG} = F(EG_+, B)^G$ for a group action may be viewed as the functions on an orbit stack for the induced G-action on the geometry associated to B. Those that arise as smashing Bousfield localizations $L_E B$, with respect to a homology theory E_*, may be viewed as open subspaces in a finer topology than the one derived from the Zariski topology on $\operatorname{Spec} \pi_0(B)$ [63, §9.3]. In the general case the connection to classical geometry is less clear.

2. Automorphisms of manifolds

Why should we be interested in brave new rings and their ring-theoretic invariants, like algebraic K-theory [26, Ch. VI], [55], other than for the sake of generalization? One good justification comes from the tight connection between the geometric topology of high-dimensional manifolds and the algebraic K-theory of strict ring spectra. This connection is given by the higher simple-homotopy theory initiated by Hatcher [36], which was fully developed by Waldhausen in the context of his algebraic K-theory of spaces [82] and the stable parametrized h-cobordism theorem [83]. On the geometric side, this theory concerns the fundamental problem of finding a parametrized classification of high-dimensional compact manifolds, up to homeomorphism, piecewise-linear homeomorphism or diffeomorphism, as appropriate for the respective geometric category. The set of path components of the resulting moduli space corresponds to the set of isomorphism classes of such manifolds, and each individual path component is a classifying space for the automorphism group $\mathrm{Aut}(X)$ of a manifold X in the respective isomorphism class.

This parametrized classification is finer than the one provided by the Browder–Novikov–Sullivan–Wall surgery theory [21, 84], which classifies manifolds up to h-cobordism (or s-cobordism), and whose associated moduli space has path components that classify the block automorphism groups of manifolds, rather than their actual automorphism groups. The difference between these two classifications is controlled by the space $H(X)$ of h-cobordisms $(W; X, Y)$ with a given manifold X at one end. Here W is a compact manifold with $\partial W = X \cup Y$, and the inclusions $X \to W$ and $Y \to W$ are homotopy equivalences. More precisely, there is one h-cobordism space $H^{\mathrm{Cat}}(X)$ for each of the three flavors of manifolds mentioned, namely $\mathrm{Cat} = \mathrm{Top}$, PL or Diff.

The original h-cobordism theorem enumerates the isomorphism classes of h-cobordisms with X at one end, i.e., the set $\pi_0 H(X)$ of path components of the h-cobordism space of X, in terms of an algebraic K-group of the integral group ring $\mathbb{Z}[\pi]$, where $\pi = \pi_1(X)$ is the fundamental group of X. One defines the Whitehead group as the quotient $\mathrm{Wh}_1(\pi) = K_1(\mathbb{Z}[\pi])/(\pm\pi)$, and associates a Whitehead torsion class $\tau(W; X, Y) \in \mathrm{Wh}_1(\pi)$ to each h-cobordism on X.

Theorem 2.1 (Smale [73], Barden, Mazur, Stallings). *Let X be a compact, connected n-manifold with $n \geq 5$ and $\pi = \pi_1(X)$. The Whitehead torsion defines a bijection*

$$\pi_0 H(X) \cong \mathrm{Wh}_1(\pi)\,.$$

These constructions involve using Morse functions or triangulations to choose a relative CW complex structure on the pair (W, X), or equivalently, a π-equivariant relative CW complex structure on the pair of universal covers $(\tilde{W}, \tilde{X})$, and to study the associated cellular chain complex $C_*(\tilde{W}, \tilde{X})$ of free $\mathbb{Z}[\pi]$-modules. This works fine as long as one is only concerned with a classification of h-cobordisms up to isomorphism, but for the parametrized problem, i.e., the study of the full homotopy type of $H(X)$, the passage from a CW complex structure to the associated cellular chain complex loses too much information. One should remember the actual attaching maps from the boundaries of cells to the preceding skeleta, not just their degrees. In a stable range this amounts to working with maps from spheres to spheres and coefficients in the sphere spectrum S, rather than with degrees and coefficients in the integers $\mathbb{Z}$. Likewise, the passage to the π-equivariant universal cover $\tilde{X} \to X$ should be replaced to a passage to a G-equivariant principal fibration $P \to X$, where P is contractible and $G \simeq \Omega X$ is a topological group that is homotopy equivalent to the loop space of $X \simeq BG$. To sum up, the parametrized analog of the Whitehead torsion must take values in a Whitehead space that is built from the algebraic K-theory of the spherical group ring $S[G] = S \wedge G_+$, a strict ring spectrum, rather than that of its discrete reduction, the integral group ring $\pi_0(S[G]) \cong \mathbb{Z}[\pi]$.

Waldhausen's algebraic K-theory of spaces, traditionally denoted $A(X)$, was first introduced without reference to strict ring spectra [80], but can be rewritten as the algebraic K-theory $A(X) = K(S[G])$ of the strict ring spectrum $S[G]$, cf. [26, Ch. VI] and [81]. This point of view is convenient for the comparison of algebraic K-theory with other ring-theoretic invariants.

In the case of differentiable manifolds, the Whitehead space $\mathrm{Wh}^{\mathrm{Diff}}(X)$ is defined to sit in a split homotopy fiber sequence of infinite loop spaces

$$\Omega^\infty(S \wedge X_+) \xrightarrow{\iota} K(S[G]) \longrightarrow \mathrm{Wh}^{\mathrm{Diff}}(X)\,.$$

In the topological case there is a homotopy fiber sequence of infinite loop spaces

$$\Omega^\infty(K(S) \wedge X_+) \xrightarrow{\alpha} K(S[G]) \longrightarrow \mathrm{Wh}^{\mathrm{Top}}(X)\,,$$

where α is known as the assembly map. The piecewise-linear Whitehead space is the same as the topological one. The stable parametrized h-cobordism theorem reads as follows.

Theorem 2.2 (Waldhausen–Jahren–Rognes [83, Thm. 0.1]). *Let X be a compact* Cat *manifold, for* $\mathrm{Cat} = \mathrm{Top}$, PL *or* Diff. *There is a natural homotopy equivalence*

$$\mathcal{H}^{\mathrm{Cat}}(X) \simeq \Omega\,\mathrm{Wh}^{\mathrm{Cat}}(X)\,,$$

where $\mathcal{H}^{\mathrm{Cat}}(X) = \mathrm{colim}_k\, H^{\mathrm{Cat}}(X \times I^k)$ is the stable Cat *h-cobordism space of X.*

When combined with connectivity results about the dimensional stabilization map

$$H(X) = H^{\mathrm{Cat}}(X) \to \mathcal{H}^{\mathrm{Cat}}(X)\,,$$

and here the main result is Igusa's stability theorem for smooth pseudoisotopies [42], knowledge of $K(S)$ and $K(S[G])$ gives good general results on the h-cobordism space $H(X)$ and the automorphism group $\mathrm{Aut}(X)$ of a high-dimensional manifold X.

Example 2.3. When G is trivial, so that $S[G] = S$ and X is contractible, the π_0-isomorphism and rational equivalence $S \to H\mathbb{Z}$ induces a rational equivalence $K(S) \to K(\mathbb{Z})$. Here $\pi_* K(\mathbb{Z}) \otimes \mathbb{Q}$ was computed by Borel [20], so

$$\pi_i \operatorname{Wh}^{\mathrm{Diff}}(*) \otimes \mathbb{Q} \cong \begin{cases} \mathbb{Q} & \text{for } i = 4k+1 \neq 1, \\ 0 & \text{otherwise.} \end{cases}$$

For $X = D^n$, Farrell–Hsiang [27] used this to show that

$$\pi_i \operatorname{Diff}(D^n) \otimes \mathbb{Q} \cong \begin{cases} \mathbb{Q} & \text{for } i = 4k-1,\ n \text{ odd}, \\ 0 & \text{otherwise,} \end{cases}$$

for i up to approximately $n/3$, where $\operatorname{Diff}(D^n)$ denotes the group of self-diffeomorphisms of D^n that fix the boundary. For instance, $\pi_3 \operatorname{Diff}(D^{13})$ is rationally nontrivial. By contrast, the group $\operatorname{Top}(D^n)$ of self-homeomorphisms of D^n that fix the boundary is contractible. Similar results follow for n-manifolds that are roughly $n/3$-connected.

The case of spherical space forms, when G is finite with periodic cohomology, has been studied by Hsiang–Jahren [41]. For closed, non-positively curved manifolds X, Farrell–Jones [28] showed that $\operatorname{Wh}^{\mathrm{Diff}}(X)$ can be assembled from copies of $\operatorname{Wh}^{\mathrm{Diff}}(*)$ and $\operatorname{Wh}^{\mathrm{Diff}}(S^1)$, indexed by the points and the closed geodesics in X, respectively. These correspond to the special cases G trivial and G infinite cyclic, respectively, so $K(S)$ and $K(S[\mathbb{Z}])$ are of fundamental importance for the parametrized classification of this large class of Riemannian manifolds. In this paper we shall focus on the case of $K(S)$, but see Hesselholt's paper [37] for the case of $K(S[\mathbb{Z}])$, and see Weiss–Williams [86] for a detailed survey about automorphisms of manifolds and algebraic K-theory.

Remark 2.4. More recent papers of Madsen–Weiss [46], Berglund–Madsen [12] and Galatius –Randal-Williams [29] give precise results about automorphism groups of manifolds of a fixed even dimension $n = 2d \neq 4$, at the expense of first forming a connected sum with many copies of $S^d \times S^d$. The latter results are apparently not closely related to the algebraic K-theory of strict ring spectra.

3. Algebraic K-theory of the sphere spectrum

We can strengthen the rational results about $A(X) = K(S[G])$, $\operatorname{Wh}^{\mathrm{Diff}}(X)$ and $\operatorname{Diff}(X)$ to integral results, or more precisely, to p-adic integral results for each prime p. From here on it will be convenient to think of algebraic K-theory as a spectrum-valued functor, and likewise for the Whitehead theories, so that there are homotopy cofiber sequences of spectra

$$S \wedge X_+ \xrightarrow{\iota} K(S[G]) \longrightarrow \operatorname{Wh}^{\mathrm{Diff}}(X)$$
$$K(S) \wedge X_+ \xrightarrow{\alpha} K(S[G]) \longrightarrow \operatorname{Wh}^{\mathrm{Top}}(X)\,,$$

and the first one is naturally split.

A key tool for this study is the cyclotomic trace map $\operatorname{trc}\colon K(B) \to TC(B;p)$ from algebraic K-theory to the topological cyclic homology of Bökstedt–Hsiang–Madsen [16]. The latter invariant of the strict ring spectrum B can sometimes be calculated by analyzing the S^1-equivariant homotopy type of the topological Hochschild homology spectrum $THH(B)$. Its power is illustrated by the following previously mentioned theorem.

Theorem 3.1 (Dundas [24]). *Let B be a connective strict ring spectrum. The square*

$$\begin{array}{ccc} K(B) & \longrightarrow & K(\pi_0(B)) \\ {\scriptstyle \mathrm{trc}}\downarrow & & \downarrow{\scriptstyle \mathrm{trc}} \\ TC(B;p) & \longrightarrow & TC(\pi_0(B);p) \end{array}$$

becomes homotopy Cartesian upon p-completion.

In the basic case $B = S$, when $K(S) \simeq S \vee \mathrm{Wh}^{\mathrm{Diff}}(*)$ determines $\mathrm{Diff}(D^n)$ for large n, this square takes the form below. Three of the four corners are quite well understood, but for widely different reasons.

$$\begin{array}{ccc} K(S) & \longrightarrow & K(\mathbb{Z}) \\ {\scriptstyle \mathrm{trc}}\downarrow & & \downarrow{\scriptstyle \mathrm{trc}} \\ TC(S;p) & \longrightarrow & TC(\mathbb{Z};p)\,. \end{array}$$

These reasons were tied together by the author for $p = 2$ in [61], and for p an odd regular prime in [62], to compute the mod p cohomology

$$H^*(K(S);\mathbb{F}_p) \cong \mathbb{F}_p \oplus H^*(\mathrm{Wh}^{\mathrm{Diff}}(*);\mathbb{F}_p)$$

as a module over the Steenrod algebra $\mathscr{A}$ of stable mod p cohomology operations. This sufficed to determine the E_2-term of the Adams spectral sequence

$$E_2^{s,t} = \mathrm{Ext}_{\mathscr{A}}^{s,t}(H^*(K(S);\mathbb{F}_p),\mathbb{F}_p) \Longrightarrow \pi_{t-s}K(S)_p$$

in a large range of degrees, and to determine the homotopy groups of $K(S)_p$ and $\mathrm{Wh}^{\mathrm{Diff}}(*)_p$ in a smaller range of degrees.

The structure of the algebraic K-theory of the integers, $K(\mathbb{Z})$, was predicted by the Lichtenbaum–Quillen conjectures [55], which were confirmed for $p = 2$ by Voevodsky [78] with contributions by Rognes–Weibel [67], and for p odd by Voevodsky [79] with contributions by Rost and Weibel. For $p = 2$ or p a regular odd prime, this led to a p-complete description of the spectrum $K(\mathbb{Z})$ in terms of topological K-theory spectra, which in turn led to an explicit description of the spectrum cohomology $H^*(K(\mathbb{Z});\mathbb{F}_p)$ as an $\mathscr{A}$-module.

The topological cyclic homology of the integers, $TC(\mathbb{Z};p)$, was computed for odd primes p by Bökstedt–Madsen [17, 18] and for $p = 2$ by the author [57–60], in papers that start with knowledge of the mod p homotopy of the S^1-spectrum $THH(\mathbb{Z})$ and inductively determine the mod p homotopy of the C_{p^n}-fixed points $THH(\mathbb{Z})^{C_{p^n}}$ for $n \geq 1$. It is then possible to recognize the p-completed spectrum level structure by comparisons with known models, using [56] for p odd, and to obtain the $\mathscr{A}$-module $H^*(TC(\mathbb{Z};p);\mathbb{F}_p)$ from this.

The topological cyclic homology of the sphere spectrum, $TC(S;p)$, was determined in the original paper [16]. There is an equivalence of spectra $TC(S;p) \simeq S \vee \Sigma\mathbb{C}P^\infty_{-1}$ after p-completion, where $\Sigma\mathbb{C}P^\infty_{-1}$ is the homotopy fiber of the dimension-shifting S^1-transfer map $t\colon \Sigma\mathbb{C}P^\infty_+ \to S$. The mod p cohomology $H^*(\Sigma\mathbb{C}P^\infty_{-1};\mathbb{F}_p)$ is well known as an $\mathscr{A}$-module. For $p = 2$ it is cyclic with

$$H^*(\Sigma\mathbb{C}P^\infty_{-1};\mathbb{F}_2) \cong \Sigma^{-1}\mathscr{A}/C\,,$$

where the ideal $C \subset \mathscr{A}$ is generated by the admissible Sq^I where $I = (i_1, \dots, i_n)$ with $n \geq 2$ or $I = (i)$ with i odd. The determination of the homotopy groups of $TC(S; p)$ is of comparable difficulty to the computation of the homotopy groups of S, due to our extensive knowledge about the attaching maps in the usual CW spectrum structure on $\Sigma\mathbb{C}P^\infty_{-1}$, cf. Mosher [52].

The linearization map $TC(S; p) \to TC(\mathbb{Z}; p)$ is only partially understood [45], but for p regular the cyclotomic trace map $K(\mathbb{Z}) \to TC(\mathbb{Z}; p)$ can be controlled by an appeal to global Tate–Poitou duality [76, Thm. 3.1], see [62, Prop. 3.1]. This leads to the following conclusion for $p = 2$. See [62, Thm. 5.4] for the result at odd regular primes.

Theorem 3.2 ([61, Thm. 4.5]). *The mod* 2 *cohomology of the spectrum* $\mathrm{Wh}^{\mathrm{Diff}}(*)$ *is given by the unique non-trivial extension of* $\mathscr{A}$*-modules*

$$0 \to \Sigma^{-2}C/\mathscr{A}(Sq^1, Sq^3) \longrightarrow H^*(\mathrm{Wh}^{\mathrm{Diff}}(*); \mathbb{F}_2) \longrightarrow \Sigma^3\mathscr{A}/\mathscr{A}(Sq^1, Sq^2) \to 0\,.$$

Using the Adams spectral sequence and related methods, the author obtained the following explicit calculations. Less complete information, in a larger range of degrees, is provided in the cited references. Previously, Bökstedt–Waldhausen [19, Thm. 1.3] had computed $\pi_i \mathrm{Wh}^{\mathrm{Diff}}(*)$ for $i \leq 3$.

Theorem 3.3 ([61, Thm. 5.8], [62, Thm. 4.7]). *The homotopy groups of* $\mathrm{Wh}^{\mathrm{Diff}}(*)$ *in degrees* $i \leq 18$ *are as follows, modulo* p*-power torsion for irregular primes* p*.*

i	0	1	2	3	4	5	6	7	8	9
$\pi_i \mathrm{Wh}^{\mathrm{Diff}}(*)$	0	0	0	$\mathbb{Z}/2$	0	$\mathbb{Z}$	0	$\mathbb{Z}/2$	0	$\mathbb{Z} \oplus \mathbb{Z}/2$

i	10	11	12	13	14
$\pi_i \mathrm{Wh}^{\mathrm{Diff}}(*)$	$\mathbb{Z}/8 \oplus (\mathbb{Z}/2)^2$	$\mathbb{Z}/6$	$\mathbb{Z}/4$	$\mathbb{Z}$	$\mathbb{Z}/36 \oplus \mathbb{Z}/3$

i	15	16	17	18
$\pi_i \mathrm{Wh}^{\mathrm{Diff}}(*)$	$(\mathbb{Z}/2)^2$	$\mathbb{Z}/24 \oplus \mathbb{Z}/2$	$\mathbb{Z} \oplus (\mathbb{Z}/2)^2$	$\mathbb{Z}/480 \oplus (\mathbb{Z}/2)^3$

Example 3.4. For $X = D^n$ with n sufficiently large, it follows that $\pi_{4p-4}\mathrm{Diff}(D^n)$ or $\pi_{4p-4}\mathrm{Diff}(D^{n+1})$ contains an element of order p, for each regular $p \geq 5$, and that $\pi_9\mathrm{Diff}(D^n)$ or $\pi_9\mathrm{Diff}(D^{n+1})$ contains an element of order 3, see [62, Thm. 6.4]. To get more precise results one needs to investigate the canonical involution on $\mathrm{Wh}^{\mathrm{Diff}}(*)$ and apply Weiss–Williams [85, Thm. A].

Remark 3.5. It would be interesting to extend these results to irregular primes. Dwyer–Mitchell [25] described the spectrum $K(\mathbb{Z})_p$ in terms of the p-primary Iwasawa module of the rationals. It should be possible to turn this into a description of the $\mathscr{A}$-module $H^*(K(\mathbb{Z}); \mathbb{F}_p)$. Next one must control the cyclotomic trace map $K(\mathbb{Z}) \to TC(\mathbb{Z}; p)$, or the closely related completion map $K(\mathbb{Z}) \to K(\mathbb{Z}_p)$, whose behavior is governed by special values of p-adic L-functions, cf. Soulé [74, Thm. 3].

4. Algebraic K-theory of topological K-theory

The calculations reviewed in the previous section extracted detailed information about $\pi_*K(S) \cong \pi_*(S) \oplus \pi_* \mathrm{Wh}^{\mathrm{Diff}}(*)$ from our knowledge of $\pi_*(\mathbb{C}P^\infty_{-1})$. However, this understanding was not

presented to us in as conceptual a way as the understanding we have of $K(\mathbb{Z})$, say in terms of Quillen's localization sequence

$$K(\mathbb{F}_p) \longrightarrow K(\mathbb{Z}) \longrightarrow K(\mathbb{Z}[1/p])$$

and the étale descent property

$$\pi_i K(\mathbb{Z}[1/p])_p \xrightarrow{\cong} K_i^{\text{ét}}(\mathbb{Z}[1/p]; \mathbb{Z}_p)$$

for $i > 0$, cf. [54, §5] and [55, §9]. It would be desirable to have a similarly conceptual understanding of $K(S)_p$ in terms of a comparison with $K(B)_p$ for suitably local strict ring spectra B, a descent property describing $K(B)_p$ as a homotopy limit of $K(C)_p$ for appropriate extensions $B \to C$, and a simple description of $K(\Omega)_p$ for a sufficiently large such extension $B \to \Omega$.

To explore this problem, we first simplify the number theory involved by working with the p-adic integers $\mathbb{Z}_p$ in place of the rational integers $\mathbb{Z}$, and then seek a conceptual understanding of $K(B)_p$ for some of the strictly commutative ring spectra B that are closest to $H\mathbb{Z}_p$, namely the p-complete connective complex K-theory spectrum ku_p and its Adams summand ℓ_p. Here $\pi_*(ku_p) = \mathbb{Z}_p[u]$ and $\pi_*(\ell_p) = \mathbb{Z}_p[v_1]$, with $|u| = 2$ and $|v_1| = 2p-2$. Let KU_p and L_p denote the associated periodic spectra, with $\pi_*(KU_p) = \mathbb{Z}_p[u^{\pm 1}]$ and $\pi_*(L_p) = \mathbb{Z}_p[v_1^{\pm 1}]$. There are multiplicative morphisms

$$\begin{array}{ccccccc} & & L_p & \xrightarrow{\phi} & KU_p & & \\ & & \uparrow & & \uparrow & & \\ S_p & \longrightarrow & \ell_p & \xrightarrow{\phi} & ku_p & \longrightarrow & H\mathbb{Z}_p \end{array} \tag{4.1}$$

of strictly commutative ring spectra, where $\phi_*(v_1) = u^{p-1}$. The group $\Delta \cong \mathbb{F}_p^\times$ of p-adic roots of unity acts by Adams operations on KU_p, and $\phi\colon L_p \to KU_p$ is a Δ-Galois extension in the sense of [63, p. 3].

Definition 4.1. Let $V(1) = S \cup_p e^1 \cup_{\alpha_1} e^{2p-1} \cup_p e^{2p}$ be the type 2 Smith–Toda complex, defined as the mapping cone of the Adams self-map $v_1\colon \Sigma^{2p-2} S/p \to S/p$ of the mod p Moore spectrum $S/p = S \cup_p e^1$. It is a ring spectrum up to homotopy for $p \geq 5$, which we now assume. We write $V(1)_*B = \pi_*(V(1) \wedge B)$ for the "mod p and v_1 homotopy" of any spectrum B. It is naturally a module over the polynomial ring $\mathbb{F}_p[v_2]$, where $v_2 \in \pi_{2p^2-2} V(1)$.

The mod p and v_1 homotopy of the topological cyclic homology of the connective Adams summand ℓ was computed by Ausoni and the author, by starting with knowledge of $V(1)_*THH(\ell)$ from [51] and inductively determining the mod p and v_1 homotopy of the fixed points $THH(\ell)^{C_{p^n}}$ for $n \geq 1$. The calculations were later extended to the full connective complex K-theory spectrum ku by Ausoni. To avoid introducing too much notation, we only describe the most striking features of the answers, referring to the original papers for more precise statements.

Theorem 4.2 (Ausoni–Rognes [5, Thm. 0.3, Thm. 0.4]). *$V(1)_*TC(\ell; p)$ is a finitely generated free $\mathbb{F}_p[v_2]$-module on $4(p+1)$ generators, which are located in degrees $-1 \leq * \leq 2p^2 + 2p - 2$. There is an exact sequence of $\mathbb{F}_p[v_2]$-modules*

$$0 \to \Sigma^{2p-3}\mathbb{F}_p \longrightarrow V(1)_*K(\ell_p) \xrightarrow{\text{trc}} V(1)_*TC(\ell; p) \longrightarrow \Sigma^{-1}\mathbb{F}_p \to 0\,.$$

Theorem 4.3 (Ausoni [4, Thm. 7.9, Thm. 8.1]). *$V(1)_*TC(ku;p)$ is a finitely generated free $\mathbb{F}_p[v_2]$-module on $4(p-1)(p+1)$ generators, which are located in degrees $-1 \le * \le 2p^2+2p-2$. There is an exact sequence of $\mathbb{F}_p[v_2]$-modules*

$$0 \to \Sigma^{2p-3}\mathbb{F}_p \longrightarrow V(1)_*K(ku_p) \xrightarrow{\mathrm{trc}} V(1)_*TC(ku;p) \longrightarrow \Sigma^{-1}\mathbb{F}_p \to 0\,,$$

and the natural map $K(\ell_p) \to K(ku_p)^{h\Delta}$ is a p-adic equivalence.

Blumberg–Mandell [14] constructed homotopy cofiber sequences

$$K(\mathbb{Z}_p) \longrightarrow K(\ell_p) \longrightarrow K(L_p) \tag{4.2}$$

and

$$K(\mathbb{Z}_p) \to K(ku_p) \to K(KU_p)\,,$$

which lead to calculations of $V(1)_*K(L_p)$ and $V(1)_*K(KU_p)$, cf. [4, Thm. 8.3]. The natural map $K(L_p) \to K(KU_p)^{h\Delta}$ is also a p-adic equivalence, which confirms the étale descent property for algebraic K-theory in this particular case.

Remark 4.4. The examples discussed above are the case $n = 1$ of a series of approximations to S associated with the Lubin–Tate spectra E_n, with coefficient rings $\pi_*E_n = \mathbb{W}\mathbb{F}_{p^n}[[u_1,\dots,u_{n-1}]][u^{\pm 1}]$, which are known to be strictly commutative ring spectra by the Goerss–Hopkins–Miller obstruction theory [31]. There are multiplicative morphisms

$$\begin{array}{ccccccc}
\hat{L}_nS & \longrightarrow & \hat{L}_nE(n) & \xrightarrow{\phi} & E_n & & \\
\uparrow & & \uparrow & & \uparrow & & \\
L_nS & \longrightarrow & BP\langle n\rangle & \longrightarrow & e_n & \longrightarrow & H\pi_0(e_n)\,,
\end{array}$$

where L_n and $\hat{L}_n$ denote Bousfield localization with respect to the Johnson–Wilson spectrum $E(n)$ and the Morava K-theory spectrum $K(n)$, respectively, and $BP\langle n\rangle$ is the truncated Brown–Peterson spectrum. The n-th extended Morava stabilizer group $\mathbb{G}_n$ acts on E_n, and $\hat{L}_nE(n) \to E_n$ is an H-Galois extension for $H \cong \mathbb{F}_{p^n}^\times \rtimes \mathbb{Z}/n$. We write e_n for the connective cover of E_n.

The algebraic K-theory computations above provide evidence for the chromatic redshift conjecture, see [5, p. 7] and [6], predicting that the algebraic K-theory $K(B)$ of a purely v_n-periodic strictly commutative ring spectrum B, such as E_n, is purely v_{n+1}-periodic in sufficiently high degrees.

5. Motivic truncation and arithmetic duality

The proven Lichtenbaum–Quillen conjectures subsume a spectral sequence

$$E^2_{s,t} = H^{-s}_{\text{ét}}(R;\mathbb{Z}_p(t/2)) \Longrightarrow \pi_{s+t}K(R)_p\,,$$

which converges for reasonable R and $s+t$ sufficiently large. Here $H^*_{\text{ét}}$ denotes étale cohomology, R is a commutative $\mathbb{Z}[1/p]$-algebra, and $\mathbb{Z}_p(t/2) = \pi_t(KU_p)$ is $\mathbb{Z}_p(m)$ when

$t = 2m$ is even, and 0 otherwise. For instance, we may take $R = \mathscr{O}_F[1/p]$ to be the ring of p-integers in a number field F, or R may be a p-adic field, i.e., a finite extension of $\mathbb{Q}_p$.

The proven Beilinson–Lichtenbaum conjectures, cf. [75] and [30], provide a more precise convergence statement. For each field F containing $1/p$ there is a spectral sequence

$$E^2_{s,t} = H^{-s}_{\mathrm{mot}}(F; \mathbb{Z}(t/2)) \Longrightarrow \pi_{s+t}K(F)\,,$$

converging in all degrees, and similarly with mod p coefficients. Here H^*_{mot} denotes motivic cohomology, which satisfies

$$H^r_{\mathrm{mot}}(F; \mathbb{Z}/p(m)) \cong \begin{cases} H^r_{\text{ét}}(F; \mathbb{Z}/p(m)) & \text{for } 0 \le r \le m, \\ 0 & \text{otherwise.} \end{cases} \tag{5.1}$$

In terms of Bloch's higher Chow groups [13], the vanishing of these groups for $r > m$ expresses the fact that there are no codimension r subvarieties of affine m-space over $\operatorname{Spec} F$. Conversely,

$$H^r_{\text{ét}}(F; \mathbb{Z}/p(*)) \cong v_1^{-1} H^r_{\mathrm{mot}}(F; \mathbb{Z}/p(*)) \tag{5.2}$$

with $v_1 \in H^0_{\mathrm{mot}}(F; \mathbb{Z}/p(p-1))$. We refer to the aspects (5.1) and (5.2) of the Beilinson–Lichtenbaum conjectures as the *motivic truncation property* for the field F.

The following prediction expresses a similar conceptual description of $K(B)$ for some strictly commutative ring spectra, and should in particular apply for $B = \ell_p$, L_p, ku_p and KU_p.

Conjecture 5.1. *For purely v_1-periodic strictly commutative ring spectra B there is a spectral sequence*

$$E^2_{s,t} = H^{-s}_{\mathrm{mot}}(B; \mathbb{F}_{p^2}(t/2)) \Longrightarrow V(1)_{s+t}K(B)\,,$$

converging for $s + t$ sufficiently large.

Here H^*_{mot} denotes a currently undefined form of motivic cohomology for strictly commutative ring spectra. The coefficient $\mathbb{F}_{p^2}(t/2)$ may be interpreted as $V(1)_t E_2$, where E_2 is the Lubin–Tate ring spectrum [31] with $\pi_* E_2 = \mathbb{W}\mathbb{F}_{p^2}[[u_1]][u^{\pm 1}]$.

More generally one might consider purely v_n-periodic ring spectra B, replace $V(1)$ by any type $n+1$ finite spectrum $F(n+1)$, see [39], and replace $V(1)_t E_2$ and $V(1)_{s+t}K(B)$ by $F(n+1)_t E_{n+1}$ and $F(n+1)_{s+t}K(B)$, respectively.

Example 5.2. Based on the detailed calculations behind Theorem 4.2, it is fairly evident that the E^2-term for the spectral sequence conjectured to converge to $V(1)_*K(\ell_p)$ will be concentrated in the four columns $-3 \le s \le 0$, and that the free $\mathbb{F}_p[v_2]$-module generators are located in the groups $H^r_{\mathrm{mot}}(\ell_p; \mathbb{F}_{p^2}(m))$ where $0 \le r \le 3$ and $r \le m < r + p^2 + p - 1$. This presumes that the spectral sequence collapses at the E^2-term, for $p \ge 5$. In addition, there is a sporadic copy of $\mathbb{F}_p$ in $V(1)_{2p-3}K(\ell_p)$.

The class $v_2 \in V(1)_{2p^2-2}K(\ell_p)$ is represented in bidegree $(s,t) = (0, 2p^2-2)$, corresponding to $(r,m) = (0, p^2-1)$. The presence of $\mathbb{F}_p[v_2]$-module generators in the range $r + p^2 - 1 \le m$ shows that $H^r_{\mathrm{mot}}(\ell_p; \mathbb{F}_{p^2}(*))$ is *not* isomorphic to $v_2^{-1}H^r_{\mathrm{mot}}(\ell_p; \mathbb{F}_{p^2}(*))$ in several bigradings (r,m) with $r \le m < r + p$. In other words, the motivic truncation property fails for ℓ_p. However, this is to be expected, since ℓ_p has the residue ring spectrum $H\mathbb{Z}_p$ and should not behave as a field.

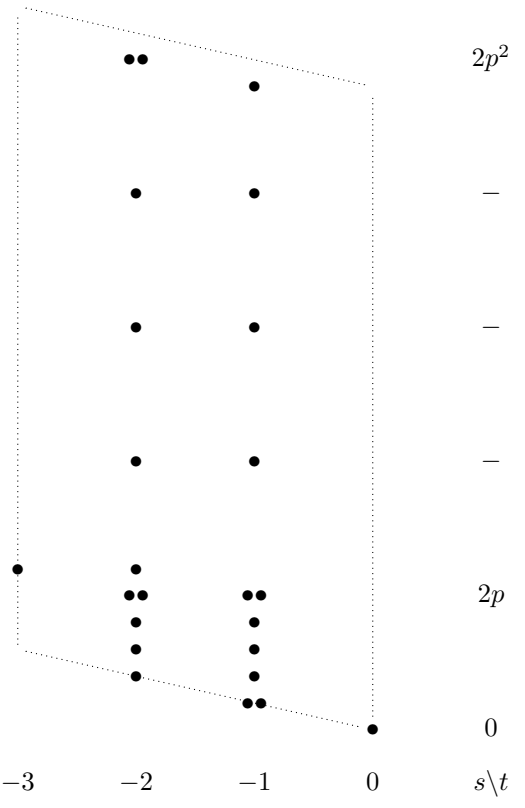

Figure 5.1. $\mathbb{F}_p[v_2]$-generators of $E^2_{s,t} = H^{-s}_{\mathrm{mot}}(L_p; \mathbb{F}_{p^2}(t/2)) \Longrightarrow V(1)_{s+t}K(L_p)$

Example 5.3. Turning instead to $V(1)_*K(L_p)$, as determined from $V(1)_*K(\mathbb{Z}_p)$ and $V(1)_*K(\ell_p)$ by the homotopy cofiber sequence (4.2), free $\mathbb{F}_p[v_2]$-module generators for the E^2-term in Conjecture 5.1 would be concentrated in the groups $H^r_{\mathrm{mot}}(L_p; \mathbb{F}_{p^2}(m))$ with $0 \le r \le 3$ and $r \le m < r + p^2 - 1$. The (s,t)-bidegrees of these $4p+4$ generators are displayed for $p = 5$ in Figure 5.1, lying in a fundamental domain in the shape of a parallelogram, of width 3 and height $2p^2 - 2$. In addition, there are sporadic copies of $\mathbb{F}_p$ in $V(1)_{2p-3}K(L_p)$ and $V(1)_{2p-2}K(L_p)$.

In this case, the motivic truncation property for L_p is perfectly satisfied, in the sense that

$$H^r_{\mathrm{mot}}(L_p; \mathbb{F}_{p^2}(m)) \cong \begin{cases} H^r_{\text{ét}}(L_p; \mathbb{F}_{p^2}(m)) & \text{for } 0 \le r \le m, \\ 0 & \text{otherwise,} \end{cases}$$

where, by definition,

$$H^r_{\text{ét}}(L_p; \mathbb{F}_{p^2}(*)) = v_2^{-1} H^r_{\mathrm{mot}}(L_p; \mathbb{F}_{p^2}(*))$$

is free over the Laurent polynomial ring $\mathbb{F}_p[v_2^{\pm 1}]$ on the same generators as in Figure 5.1.

The (additive) Euler characteristic

$$\chi(L_p; \mathbb{F}_{p^2}(m)) = \sum_{r=0}^{3} (-1)^r \dim_{\mathbb{F}_p} H^r_{\mathrm{mot}}(L_p; \mathbb{F}_{p^2}(m))$$

is zero for each m, cf. [76, Thm. 2.2]. To the eyes of algebraic K-theory and the hypothetical motivic cohomology, the strictly commutative ring spectrum L_p behaves much like a brave new field. We discuss the role of its (non-commutative) residue ring L/p in the next section.

The étale cohomology of a p-adic field F satisfies local Tate–Poitou duality [76, Thm. 2.1]. In the case of mod p coefficients, this is a perfect pairing

$$H^r_{\text{ét}}(F; \mathbb{Z}/p(m)) \otimes H^{2-r}_{\text{ét}}(F; \mathbb{Z}/p(1-m)) \xrightarrow{\cup} H^2_{\text{ét}}(F; \mathbb{Z}/p(1)) \cong \mathbb{Z}/p$$

for each r and m. For general p-power torsion coefficients there is a perfect pairing taking values in the larger group $H^2_{\text{ét}}(F; \mathbb{Z}/p^\infty(1)) \cong \mathbb{Z}/p^\infty$, cf. [72, p. 130]. The multiplicative structure on $V(1)_*K(L_p)$ is compatible with an algebra structure on $H^*_{\mathrm{mot}}(L_p; \mathbb{F}_{p^2}(*))$ such that the resulting multiplicative structure on $H^*_{\text{ét}}(L_p; \mathbb{F}_{p^2}(*))$ also satisfies *arithmetic duality*. This can be seen as a rotational symmetry about $(s,t) = (-3/2, p+1)$ in the variant of Figure 5.1 where v_2 has been inverted.

Conjecture 5.4. *For finite extensions B of L_p there is a perfect pairing*

$$H^r_{\text{ét}}(B; \mathbb{F}_{p^2}(m)) \otimes H^{3-r}_{\text{ét}}(B; \mathbb{F}_{p^2}(p+1-m)) \xrightarrow{\cup} H^3_{\text{ét}}(B; \mathbb{F}_{p^2}(p+1)) \cong \mathbb{Z}/p$$

for each r and m.

Remark 5.5. The dependence of the twist in $\mathbb{F}_{p^2}(p+1)$ on the prime p may be an artifact of the passage to mod p and v_1 coefficients. Let $E_2/(p^\infty, u_1^\infty)$ be the E_2-module spectrum defined by the homotopy cofiber sequences $E_2 \to p^{-1}E_2 \to E_2/p^\infty$ and $E_2/p^\infty \to u_1^{-1}E_2/p^\infty \to E_2/(p^\infty, u_1^\infty)$. Its homotopy groups $\pi_*E_2/(p^\infty, u_1^\infty) = \mathbb{W}\mathbb{F}_{p^2}[[u_1]]/(p^\infty, u_1^\infty)[u^{\pm 1}]$ are Pontryagin dual to those of E_2. Then

$$\mathbb{F}_{p^2}(p+1) = V(1)_{2p+2}E_2 \cong V(1)_{2p+3}(E_2/p^\infty) \cong V(1)_{2p+4}E_2/(p^\infty, u_1^\infty)$$

and

$$\begin{aligned} V(1)_{2p+4}E_2/(p^\infty, u_1^\infty) &\subset (S/p)_5E_2/(p^\infty, u_1^\infty) \\ &\subset \pi_4E_2/(p^\infty, u_1^\infty) = \mathbb{W}\mathbb{F}_{p^2}[[u_1]]/(p^\infty, u_1^\infty)(2)\,. \end{aligned}$$

The conjectured arithmetic duality for mod p and v_1 coefficients may be a special case of a duality for p- and u_1-power torsion coefficients, taking values in

$$H^3_{\text{ét}}(B; \mathbb{W}\mathbb{F}_{p^2}[[u_1]]/(p^\infty, u_1^\infty)(2))\,.$$

It would be desirable to find a canonical identification of this group, like the Hasse invariant in the classical case of p-adic fields and Kato's work [43] on the Galois cohomology of higher-dimensional local fields.

6. Fraction fields and ramified extensions

The étale cohomology of a field is, by construction, the same as its Galois cohomology, i.e., the continuous group cohomology of its absolute Galois group. There is no such direct description of $H^r_{\text{ét}}(L_p; \mathbb{F}_{p^2}(m))$, since according to Baker–Richter [8] the maximal connected pro-Galois extension of L_p is the composite

$$L_p \xrightarrow{\phi} KU_p \longrightarrow KU_p^{\mathrm{nr}}\,,$$

where $\pi_*(KU_p^{\mathrm{nr}}) = \mathbb{W}\bar{\mathbb{F}}_p[u^{\pm 1}]$. The unramified extensions of $\pi_0(KU_p) = \mathbb{Z}_p$ are spectrally realized, using the methods of Schwänzl–Vogt–Waldhausen [71, Thm. 3] or Goerss–Hopkins–Miller [31], but the associated Galois group only has p-cohomological dimension 1, whereas L_p would have p-cohomological dimension 3. Likewise, the maximal connected pro-Galois extension of E_n is E_n^{nr}, with $\pi_*(E_n^{\mathrm{nr}}) = \mathbb{W}\bar{\mathbb{F}}[[u_1, \dots, u_{n-1}]][u^{\pm 1}]$, of p-cohomological dimension 1 over E_n and $\hat{L}_n E(n)$.

To allow for ramification at p, one might simply invert that prime. However, the resulting strictly commutative ring spectrum $p^{-1}L_p$, with $\pi_*(p^{-1}L_p) = \mathbb{Q}_p[v_1^{\pm 1}]$, is an algebra over $p^{-1}S_p = H\mathbb{Q}_p$, so $V(1)_*K(p^{-1}L_p)$ is an algebra over $V(1)_*K(\mathbb{Q}_p)$, where v_2 acts trivially. Hence $H^r_{\text{ét}}(p^{-1}L_p; \mathbb{F}_{p^2}(*))$ would be zero.

A milder form of localization may be appropriate. By Waldhausen's localization theorem [82], the homotopy fiber of $K(L_p) \to K(p^{-1}L_p)$ is given by the algebraic K-theory of the category with cofibrations of finite cell L_p-modules with p-power torsion homotopy, equipped with the usual weak equivalences. We might instead step back to a category with cofibrations of coherent L/p^ν-modules (i.e., having degreewise finite homotopy groups, see Barwick–Lawson [9]), for some natural number ν, and suppose that these have the same algebraic K-theory as the category with cofibrations of finite cell L/p-modules. Here $L/p = K(1)$ is the first Morava K-theory, which by Angeltveit [2] is a strict ring spectrum, but not strictly commutative. By Davis–Lawson [22, Cor. 6.4] the tower $\{L/p^\nu\}_\nu$ is as commutative as possible in the category of pro-spectra:

$$L/p \longleftarrow \{L/p^\nu\}_\nu \longleftarrow L_p \longrightarrow p^{-1}L_p\,.$$

Definition 6.1. Let $K(\!\!f L_p)$ be defined by the homotopy cofiber sequence

$$K(L/p) \xrightarrow{i_*} K(L_p) \longrightarrow K(\!\!f L_p)\,,$$

where i_* is the transfer map associated to $i\colon L_p \to L/p$.

We think of $K(\!\!f L_p)$ as the algebraic K-theory of a hypothetical *fraction field* of L_p, intermediate between L_p and $p^{-1}L_p$, and similar to the 2-dimensional local field $\mathbb{Q}_p(\!(u)\!)$. Its mod p and v_1 homotopy groups can be calculated using the following result, in combination with the homotopy cofiber sequence $K(\mathbb{F}_p) \to K(\ell/p) \to K(L/p)$.

Theorem 6.2 (Ausoni–Rognes [7, Thm. 7.6, Thm. 7.7]). *$V(1)_*TC(\ell/p; p)$ is a finitely generated free $\mathbb{F}_p[v_2]$-module on $2p^2 - 2p + 8$ generators, which are located in degrees $-1 \le * \le 2p^2 + 2p - 2$. There is an exact sequence of $\mathbb{F}_p[v_2]$-modules*

$$0 \to V(1)_*K(\ell/p) \xrightarrow{\mathrm{trc}} V(1)_*TC(\ell/p; p) \longrightarrow \Sigma^{-1}\mathbb{F}_p \oplus \Sigma^{2p-2}\mathbb{F}_p \to 0\,.$$

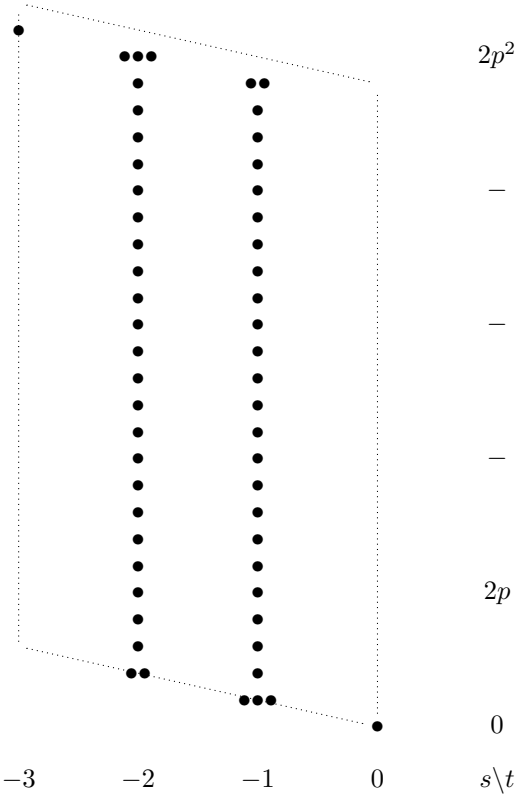

Figure 6.1. $\mathbb{F}_p[v_2]$-generators of $E^2_{s,t} = H^{-s}_{\mathrm{mot}}(\mathit{ff}\, L_p; \mathbb{F}_{p^2}(t/2)) \Longrightarrow V(1)_{s+t}K(\mathit{ff}\, L_p)$

Example 6.3. The expected E^2-term for a spectral sequence

$$E^2_{s,t} = H^{-s}_{\mathrm{mot}}(\mathit{ff}\, L_p; \mathbb{F}_{p^2}(t/2)) \Longrightarrow V(1)_{s+t}K(\mathit{ff}\, L_p)$$

is displayed for $p = 5$ in Figure 6.1. In addition there are four sporadic copies of $\mathbb{F}_p$, in degrees $2p-3$, $2p-2$, $2p-2$ and $2p-1$. The motivic truncation properties for $\mathit{ff}\, L_p$, analogous to (5.1) and (5.2), are clearly visible, and conjecturally there is now a perfect arithmetic duality pairing

$$H^r_{\text{ét}}(\mathit{ff}\, L_p; \mathbb{F}_{p^2}(m)) \otimes H^{3-r}_{\text{ét}}(\mathit{ff}\, L_p; \mathbb{F}_{p^2}(2-m)) \xrightarrow{\cup} H^3_{\text{ét}}(\mathit{ff}\, L_p; \mathbb{F}_{p^2}(2)) \cong \mathbb{Z}/p\,.$$

After such localization of L_p away from L/p, it may be possible to construct enough Galois extensions of $\mathit{ff}\, L_p$ to realize its v_2-localized motivic cohomology as continuous group cohomology

$$H^r_{\text{ét}}(\mathit{ff}\, L_p; \mathbb{F}_{p^2}(m)) \cong H^r_{\mathrm{gp}}(G_{\mathit{ff}\, L_p}; \mathbb{F}_{p^2}(m))\,,$$

for an absolute Galois group $G_{\mathit{ff}\, L_p}$ of p-cohomological dimension 3, corresponding to some maximal extension $\mathit{ff}\, L_p \to \Omega_1$. If each Galois extension of $\mathbb{Q}_p$ can be lifted to an extension of $\mathit{ff}\, L_p$, we get a short exact sequence

$$1 \to I_{v_1} \longrightarrow G_{\mathit{ff}\, L_p} \longrightarrow G_{\mathbb{Q}_p} \to 1\,,$$

with I_{v_1} the inertia group over (v_1). Here $G_{\mathbb{Q}_p}$ has p-cohomological dimension 2, and I_{v_1} will have p-cohomological dimension 1.

In the less structured setting of ring spectra up to homotopy it is possible to construct totally ramified extensions of KU_p, complementary to the unramified extension KU_p^{nr}, without inverting p. Torii [77, Thm. 2.5] shows that for each $r \geq 1$ the homotopy cofiber

$$F(B\mathbb{Z}/p_+^{r-1}, KU_p) \xrightarrow{\tau_r^\#} F(B\mathbb{Z}/p_+^r, KU_p) \longrightarrow KU_p[\zeta_{p^r}]\,,$$

of the map of function spectra induced by the stable transfer map $\tau_r\colon B\mathbb{Z}/p_+^r \to B\mathbb{Z}/p_+^{r-1}$, is a ring spectrum up to homotopy with $\pi_* KU_p[\zeta_{p^r}] \cong \mathbb{Z}_p[\zeta_{p^r}][u^{\pm 1}]$, where ζ_{p^r} denotes a primitive p^r-th root of unity. (He has similar realization results in the $K(n)$-local category.) However, it does not make sense to talk about the algebraic K-theory of a ring spectrum up to homotopy, so these constructions are only helpful if they can be made strict.

It is not possible to realize $KU_p[\zeta_{p^r}]$ as a strictly commutative ring spectrum. Angeltveit [1, Rem. 5.18] uses the identity $\psi^p(x) = x^p + p\theta(x)$ among power operations in π_0 of a $K(1)$-local strictly commutative ring spectrum to show that if $-p$ admits a k-th root in such a ring, with $k \geq 2$, then p is invertible in that ring. For $r = 1$ we have $\mathbb{Z}_p[\zeta_p] = \mathbb{Z}_p[\xi]$ where $\xi^{p-1} = -p$, so for p odd this proves that adjoining ζ_p to KU_p in a strictly commutative context will also invert p.

It is, however, possible to adjoin ζ_p to π_0 of the connective cover ku_p, in the category of strictly commutative ring spectra, without fully inverting p. Instead, one must make some positive power of the Bott element $u \in \pi_2(ku_p)$ singly divisible by p. If one thereafter inverts u, it follows that p has also become invertible. To achieve this, we modify Torii's construction for $r = 1$ by replacing the transfer map with a norm map. This leads to the G-Tate construction

$$B^{tG} = t_G(B)^G = [\widetilde{EG} \wedge F(EG_+, i_*B)]^G$$

for a spectrum B with G-action, cf. Greenlees–May [35, p. 3]. This construction preserves strictly commutative ring structures, see McClure [50, Thm. 1].

Example 6.4. Let $KU'_p[\xi] = (ku_p)^{t\mathbb{Z}/p}$ denote the $\mathbb{Z}/p$-Tate construction on the spectrum ku_p with trivial $\mathbb{Z}/p$-action, and let $ku'_p[\xi] = KU'_p[\xi][0,\infty)$ be its connective cover. Additively, these are generalized Eilenberg–Mac Lane spectra, cf. Davis–Mahowald [23] and [35, Thm. 13.5]. Multiplicatively, $\pi_*(KU'_p[\xi]) \cong \mathbb{Z}_p[\xi][v^{\pm 1}]$ where $p + \xi^{p-1} = 0$ and $|v| = 2$. Furthermore,

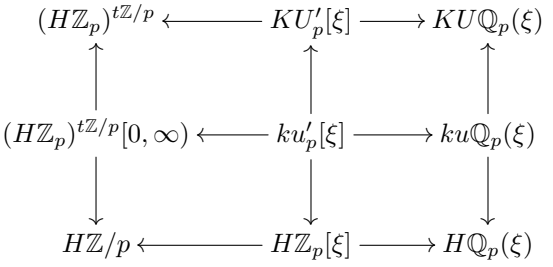
$$\pi_*(ku'_p[\xi]) \cong \mathbb{Z}_p[\xi][v]\,,$$

and a morphism $ku_p \to ku'_p[\xi]$ of strictly commutative ring spectra induces the ring homomorphism $\mathbb{Z}_p[u] \to \mathbb{Z}_p[\xi][v]$ that maps u to $\xi \cdot v$. There is no multiplicative morphism $KU_p \to KU'_p[\xi]$, but

$$KU_p \wedge_{ku_p} ku'_p[\xi] = u^{-1} ku'_p[\xi] \simeq KU\mathbb{Q}_p(\xi) = KU\mathbb{Q}_p(\zeta_p)$$

is a totally ramified extension of $KU\mathbb{Q}_p = p^{-1}KU_p$. We get a diagram of strictly commu-

tative ring spectra



with horizontal maps reducing modulo or inverting ξ, and vertical maps reducing modulo or inverting v. Here $\pi_*((H\mathbb{Z}_p)^{t\mathbb{Z}/p}) \cong \hat{H}^{-*}(\mathbb{Z}/p;\mathbb{Z}_p) = \mathbb{Z}/p[v^{\pm 1}]$. We view $ku'_p[\xi]$ as an integral model for a 2-dimensional local field close to $KU\mathbb{Q}_p(\xi)$, but note that $ku'_p[\xi]$ is not finite as a ku_p-module.

Example 6.5. Let $(\mathbb{Z}/p)^\times$ act on the group $\mathbb{Z}/p$ by multiplication, hence also on the $\mathbb{Z}/p$-Tate construction $KU'_p[\xi] = (ku_p)^{t\mathbb{Z}/p}$. Let

$$KU'_p = (KU'_p[\xi])^{h(\mathbb{Z}/p)^\times}$$

be the homotopy fixed points, and let $ku'_p = KU'_p[0,\infty)$ be its connective cover. These are strictly commutative ring spectra, with $\pi_*(KU'_p) \cong \mathbb{Z}_p[u, w^{\pm 1}]/(pw + u^{p-1})$ where $|w| = 2p-2$, and $\pi_*(ku'_p) \cong \mathbb{Z}_p[u,w]/(pw+u^{p-1})$. Multiplicative morphisms $ku_p \to ku'_p \to ku'_p[\xi]$ induce the inclusions $\mathbb{Z}_p[u] \to \mathbb{Z}_p[u,w]/(pw+u^{p-1}) \to \mathbb{Z}_p[\xi][v]$ where w maps to v^{p-1}.

The morphism $KU'_p \to KU'_p[\xi]$ is a $(\mathbb{Z}/p)^\times$-Galois extension in the sense of [63]. The morphism $ku'_p \to ku'_p[\xi]$ becomes $(\mathbb{Z}/p)^\times$-Galois after inverting p or w. It remains to be determined whether $V(1)_*K(ku'_p)$ remains purely v_2-periodic, i.e., whether the multiplicative approximation $ku_p \to ku'_p$ counters the additive splitting of ku'_p as a sum of suspended Eilenberg–Mac Lane spectra.

Example 6.6. More generally, for $r \geq 1$ let $G = \mathbb{Z}/p^r$, let $\mathscr{P}$ be the family of proper subgroups of G, and let $KU_G[0,\infty)$ be the "brutal" truncation of G-equivariant periodic K-theory, cf. [34, p. 129]. Define

$$KU'_p[\zeta_{p^r}] = (KU_G[0,\infty))^{t\mathscr{P}} = [\widetilde{E\mathscr{P}} \wedge F(E\mathscr{P}_+, KU_G[0,\infty))]^G$$

to be the $\mathscr{P}$-Tate construction, as in Greenlees–May [35, §17], and let $ku'_p[\zeta_{p^r}]$ be its connective cover. Then $\pi_*(KU'_p[\zeta_{p^r}]) \cong \mathbb{Z}_p[\zeta_{p^r}][v^{\pm 1}]$ and

$$\pi_*(ku'_p[\zeta_{p^r}]) \cong \mathbb{Z}_p[\zeta_{p^r}][v]\,.$$

The map $(KU_G[0,\infty))^{t\mathscr{P}} \to (KU_G)^{t\mathscr{P}}$ induces the inclusion $\mathbb{Z}_p[\zeta_{p^r}] \subset \mathbb{Q}_p[\zeta_{p^r}]$ in each even degree. To prove this, one can compute Amitsur–Dress homology for the family $\mathscr{P}$, use the generalized Tate spectral sequence from [35, §22], and then compare with the calculation in [35, §19] of the periodic case. The cyclotomic extension $\mathbb{Z}_p[\zeta_{p^r}]$ arises as $(R(G)/J'\mathscr{P})^\wedge_{J\mathscr{P}}$, where $R(G)$ is the representation ring, $J\mathscr{P}$ is the kernel of the restriction map $R(G) \to R(H)$, and $J'\mathscr{P}$ is the image of the induction map $R(H) \to R(G)$, where H is the index p subgroup in G.

7. Logarithmic ring spectra

The heuristics from the last two sections suggest that we should attempt to construct ramified finite extensions $B \to C$ of strictly commutative ring spectra B like ℓ_p, ku_p and e_n. The Goerss–Hopkins–Miller obstruction theory [31] for strictly commutative B-algebra structures on such spectra C has vanishing obstruction groups in the case of unramified extensions, but appears to be less useful in the case of ramification over (p), due to the presence of nontrivial (topological) André–Quillen cohomology groups [11].

The same heuristics also suggest that we should approach the extension problem by passing to mildly local versions of B, intermediate between B and $p^{-1}B$. In arithmetic algebraic geometry, one such intermediary is provided by logarithmic geometry, cf. Kato [44]. An affine pre-log scheme $(\operatorname{Spec} R, M)$ is a scheme $\operatorname{Spec} R$, a commutative monoid M, and a homomorphism $\alpha\colon M \to (R, \cdot)$ to the underlying multiplicative monoid of R. More precisely, M and α live étale locally on $\operatorname{Spec} R$. In this wider context, there is a factorization

$$\operatorname{Spec} R[M^{-1}] \longrightarrow (\operatorname{Spec} R, M) \longrightarrow \operatorname{Spec} R$$

of the natural inclusion, and the right-hand map is often a well-behaved proper replacement for the composite open immersion. Logarithmic structures on valuation rings in p-adic fields were successfully used by Hesselholt–Madsen [38] to analyze the topological cyclic homology and algebraic K-theory of these classical rings.

A theory of logarithmic structures on strictly commutative ring spectra was started by the author in [64], and developed further in joint work with Sagave and Schlichtkrull. To present it, we take the category $\mathcal{C}\mathrm{Sp}^\Sigma$ of commutative symmetric ring spectra [40], with the positive stable model structure [48, §14], as our model for strictly commutative ring spectra.

By the graded underlying space of a symmetric spectrum A we mean a diagram

$$\Omega^{\mathcal{J}}(A)\colon (\mathbf{n}_1, \mathbf{n}_2) \longmapsto \Omega^{n_2} A_{n_1}$$

of spaces, where $(\mathbf{n}_1, \mathbf{n}_2)$ ranges over the objects in a category $\mathcal{J}$. We call such a diagram a $\mathcal{J}$-space. Following Sagave, the natural category $\mathcal{J}$ to consider turns out to be isomorphic to Quillen's construction $\Sigma^{-1}\Sigma$, where Σ is the permutative groupoid of finite sets and bijections. Its nerve $B\mathcal{J} \cong B(\Sigma^{-1}\Sigma)$ is homotopy equivalent to $QS^0 = \Omega^\infty S$. For any $\mathcal{J}$-space X, the homotopy colimit $X_{h\mathcal{J}} = \operatorname{hocolim}_{\mathcal{J}} X$ is augmented over $B\mathcal{J}$, so we say that X is QS^0-graded. A map $X \to Y$ of $\mathcal{J}$-spaces is called a $\mathcal{J}$-equivalence if the induced map $X_{h\mathcal{J}} \to Y_{h\mathcal{J}}$ is a weak equivalence.

If A is a commutative symmetric ring spectrum, then $\Omega^{\mathcal{J}}(A)$ is a commutative monoid with respect to a convolution product in the category of $\mathcal{J}$-spaces. The category $\mathcal{CS}^{\mathcal{J}}$ of commutative $\mathcal{J}$-space monoids has a positive projective model structure [70, §4], with the $\mathcal{J}$-equivalences as the weak equivalences, and is Quillen equivalent to a category of E_∞ spaces over $B\mathcal{J}$. The functor $\Omega^{\mathcal{J}}\colon \mathcal{C}\mathrm{Sp}^\Sigma \to \mathcal{CS}^{\mathcal{J}}$ admits a left adjoint $M \mapsto S^{\mathcal{J}}[M]$, and $(S^{\mathcal{J}}[-], \Omega^{\mathcal{J}})$ is a Quillen adjunction.

There is a commutative submonoid of graded homotopy units $\iota\colon GL_1^{\mathcal{J}}(A) \subset \Omega^{\mathcal{J}}(A)$. A *pre-log ring spectrum* (A, M, α) is a commutative symmetric ring spectrum A with a pre-log structure (M, α), i.e., a commutative $\mathcal{J}$-space monoid M and a map $\alpha\colon M \to \Omega^{\mathcal{J}}(A)$ in $\mathcal{CS}^{\mathcal{J}}$. If the pullback $\alpha^{-1}(GL_1^{\mathcal{J}}(A)) \to GL_1^{\mathcal{J}}(A)$ is a $\mathcal{J}$-equivalence we call (M, α) a log structure and (A, M, α) a *log ring spectrum*. We often omit α from the notation.

In order to classify extensions $(A, M) \to (B, N)$ of pre-log ring spectra, one is led to study infinitesimal deformations and derivations in this category. Derivations are corepre-

sented by a logarithmic version $TAQ(A, M)$ of topological André–Quillen homology, defined by a pushout

$$\begin{array}{ccc} A \wedge_{S^{\mathcal{J}}[M]} TAQ(S^{\mathcal{J}}[M]) & \xrightarrow{\psi} & A \wedge \gamma(M) \\ \downarrow{\scriptstyle \alpha} & & \downarrow \\ TAQ(A) & \longrightarrow & TAQ(A, M) \end{array}$$

of A-module spectra, cf. [64, Def. 11.19] and [69, Def. 5.20]. Here $TAQ(A)$ is the ordinary topological André–Quillen homology, as defined by Basterra [10], and $\gamma(M)$ is the connective spectrum associated to the E_∞ space $M_{h\mathcal{J}}$. A morphism $(A, M) \to (B, N)$ is formally log étale if $B \wedge_A TAQ(A, M) \to TAQ(B, N)$ is an equivalence.

Let $j\colon e \to E$ be a fibration of commutative symmetric ring spectra. The direct image of the trivial log structure on E is the log structure $(j_*GL_1^{\mathcal{J}}(E), \alpha)$ on e given by the pullback

$$\begin{array}{ccc} j_*GL_1^{\mathcal{J}}(E) & \longrightarrow & GL_1^{\mathcal{J}}(E) \\ \downarrow{\scriptstyle \alpha} & & \downarrow{\scriptstyle \iota} \\ \Omega^{\mathcal{J}}(e) & \xrightarrow{\Omega^{\mathcal{J}}(j)} & \Omega^{\mathcal{J}}(E) \end{array}$$

in $\mathcal{CS}^{\mathcal{J}}$. Applying this natural construction to the vertical maps in (4.1), we get the following example. Note that $\ell_p \to ku_p$ is not étale, while $L_p \to KU_p$ is Δ-Galois, hence étale.

Theorem 7.1 (Sagave [69, Thm. 6.1]). *The morphism*

$$\phi\colon (\ell_p, j_*GL_1^{\mathcal{J}}(L_p)) \longrightarrow (ku_p, j_*GL_1^{\mathcal{J}}(KU_p))$$

is log étale.

In order to approximate algebraic K-theory, one is likewise led to study logarithmic topological Hochschild homology and logarithmic topological cyclic homology. The former is defined by a pushout

$$\begin{array}{ccc} S^{\mathcal{J}}[B^{\mathrm{cy}}(M)] & \xrightarrow{\rho} & S^{\mathcal{J}}[B^{\mathrm{rep}}(M)] \\ \downarrow{\scriptstyle \alpha} & & \downarrow \\ THH(A) & \longrightarrow & THH(A, M) \end{array}$$

in $\mathcal{C}\mathrm{Sp}^\Sigma$, cf. [65, §4]. Here $THH(A)$ is the ordinary topological Hochschild homology of A, given by the cyclic bar construction of A in $\mathcal{C}\mathrm{Sp}^\Sigma$. The cyclic bar construction $B^{\mathrm{cy}}(M)$ is formed in $\mathcal{CS}^{\mathcal{J}}$, and is naturally augmented over M. The *replete bar construction* $B^{\mathrm{rep}}(M)$ can be viewed as a fibrant replacement of $B^{\mathrm{cy}}(M)$ over M in a group completion model structure on $\mathcal{CS}^{\mathcal{J}}$, cf. [68, Thm. 1.6], but also has a more direct description as the (homotopy) pullback in the right hand square below:

$$\begin{array}{ccccc} B^{\mathrm{cy}}(M) & \xrightarrow{\rho} & B^{\mathrm{rep}}(M) & \longrightarrow & B^{\mathrm{cy}}(M^{\mathrm{gp}}) \\ \downarrow{\scriptstyle \epsilon} & & \downarrow & & \downarrow{\scriptstyle \epsilon} \\ M & \xrightarrow{=} & M & \xrightarrow{\eta} & M^{\mathrm{gp}}. \end{array}$$

Here $\eta\colon M \to M^{\mathrm{gp}}$ is a group completion in $\mathcal{CS}^{\mathcal{J}}$, which means that $(M^{\mathrm{gp}})_{h\mathcal{J}}$ is a group completion of the E_∞ space $M_{h\mathcal{J}}$. The role of repletion in homotopy theory is similar to that of working within the subcategory of fine and saturated logarithmic structures in the discrete setting [44, §2].

A morphism $(A, M) \to (B, N)$ is formally log thh-étale if $B \wedge_A THH(A, M) \to THH(B, N)$ is an equivalence. The following theorem strengthens the previous result.

Theorem 7.2 (Rognes–Sagave–Schlichtkrull [66, Thm. 1.5]). *The morphism*

$$\phi\colon (\ell_p, j_*GL_1^{\mathcal{J}}(L_p)) \longrightarrow (ku_p, j_*GL_1^{\mathcal{J}}(KU_p))$$

is log thh-étale.

Remark 7.3. These results harmonize with the classical correspondence between tamely ramified extensions and log étale extensions. By Noether's theorem [53], tame ramification corresponds locally to the existence of a normal basis. This conforms with the observation that ku_p is a retract of a finite cell $\ell_p[\Delta]$-module, so that $\ell_p \to ku_p$ is tamely ramified. By contrast, ku_2 is not a retract of a finite cell $ko_2[C_2]$-module, e.g. because $(ku_2)^{tC_2}$ is nontrivial, so $ko_2 \to ku_2$ is wildly ramified.

We say that a commutative symmetric ring spectrum E is d-periodic if d is the minimal positive integer such that $\pi_*(E)$ contains a unit in degree d.

Theorem 7.4 (Rognes–Sagave–Schlichtkrull [65, Thm. 1.5]). *Let E in $\mathcal{C}\mathrm{Sp}^{\Sigma}$ be d-periodic, with connective cover $j\colon e \to E$. There is a natural homotopy cofiber sequence*

$$THH(e) \xrightarrow{\rho} THH(e, j_*GL_1^{\mathcal{J}}(E)) \xrightarrow{\partial} \Sigma THH(e[0, d))\,,$$

where $e[0, d)$ is the $(d-1)$-th Postnikov section of e.

These results allow us to realize the strategy outlined in [3, §10] to compute the $V(1)$-homotopy of $THH(ku_p)$ by way of

$$THH(\ell_p)\,, THH(\ell_p, j_*GL_1^{\mathcal{J}}(L_p)) \text{ and } THH(ku_p, j_*GL_1^{\mathcal{J}}(KU_p)).$$

The details are given in [66, §7, §8].

When $e[0, d) = H\pi_0(e)$ with $\pi_0(e)$ regular, Blumberg–Mandell [15, Thm. 4.2.1] have constructed a map of horizontal homotopy cofiber sequences

$$\begin{array}{ccccc} K(\pi_0(e)) & \xrightarrow{i_*} & K(e) & \xrightarrow{j^*} & K(E) \\ \downarrow & & \downarrow & & \downarrow \\ THH(\pi_0(e)) & \xrightarrow{i_*} & THH(e) & \xrightarrow{j^*} & WTHH^{\Gamma}(e|E) \end{array}$$

where the vertical arrows are trace maps.

Conjecture 7.5. *There is an equivalence of cyclotomic spectra*

$$THH(e, j_*GL_1^{\mathcal{J}}(E)) \simeq WTHH^{\Gamma}(e|E)\,,$$

compatible with the maps from $THH(e)$ and to $\Sigma THH(\pi_0(e))$.

The author hopes that a logarithmic analog of the Goerss–Hopkins–Miller obstruction theory [31] can be developed to classify log extensions of log ring spectra, and that in the case of log étale extensions the obstruction groups will vanish in such a way as to enable the construction of interesting examples. The underlying strictly commutative ring spectra should then provide novel examples of tamely ramified extensions, and realize a larger part of motivic cohomology as a case of Galois cohomology.

The topology of positive scalar curvature

Thomas Schick

Abstract. Given a smooth closed manifold M we study the space of Riemannian metrics of positive scalar curvature on M. A long-standing question is: when is this space non-empty (i.e. when does M admit a metric of positive scalar curvature)? More generally: what is the topology of this space? For example, what are its homotopy groups? Higher index theory of the Dirac operator is the basic tool to address these questions. This has seen tremendous development in recent years, and in this survey we will discuss some of the most pertinent examples. In particular, we will show how advancements of *large scale index theory* (also called *coarse index theory*) give rise to new types of obstructions, and provide the tools for a systematic study of the existence and classification problem via the K-theory of C^*-algebras. This is part of a program "mapping the topology of positive scalar curvature to analysis". In addition, we will show how advanced surgery theory and smoothing theory can be used to construct the first elements of infinite order in the k-th homotopy groups of the space of metrics of positive scalar curvature for arbitrarily large k. Moreover, these examples are the first ones which remain non-trivial in the moduli space of such metrics.

Mathematics Subject Classification (2010). Primary 53C21; Secondary 53C27, 58D17, 53C20, 58D27, 58B05, 53C23, 19K56, 58J22, 19K33, 46L80, 57R15, 57N16, 57R65.

Keywords. Positive scalar curvature, higher index theory, large scale index theory, coarse index theory, coarse geometry, C^*-index theory.

1. Introduction

One of the fundamental questions at the interface of geometry and topology concerns the relation between local geometry and global topology.

More specifically, given a compact smooth manifold M without boundary, what are the possibilities for Riemannian metrics on M? Even more specifically, can we find a metric of positive scalar curvature on M and if yes, what does the space of such metrics look like?

Recall the following definition of the scalar curvature function.

Definition 1.1. Given an n-dimensional smooth Riemannian manifold (M, g), the *scalar curvature* at x describes the volume expansion of small balls around x via

$$\frac{\mathrm{vol}(B_\epsilon(M,x))}{\mathrm{vol}(B_\epsilon(\mathbb{R}^n,0))} = 1 - \frac{\mathrm{scal}(x)}{6(n+2)}\epsilon^2 + O(\epsilon^4),$$

compare [3, 0.60]. In particular, this means that if $\mathrm{scal}(x) > 0$ then geodesic balls around x for small radius have smaller volume than the comparison balls in Euclidean space. Of

Proceedings of the International Congress of Mathematicians, Seoul, 2014

course, alternatively, $\mathrm{scal}(x)$ can be defined as a second contraction of the Riemannian curvature operator at x.

The most important tool to investigate these questions goes back to Erwin Schrödinger [30], rediscovered by André Lichnerowicz [22]: If M has positive scalar curvature and a spin structure then the Dirac operator on M is invertible. This forces its index (which is the super-dimension of the null space) to vanish.

Recall that a spin structure is a (global) differential geometric datum for a Riemannian manifold M which allows to construct a specific Riemannian vector bundle S, the spinor bundle, together with a specific differential operator of order 1, the Dirac operator D (compare e.g. [21] for a nice introduction).

On the other hand non-vanishing of the index follows from index theorems, giving rise to powerful *obstructions* to positive scalar curvature. For example, the Atiyah-Singer index theorem says that $\mathrm{ind}(D) = \hat{A}(M)$, where the $\hat{A}$-genus is a fundamental differential topological invariant (not depending on the metric!).

The most intriguing question around this method to rule out positive scalar curvature asks to which extent a sophisticated refinement of $\mathrm{ind}(D)$ the *Rosenberg index* $\alpha^{\mathbb{R}}(M)$, what takes values in the K-theory of the (real) C^*-algebra of the fundamental group Γ of M, is the only obstruction. This is the content of the (stable) Gromov-Lawson-Rosenberg conjecture.

Conjecture 1.2. *Let M be a connected closed spin manifold of dimension ≥ 5. The* Gromov-Lawson-Rosenberg conjecture *asserts that M admits a metric with positive scalar curvature if and only if $\alpha^{\mathbb{R}}(M) = 0 \in KO_*(C^*_{\mathbb{R}}\pi_1(M))$.*

The stable Gromov-Lawson-Rosenberg conjecture *claims that $\alpha^{\mathbb{R}}(M) = 0$ if and only if there is $k \in \mathbb{N}$ such that $M \times B^k$ admits a metric with positive scalar curvature. Here, B is any so-called* Bott manifold *i.e. a simply connected 8-dimensional spin manifold with $\hat{A}(M) = 1$.*

To put the stable version in context: given two closed manifolds M, B such that M admits a metric of positive scalar curvature, so does $M \times B$, simply using the product of a sufficiently scaled metric on M with any metric on B. Therefore the unstable Gromov-Lawson-Rosenberg conjecture implies the stable one.

Recall here that for a discrete group Γ the *maximal group C^*-algebra* $C^*_{max}\Gamma$ is defined as the completion of the group ring $\mathbb{C}[\Gamma]$ with respect to the maximal possible C^*-norm on $\mathbb{C}[\Gamma]$, and the *reduced group C^*-algebra* $C^*_r\Gamma$ is defined as the norm closure of $\mathbb{C}[\Gamma]$, embedded in $\mathcal{B}(l^2(\Gamma))$ via the regular representation. The *real* group C^*-algebras $C^*_{\mathbb{R},r}\Gamma$ and $C^*_{\mathbb{R},max}\Gamma$ replace $\mathbb{C}$ by $\mathbb{R}$ throughout. Using them gives more information, necessary in the Gromov-Lawson-Rosenberg conjecture. In this survey, for simplicity we will not discuss them but concentrate on the complex versions. For the Rosenberg index one can use them all, where a priori $\alpha_{max}(M) \in K_*(C^*_{max}\pi_1(M))$ is stronger than $\alpha_r(M) \in K_*(C^*_r\pi_1(M))$. The *Baum-Connes isomorphism conjecture*, compare [2], predicts the calculation of $K_*(C^*_r\Gamma)$ in terms of the equivariant K-homology of a suitable classifying space. The *strong Novikov conjecture* predicts that this equivariant K-homology at least embeds.

In celebrated work Stephan Stolz [32, 33] has established the following two partial positive results.

Theorem 1.3. *The Gromov-Lawson-Rosenberg conjecture is true for manifolds with trivial fundamental group. In other words, if M is a closed connected spin manifold of dimension*

≥ 5 with trivial fundamental group, then M admits a Riemannian metric with positive scalar curvature if and only if $\alpha^{\mathbb{R}}(M) = 0$.

More generally, if $\pi_1(M)$ satisfies the strong Novikov conjecture then the stable Gromov-Lawson-Rosenberg conjecture is true for M.

On the other hand, recall the counterexamples of [6, 28] which show that the unstable Gromov-Lawson-Rosenberg conjecture is not always true.

Theorem 1.4. *For $5 \leq n \leq 8$ there exist closed spin manifolds M^n of dimension n such that $\alpha(M^n) = 0$, but such that M^n does not admit a metric with positive scalar curvature.*

The manifolds M_n can be constructed with fundamental groups $\mathbb{Z}^{n-1} \times \mathbb{Z}/3\mathbb{Z}$ or with appropriately chosen torsion-free fundamental group, but not with a free abelian fundamental group [19]. It remains one of the most intriguing open questions whether the Gromov-Lawson-Rosenberg conjecture is true for all n-dimensional manifolds with fundamental group $(\mathbb{Z}/3\mathbb{Z})^n$.

The obstructions used in the counterexamples of Theorem 1.4 are not based on index theory, but on the minimal hypersurface method of Richard Schoen and Shing-Tung Yau [29] which we will not discuss further in this survey.

As a companion to the Gromov-Lawson-Rosenberg conjecture we suggest a slightly weaker conjecture about the strength of the Rosenberg index:

Conjecture 1.5. *Let M be a closed spin manifold. Every obstruction to positive scalar curvature for manifolds of dimension ≥ 5 which is based on index theory of Dirac operators can be read off the Rosenberg index $\alpha^{\mathbb{R}}(M) \in KO_*(C^*_{\mathbb{R}}\pi_1(M))$.*

This is vague because the statement "based on index theory of Dirac operators" certainly leaves room for interpretation.

By Stolz' Theorem 1.3, Conjecture 1.5 follows from the strong Novikov conjecture. On the other hand, every index theoretic obstruction which is not (yet) understood in terms of the Rosenberg index is particularly interesting. After all, it is a potential starting point to obtain counterexamples to the strong Novikov conjecture.

Around this question we discuss the following results [8, 10, 11].

Theorem 1.6. *Let M be an area-enlargeable spin manifold (which implies by the work of Mikhail Gromov and Blaine Lawson [7] that M does not admit a metric of positive scalar curvature).*

Then $\alpha_{max}(M) \neq 0 \in K_*(C^*_{max}\pi_1(M))$.

If M is even (length)-enlargeable, then $\alpha_r(M) \neq 0 \in K_*(C^*_r\pi_1(M))$.

Recall that a closed n-dimensional manifold M is called *enlargeable* if it admits a sequence of coverings $M_i \to M$ which come with compactly supported maps $f_i \colon M_i \to S^n$ of non-zero degree but such that $\sup_{x \in M_i} \|D_x f_i\|$ tends to 0 as $i \to \infty$. It is *area-enlargeable* if the same holds with $\left\|\Lambda^2 D_x f_i\right\|$ (a weaker condition). For the definition of the norms, we use a fixed metric on M and its pull-backs to M_i and a fixed metric on S^n.

As a potential counterexample to Conjecture 1.5 we describe a *codimension*-2 obstruction to positive scalar curvature (in a special form introduced by Mikhail Gromov and Blaine Lawson in [7, Theorem 7.5]) which is based on index theory of the Dirac operator, but which so far is not known to be encompassed by the Rosenberg index.

Theorem 1.7 (compare [9, Section 4]). *Let M be a closed connected spin manifold with vanishing second homotopy group. Assume that $N \subset M$ is a smooth submanifold of codimension 2 with trivial normal bundle and such that the inclusion induces an injection on the level of fundamental groups $\pi_1(N) \hookrightarrow \pi_1(M)$. Finally, assume that the Rosenberg index of the Dirac operator on the submanifold N does not vanish: $0 \neq \alpha(N) \in K_*(C^*\pi_1 N)$.*

Then M does not admit a Riemannian metric with positive scalar curvature.

(Secondary) index invariants of the Dirac operator can be used in the *classification* of metrics of positive scalar curvature, if applied to appropriately constructed examples. "Classification" means in particular to understand how many deformation classes of metrics of positive scalar curvature a given manifold carries, or more generally what the topology of the space of such metrics looks like.

A promising tool to systematically study the existence and classification problem is the "Stolz positive scalar curvature long exact sequence". It has the form

$$\cdots \to R_{n+1}(\pi_1(M)) \to \mathrm{Pos}_n(M) \to \Omega_n^{\mathrm{spin}}(M) \to R_n(\pi_1(M)) \to \cdots$$

Here the group we would like to understand is $\mathrm{Pos}_n(M)$, the structure group of metrics of positive scalar curvature (on the spin manifold M and related manifolds, and modulo a suitable bordism relation). The group $\Omega_n^{\mathrm{spin}}(M)$ is the usual spin bordism group from algebraic topology, which is very well understood. Finally, $R_*(\pi_1(M))$ indeed depends only on the fundamental group of the manifold in question. Note that this positive scalar curvature sequence is very similar in spirit to the surgery exact sequence coming up in the classification of manifolds.

Unfortunately we have not yet been able to fully compute all the terms in this exact sequence, even for the simplest possible case of trivial fundamental group. However, a lot of information can be gained using index theory by mapping out to more manageable targets. Here, we refer in particular to [23], joint with Paolo Piazza, where we construct a commutative diagram of maps, using *large scale index theory*, to the K-theory sequence of associated C^*-algebras

$$\cdots \to K_{n+1}(C_r^*\Gamma) \to K_{n+1}(D^*\tilde{M}^\Gamma) \to K_n(M) \xrightarrow{\alpha} K_n(C_r^*\Gamma) \to \cdots$$

We again abbreviate $\Gamma = \pi_1(M)$. This sequence was introduced by Nigel Higson and John Roe [14] and called there the *analytic surgery exact sequence*. A lot is known about this K-theory sequence: $K_n(M)$ is just the usual topological K-homology of M (an important generalized homology theory). Moreover, α is the Baum-Connes assembly map.

A good deal of this survey will discuss the *large scale index theory* underlying the constructions. In particular, we will explain two primary and secondary index theorems which play key roles in the application of this theory:

- A vanishing theorem for the large scale index of the Dirac operator under partial positivity of the scalar curvature, Theorem 6.1.
- A higher secondary index theorem, that shows how the large scale index of a manifold with boundary (which has positive scalar curvature near the boundary) determines a structure invariant of the boundary's metric of positive scalar curvature.

A fundamental problem in the use of (higher) index theory centers around the question whether there is a difference between *topological information* (which typically can be

computed much more systematically) and analytical information (which has the desired geometric consequences but often is hard to compute). This is answered (conjecturally) by the strong Novikov conjecture. This explains why these conjectures play such a central role in higher index theory. The appropriate version for large scale index theory is the *coarse Baum-Connes conjecture* (here, "with coefficients", for details compare Section 4).

Conjecture 1.8. *Given a locally compact metric space X of bounded geometry and an auxiliary coefficient C^*-algebra A, then in the composition*

$$K_*^{lf}(X;A) \to KX_*(X;A) \to K_*(C^*(X;A))$$

the second map is an isomorphism. Here, $K_*^{lf}(X)$ is the topologists' locally finite K-homology (a generalized homology theory) of the space X, and $K_*^{lf}(X;A)$ is a version with coefficients, still a generalized cohomology theory. Finally $KX_*(X;A)$, the coarse K-homology, is a variant which depends only on the large scale geometry of X.

This conjecture has many concrete applications. It implies the strong Novikov conjecture. However, I expect that counterexamples to these conjectures eventually will be found.

Concerning the classification question mentioned above, in the last part of the survey we will discuss a new construction method, based on advanced surgery theory and smoothing theory in the topology of manifolds.

Definition 1.9. We define $\mathrm{Riem}^+(M)$ to be the space of Riemannian metrics of positive scalar curvature on M, an infinite dimensional manifold.

The main result is that $\pi_k(\mathrm{Riem}^+(M))$ is very often non-trivial, even its image in the moduli space of such metrics remains non-trivial.

More precisely, we have the following theorem, derived in joint work with Bernhard Hanke and Wolfgang Steimle (compare [12, Theorem 1.1]).

Theorem 1.10. *For every $k \in \mathbb{N}$, there is $n_k \in \mathbb{N}$ such that, whenever M is a connected closed spin manifold with a metric g_0 of positive scalar curvature and with $\dim(M) > n_k$ and $k+\dim(M)+1 \equiv 0 \pmod 8$, then $\pi_k(\mathrm{Riem}^+(M), g_0)$ contains an element of infinite order.*

If M is a sphere, then the image of this element in $\pi_k(\mathrm{Riem}^+(M)/\mathrm{Diffeo}_{x_0}(M))$ also has infinite order, where the diffeomorphism group acts by pullback.

The second part of the theorem implies that the examples constructed do not rely on the homotopy properties of the diffeomorphism group of M. This is in contrast to all previous known cases, compare in particular [5, 17].

Here, $\mathrm{Diffeo}_{x_0}(M)$ is the subgroup of the full diffeomorphism group consisting of diffeomorphisms of M which fix the point $x_0 \in M$ and whose differential at x_0 is the identity. It is much more reasonable to use this subgroup instead of the full diffeomorphism group, because it ensures that the moduli space $\mathrm{Riem}^+(M)/\mathrm{Diffeo}_{x_0}(M)$ remains an infinite dimensional manifold, instead of producing a very singular space.

Remark 1.11. Most of the results mentioned so far display also how poorly the topology of positive scalar curvature is understood: the method relies on the index theory of the Dirac operator and the Schrödinger-Lichnerowicz formula. This is quite a miraculous relation which certainly is very helpful. But it requires the presence of a spin structure. Manifolds

without spin structure (and where not even the universal covering admits a spin structure) a priori shouldn't be very different from manifolds with spin structure, i.e. one would expect that many of them do not admit a metric of positive scalar curvature. But until now we have almost no tools to decide this (apart from the minimal surface method, which is only established in small dimensions).

Almost any progress in this direction would be a real breakthrough. An interesting recent contribution is the work of Dmitri Bolotov and Alexander Dranishnikov, which deals in particular with n-dimensional non-spin manifolds with fundamental group free abelian of rank n [4].

2. Index theory and obstructions to positive scalar curvature

The underlying principle how scalar curvature is coupled to the Dirac operator comes from a formula of Schrödinger [30], rediscovered and first applied by Lichnerowicz [22]. The starting point is a spin manifold (M, g), with spinor bundle S and *Dirac operator* D. Schrödinger's formula says

$$D^2 = \nabla^*\nabla + \frac{\mathrm{scal}}{4}.$$

The first term on the right is the "rough Laplacian", by definition a non-negative unbounded operator on the L^2-sections of S. The second term stands for point-wise multiplication with the scalar curvature function. If the scalar curvature is uniformly positive, this is a positive operator and hence D is invertible.

Let us recall the basics of the index theory of the Dirac operator, formulated in the language of operator algebras and K-theory. This is the most convenient setup for the generalizations we have in mind.

We start with a very brief introduction to the K-theory of C^*-algebras.

1. The assignment $A \mapsto K_*(A)$ is a functor from the category of C^*-algebras to the category of graded abelian groups.
2. We can (for a unital C^*-algebra A) define $K_0(A)$ as the group of equivalence classes of projectors in A and the matrix algebras $M_n(A)$.
3. We can (for a unital C^*-algebra A) define $K_1(A)$ as the group of equivalence classes of invertible elements in A and $M_n(A)$.
4. There is a natural Bott periodicity isomorphism $K_n(A) \to K_{n+2}(A)$.
5. For each short exact sequence of C^*-algebras $0 \to I \to A \to Q \to 0$ there is naturally associated a long exact sequence in K-theory

$$\cdots \to K_{n+1}(Q) \xrightarrow{\delta} K_n(I) \to K_n(A) \to K_n(Q) \to \cdots .$$

6. One can generalize K-theory for real and graded C^*-algebras. In the former case Bottperiodicity has period 8.
7. On can use extra symmetries based on Clifford algebras to give descriptions of $K_n(A)$ which are adapted to the treatment of n-dimensional spin manifolds.

On an even dimensional manifold, the spinor bundle canonically splits into $S = S^+ \oplus S^-$ and the Dirac operator is odd, i.e. has the form $D = \begin{pmatrix} 0 & D^- \\ D^+ & 0 \end{pmatrix}$. Let $\chi\colon \mathbb{R} \to \mathbb{R}$ be any continuous function which is odd (i.e. $\chi(-x) = \chi(x)$ for $x \in \mathbb{R}$) and with $\lim_{x\to\infty} \chi(x) = 1$. Functional calculus allows to define $\chi(D)$, which is an odd bounded operator acting on $L^2(S)$. Choosing an isometry $U\colon L^2(S^-) \to L^2(S^+)$ we form $U\chi(D)^+ \in \mathcal{B} := \mathcal{B}(L^2(S^+))$, the C^*-algebra of all bounded operators on $L^2(S^+)$. If M is *compact*, ellipticity of D implies that $U\chi(D)^+$ is invertible modulo the ideal $\mathcal{K} := \mathcal{K}(L^2(S^+))$ of compact operators. The short exact sequence of C^*-algebras $0 \to \mathcal{K} \to \mathcal{B} \to \mathcal{B}/\mathcal{K} \to 0$ gives rise to a long exact K-theory sequence and the relevant piece of this exact sequence for us is

$$\cdots \to K_1(\mathcal{B}) \to K_1(\mathcal{B}/\mathcal{K}) \xrightarrow{\delta} K_0(\mathcal{K}) \to \dots \tag{2.1}$$

As invertible elements in A represent classes in $K_1(A)$, the above spectral considerations yield a class $[U\chi(D)^+] \in K_1(\mathcal{B}/\mathcal{K})$ and we define the index to be $\operatorname{ind}(D) := \delta(U\chi(D)^+) \in K_0(\mathcal{K})$.

Of course, for the compact operators, $K_0(\mathcal{K})$ is isomorphic to $\mathbb{Z}$, generated by any rank 1 projector in $\mathcal{K}$. In our case $\delta(U\chi(D)^+)$ is represented by the projector onto the kernel of D^+ minus the projector onto the kernel of D^-, so that we arrive at the usual $\operatorname{ind}(D) := \dim\ker(D^+) - \dim\ker(D^-)$.

Analysing the situation more closely, the additional geometric information of positive scalar curvature implies invertibility of D which translates to the fact that $U\chi(D)^+$ is invertible already in $\mathcal{B}$ and then $[U\chi(D)^+] \in K_1(\mathcal{B}/\mathcal{K})$ in the sequence (2.1) has a lift to $K_1(\mathcal{B})$. Exactness implies $\operatorname{ind}(D) = 0$.

A second main ingredient concerning the index of the Dirac operator is the Atiyah-Singer index theorem [1]. A priori $\operatorname{ind}(D)$ (like the operator D) depends on the Riemannian metric on M. However, the index theorem expresses it in terms which are independent of the metric. More specifically, $\operatorname{ind}(D) = \hat{A}(M)$, the $\hat{A}$-genus of M.

This result has vast generalizations in many directions. A very important one (introduced by Jonathan Rosenberg [27]) modifies the Dirac operator by "twisting" with a smooth flat bundle E of (finitely generated projective) modules over an auxiliary C^*-algebra A. One then obtains an index in $K_*(A)$. Indeed, the construction is pretty much the same as above, with the important innovation that one replaces the scalars $\mathbb{C}$ by the more interesting C^*-algebra A, as detailed in Section 3.

The second generalization works for a non-compact manifold X. In this case the classical Fredholm property of the Dirac operator fails. To overcome this, *large scale index theory*, synonymously called *coarse index theory* is developing. Again this is based on C^*-techniques and pioneered by John Roe [24]. It is tailor-made for the non-compact setting. One obtains an index in the K-theory of the Roe algebra $C^*(X; A)$. In C^*-algebras, positivity implies invertibility, which finally implies that all the generalized indices vanish if one starts with a metric of uniformly positive scalar curvature.

The general pattern (from the point of view adopted in this article) of index theory is the following:

1. The geometry of the manifold M produces an interesting operator D.
2. This operators defines an element in an operator algebra A, which depends on the precise context.

3. The operator satisfies a Fredholm condition, which means it is invertible module an ideal I of the algebra A, again depending on the context.
4. The algebras in question are C^*-algebras. This implies that "positivity" of elements is defined, and moreover "positivity" implies invertibility.
5. A very special additional geometric input implies positivity and hence honest invertibility of our operator. For us, this special context will be the fact that we deal with a metric of uniformly positive scalar curvature.
6. Indeed, any element which is invertible in A modulo an ideal I defines an element in $K_{n+1}(A/I)$, where $n = \dim(M)$. (Instead of getting K_1, the fact that we deal with the Dirac operator of an n-dimensional manifold produces additional symmetries (related to actions of the Clifford algebra Cl_n) which give rise to the element in $K_{n+1}(A/I)$.)
7. We interpret the class defined by the Dirac operator as a fundamental class $[M] \in K_{n+1}(A/I)$. Homotopy invariance of K-theory implies that $[M]$ does not depend on the full geometric data which goes in the construction of the operator D, but only on the topology of M.
8. The K-theory exact sequence of the extension $0 \to I \to A \to A/I \to 0$ contains the boundary map δ. We call the image of $[M]$ under δ the index

$$\delta\colon K_{n+1}(A/I) \to K_n(I) \ ; \ [M] \mapsto \operatorname{ind}(D).$$

   Note that the degree arises from additional dimension-dependent symmetries which we do not discuss in this survey.
9. The additional *geometric* positivity assumption (uniformly positive scalar curvature) which implies invertibility already in A, gives rise to a canonical lift of $[M]$ to an element $\rho(M,g) \in K_{n+1}(A)$. Because of this, we think of $K_{n+1}(A)$ as a *structure group* and $\rho(M,g)$ is a *structure class*. It contains information about the underlying geometry.

Indeed, we want to advocate here the idea that the setup just described has quite a number of different manifestations, depending on the situation at hand. It can be adapted in rather flexible ways. The next section treats one example.

3. Large scale index theory

We describe "large scale index theory" for a complete Riemannian manifold of positive dimension.

Therefore, let (M,g) be such a complete Riemannian manifold. Fix a Hermitian vector bundle $E \to M$ of positive dimension. We first describe the operator algebras which are relevant. They are all defined as norm-closed subalgebras of $\mathcal{B}(L^2(M;E))$.

Definition 3.1. We need the following concepts.

- An operator $T\colon L^2(M;E) \to L^2(M;E)$ has *finite propagation* (namely $\leq R$) if $\phi T \psi = 0$ whenever $\phi, \psi \in C_c(M)$ are compactly supported continuous functions whose supports have distance at least R.

Here, we think of ϕ also as bounded operator on $L^2(M;E)$, acting by point-wise multiplication.

- T as above is called *locally compact* if ϕT and $T\phi$ are compact operators whenever $\phi \in C_c(M)$.
- T is called *pseudolocal* if $\phi T \psi$ is compact whenever $\phi, \psi \in C_c(M)$ with disjoint supports, i.e. such that $\phi\psi = 0$.
- The *Roe algebra* $C^*(M)$ is defined as the norm closure of the algebra of all bounded finite propagation operators which are locally compact. It is an ideal in the *structure algebra* $D^*(M)$ which is defined as the closure of the algebra of finite propagation pseudolocal operators.
- Assume that a discrete group Γ acts by isometries on M. Requiring in the above definitions that the finite propagation operators are in addition Γ-equivariant and then completing, we obtain the pair $C^*(M)^\Gamma \subset D^*(M)^\Gamma$.

Remark 3.2. For technical reasons, one actually should replace the bundle E by the bundle $E \otimes l^2(\mathbb{N})$ whose fibers are separable Hilbert spaces (or in the equivariant case by $E \otimes l^2(\mathbb{N}) \otimes l^2(\Gamma)$). Via the embedding $\mathcal{B}(L^2(M;E)) \to \mathcal{B}(L^2(M; E \otimes l^2(\mathbb{N})))$ implicitly we think of operators on $L^2(M;E)$ as operators in the bigger algebra without mentioning this. Using the larger bundle guarantees functoriality and independence on E, implicit in our notion $D^*(M)$.

Let A be an auxiliary C^*-algebra. Typical examples arise from a discrete group Γ, namely $C^*_{max}\Gamma$ or $C^*_r\Gamma$. An important role is then played by smooth bundles E over M with fibers finitely generated projective A-modules. These inherit fiberwise A-valued inner products (or more precisely Hilbert A-module structures in the sense of [20]). Integrating the fiberwise inner product then also defines a Hilbert A-module structure on the space of continuous compactly supported sections of E. By completion, we obtain the Hilbert A-module $L^2(M;E)$. The bounded, adjointable, A-linear operators on $L^2(M;E)$ form the Banach algebra $\mathcal{B}(L^2(M;A))$. The ideal of *A-compact operators* is defined as the norm closure of the ideal generated by operators of the form $s \mapsto v \cdot \langle s, w\rangle; L^2(M;E) \to L^2(M;E)$, with $v, w \in L^2(M;E)$.

We now define $C^*(M;A)$ and $D^*(M;A)$ mimicking Definition 3.1, but replacing the Hilbert space concepts by the Hilbert A-module concepts throughout. In particular, we use A-compact operators instead of compact operators. Also, the stabilization as discussed in Remark 3.2 is replaced suitably.

Example 3.3. Given a connected manifold M with fundamental group Γ, there is a canonical $C^*\Gamma$-module bundle, the *Mishchenko bundle* $\mathcal{L}$. It is the flat bundle associated to the left multiplication action of Γ on $C^*\Gamma$, where we treat $C^*\Gamma$ as the free right $C^*\Gamma$-module of rank 1, i.e. $\mathcal{L} = \tilde{M} \times_\Gamma C^*\Gamma$.

The construction of the large scale index is now based on two principles.

Proposition 3.4. *Let M be a complete Riemannian spin manifold, A an auxiliary C^*-algebra and $E \to M$ a smooth bundle of (finitely generated projective) A-modules with compatible connection. We form the twisted Dirac operator D_E as an unbounded operator on the Hilbert A-module of L^2-spinors on M with values in E.*

For the operator D_E, there exists a functional calculus. In particular, we can form $f(D_E)$ for $f\colon \mathbb{R} \to \mathbb{R}$ a continuous function which vanishes at ∞ or which has limits as $t \to \pm\infty$. Moreover, $f(D_E)$ depends only on the restriction of f to the spectrum of D_E. Then

(1) *if f has a compactly supported (distributional) Fourier transform then $f(D_E)$ has finite propagation.*

(2) *if f vanishes at infinity, then $f(D_E)$ is locally compact; if $f(t)$ converges as $t \to \pm\infty$ then $f(D_E)$ is at least pseudolocal.*

The first property is a rather direct consequence of unit propagation speed for the fundamental solution of the heat equation. The second one is an incarnation of ellipticity and local elliptic regularity.

These results are well known and have been used a lot in the literature (compare in particular [24]), indeed they form the basis of "large scale index theory". For the very general case needed in the proposition (with coefficients, arbitrary complete M), a complete proof is given in [9].

The construction of the large scale index is now rather straight-forward:

1. Take any continuous function $\psi\colon \mathbb{R} \to \mathbb{R}$ (later assumed to be odd) with $\lim_{t\to\infty} \psi(t) = 1$. Then Proposition 3.4 implies that $\psi(D_E)$ belongs to $D^*(M;A)$. Even better, $1-\psi^2$ vanishes at infinity, so that $1-\psi(D_E)^2$ belongs to $C^*(M;A)$.
2. By the principles listed at the end of Section 2, $\psi(D_E)$ gives rise to an element $[M;E]$ in $K_{n+1}(D^*(M;A)/C^*(M;A))$. (Here, we again avoid the discussion of the additional symmetries which raise the index by n). Homotopy invariance of C^*-algebra K-theory implies that this element is independent of the choice of ψ and depends only on the large scale features of the metric on M.
3. We define the large scale index (or synonymously "coarse index")
$$\operatorname{ind}(D_E) \in K_n(C^*(M;A))$$
as the image of $[M;E]$ under the boundary map of the long exact K-theory sequence.
4. If M has uniformly positive scalar curvature and E is flat, the Lichnerowicz-Weitzenböck formula implies that 0 is not in the spectrum of D_E. Then we can choose a function ψ which is equal to -1 on the negative part of the spectrum of D_E and equal to $+1$ on the positive part of the spectrum of D_E, so that $1-\psi^2$ vanishes on the spectrum of D_E, i.e. $\psi^2(D_E) = 1$. This means that $[M;E]$ lifts in a canonical way to $\rho(D;E) \in K_{n+1}(D^*(M;A))$ (this class depends on the metric of positive scalar curvature) and it implies that $\operatorname{ind}(D_E) = 0$.
5. A special feature is that $K_{n+1}(D^*(M;A)/C^*(M;A))$ indeed is homological in nature: it is canonically isomorphic to the locally finite K-homology $K_n^{lf}(M;A)$, satisfying the Eilenberg-Steenrod axioms of a (locally finite) generalized homology theory.

Example 3.5. If we apply this construction to a closed n-dimensional spin manifold M and the Mishchenko bundle $\mathcal{L}$ on M, we obtain $\operatorname{ind}(D_{\mathcal{L}}) \in K_n(C^*(M;C^*\Gamma))$.

However, there is a canonical isomorphism $K_*(C^*(M;C^*\Gamma)) \cong K_*(C^*\Gamma)$. Using this isomorphism, the Rosenberg index mentioned above is exactly $\operatorname{ind}(D_{\mathcal{L}})$:

$$\alpha(M) = \operatorname{ind}(D_{\mathcal{L}}) \in K_n(C^*\Gamma) \cong K_n(C^*(M;C^*\Gamma)).$$

The reduced C^*-algebra $C^*_r\Gamma$ of a discrete group is a canonical construction which captures many features of the group Γ, e.g. concerning its representation theory. However, it is very rigid. In particular, it is not functorial: a homomorphism $\Gamma_1 \to \Gamma_2$ will in general not induce a homomorphism $C^*_r\Gamma_1 \to C^*_r\Gamma_2$. As a consequence it is very hard to find homomorphisms out of $C^*_r\Gamma$ and also out of $K_*(C^*_r\Gamma)$.

Coarse geometry, however, immediately provides such a homomorphism (which allows one to detect elements in $K_*(C^*_r\Gamma)$). This is based on simple calculation: If a discrete group Γ isometrically acts freely and cocompactly on a metric space X, then C^*X^Γ is isomorphic to $C^*_r(\Gamma)\otimes\mathcal{K}$. "Forgetting equivariance" therefore gives the composite homomorphism

$$C^*_r\Gamma \hookrightarrow C^*_r\Gamma\otimes\mathcal{K} \cong C^*X^\Gamma \hookrightarrow C^*X.$$

The induced map in K-theory allows one to detect elements in $K_*(C^*_r\Gamma)$ using large scale index theory, as we will show in one case in Section 5.

4. The coarse Baum-Connes conjecture

Being the home of important index invariants, it is very important to be able to compute the K-theory of the Roe algebras $C^*(M;A)$ for arbitrary complete manifolds M and coefficient C^*-algebras A. It turns out that there are quite a number of tools to do this. Even better, at least conjecturally there is a purely homological answer to this task.

Let us start with the three most important computational tools.

1. $K_*(C^*(M;A))$ is invariant under *coarse homotopy*, compare [13].
2. There are powerful *vanishing theorems* for $K_*(C^*(M;A))$. An important one is valid if M is *flasque* [24, Proposition 9.4]. This means that M admits a shift map $f\colon M\to M$ such that, on the one hand, f is uniformly close to the identity (i.e. there is a constant C such that $d(f(x),x)<C$ for all $x\in M$). On the other hand, f moves everything to infinity in the sense that for each compact subset K of M, $\mathrm{im}(f^k)\cap K=\emptyset$ for all sufficiently large iterations f^k of f.
3. The group $K_*(C^*(M;A))$ satisfies a Mayer-Vietoris principle. For this, one needs a *coarsely excisive* decomposition $M=M_1\cup M_2$, which means that the intersection $M_0:=M_1\cap M_2$ captures all the large scale features of the relation between M_1 and M_2. The technical definition is that for each $R>0$ there is an $S>0$ such that the S-neighborhood of $M_1\cap M_2$ contains the intersection of the R-neighborhoods of M_1 and M_2.

   In this situation, there is a long exact Mayer-Vietoris sequence (compare [16, 31])

$$\begin{aligned}\cdots\to K_i(C^*(M_1;A))\oplus K_i(C^*(M_2;A))\to K_i(C^*(M;A))\to\\ K_{i-1}(C^*(M_0;A))\to K_i(C^*(M_1;A))\oplus K_i(C^*(M_2;A))\to\cdots\end{aligned}$$

One of the powerful principles for the K-theory of C^*-algebras is their close relation to purely topological quantities via isomorphism conjectures. Most prominent here is the Baum-Connes conjecture for the computation of $K_*(C^*_r\Gamma)$. The properties of $K_*(C^*(M;A))$ listed above indicate that a similar "topological expression" should be possible here. Indeed, we have the *coarse Baum-Connes conjecture (with coefficients)* [24, Conjecture 8.2], verified in many cases.

Conjecture 4.1. *Given a metric space X of bounded geometry, in the composition*

$$K_*^{lf}(X;A) \to KX_*(X;A) \to K_*(C^*(X;A))$$

the second map is an isomorphism.

Here $K_*^{lf}(X)$ is the usual locally finite K-homology of the space X, defined analytically as $K_{*+1}(D^*X/C^*X)$, and as we saw above it is no problem to introduce as coefficients a C^*-algebra A. The *coarse K-homology* KX_* is obtained as the limit of $K_*^{lf}(|\mathfrak{U}_i|)$, where the $\mathfrak{U}_i$ form a sequence of coverings of X which become coarser as $i \to \infty$. Here $|\mathfrak{U}_i|$ is the geometric realization of the associated Čech simplicial complex. If X is uniformly locally contractible, e.g. if X is the universal covering of a closed non-positively curved manifold, then the "coarsening map" $K_*^{lf}(X;A) \to KX_*(X;A)$ is an isomorphism.

Recall that (in the context of large scale geometry) "bounded geometry" means that X contains a discrete subset T such that on the one hand T coarsely fills the space (i.e. there is an $R > 0$ such that the R-neighborhood of T is all of X), but on the other hand T is uniformly discrete (i.e. for each $R > 0$ the number of elements of T contained in any R-ball is uniformly bounded from above).

The coarse Baum-Connes conjecture has a number of important consequences. Most notably, there is a principle of descent [24, Section 5] that uses the close relation between $C_r^*\Gamma$ and C^*X for any metric space X on which Γ acts properly and cocompactly. The principle of descent asserts that if such a space satisfies the coarse Baum-Connes conjecture, then the strong Novikov conjecture for Γ is true.

On the other hand, the "bounded geometry" condition of the coarse Baum-Connes conjecture is indispensable. Guoliang Yu has constructed a metric space which is a disjoint union of (scaled) spheres of growing dimension for which the analysis of the Dirac operator shows easily that the coarse assembly map is not injective. Despite its simplicity, this example remains intriguing. It is important to understand this better and to construct other examples. We believe that the coarse Baum-Connes conjecture will not be satisfied in full generality.

5. Enlargeability and index

Let M be an (area)-enlargeable closed spin manifold. Recall that this means that M comes with a sequence of (not necessarily compact) coverings M_i with compactly supported maps of non-zero degree $f_i\colon M_i \to S^n$ which are arbitrarily (area) contracting.

Mikhail Gromov and Blaine Lawson show in [7] that an enlargeable spin manifold does not admit a metric of positive scalar curvature. Theorem 1.6 verifies Conjecture 1.5 for this "enlargeability obstruction", i.e. shows that the Rosenberg index is non-zero in this situation. This was achieved in [11] by refining the construction of Gromov and Lawson as follows:

1. One constructs vector bundles E_i on M_i of small curvature which represent interesting K-theory classes.
2. Next one produces associated bundles $M(E_i)$ on M. If $M_i \to M$ is a finite covering, this is finite dimensional. If the covering $M_i \to M$ is infinite, we canonically obtain an associated "structure C^*-algebra" C_i such that $M(E_i)$ is a Hilbert C_i-module bundle with finitely generated projective fiber.

3. The crucial step is the construction of a bundle $E := \prod_i M(E_i)/\bigoplus_i M(E_i)$ which becomes a *flat* Hilbert A-module bundle where $A = \prod_i C_i/\bigoplus_i C_i$. Being flat, this corresponds to a representation of $\pi_1(M)$.
4. As E is flat, the Schrödinger-Lichnerowicz formula implies that $\mathrm{ind}(D_E) \in K_*(A)$ is an obstruction to positive scalar curvature.
5. On the other hand, the universal property of $C^*_{max}\pi_1(M)$ implies that the representation of $\pi_1(M)$ which gives rise to the bundle E induces a C^*-algebra homomorphism $C^*_{max}\pi_1(M) \to A$. Moreover, the induced map in K-theory sends $\alpha_{max}(M) \in K_*(C^*_{max}\pi_1(M))$ to $\mathrm{ind}(D_E) \in K_*(A)$.
6. Finally, an index theorem computes $\mathrm{ind}(D_E)$ in terms of the degrees of the maps f_i and in particular shows that $\mathrm{ind}(D_E) \neq 0$. It follows that $\alpha_{max}(D) \neq 0 \in K_*(C^*_{max}\pi_1(M))$.

A main innovation is the technically quite non-trivial construction of an associated honestly flat bundle, but with infinite dimensional fibers.

In [8] we relate enlargeability to the classical strong Novikov conjecture, which deals with $C^*_r\Gamma$ instead of $C^*_{max}\Gamma$.

The main idea here is to use the functoriality of the large scale index. The argument becomes technically easier if we assume that all the covering spaces which determine the enlargeability of M are the universal covering $\tilde{M}$. In this situation, the first main point is that the geometry allows us to combine all the maps $f_i\colon \tilde{M} \to S^n$ into one map $F\colon \tilde{M} \to B_\infty$, where B_∞ is the "infinite balloon space", sketched in Figure 5.1. It is defined using a collection of n-spheres of increasing radii $i = 1, 2, 3, \ldots$, with the sphere of radius i attached to the point $i \in [0, \infty)$ at the south pole of S^n, and is equipped with the path metric.

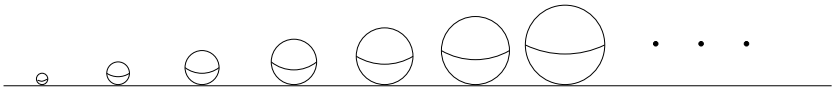

Figure 5.1. The connected balloon space B_∞

Using the Mayer-Vietoris sequence and induction on the dimension, one can calculate the coarse K-homology of B_∞ and the K-theory of its Roe algebra C^*B_∞. In particular, we obtain $KX_n(B_\infty) \cong \prod_{i\in\mathbb{N}} \mathbb{Z}/\bigoplus_{i\in\mathbb{N}} \mathbb{Z}$ and the direct calculation allows us to establish the coarse Baum-Connes conjecture for this space. We obtain a commutative diagram of K-homology and K-theory groups as follows:

$$
\begin{array}{ccccccc}
K_n(M) & \xrightarrow{\cong} & K_{n+1}(D^*\tilde{M}^\Gamma/C^*\tilde{M}^\Gamma) & \longrightarrow & K_n(C^*\tilde{M}^\Gamma) & \xrightarrow{\cong} & K_n(C^*_r\Gamma) \\
 & & \downarrow & & \downarrow & & \\
 & & K_{n+1}(D^*\tilde{M}/C^*\tilde{M}) & \longrightarrow & K_n(C^*\tilde{M}) & & \\
 & & \downarrow & & \downarrow & & \\
 & & K_{n+1}(D^*B_\infty/C^*B_\infty) & \longrightarrow & K_n(C^*B_\infty) & & \\
 & & \downarrow & & \downarrow{=} & & \\
\prod \mathbb{Z}/\bigoplus \mathbb{Z} & \xrightarrow{\cong} & KX_n(B_\infty) & \xrightarrow{\cong} & K_n(C^*B_\infty) & &
\end{array}
$$

A topological calculation allows to work out the image of the fundamental class of M in $KX_n(B_\infty) \cong \prod \mathbb{Z}/\bigoplus \mathbb{Z}$: it is the class represented by the sequence of degrees $(\deg(f_i))_{i\in\mathbb{N}}$ which by assumption is non-zero. Because of the coarse Baum-Connes conjecture, the image in the bottom right corner is also non-zero, which finally implies that also the image $\alpha(M) \in K_n(C^*_r\Gamma)$ is non-zero, as claimed by the theorem.

6. Vanishing of the index under partial positivity

The main reason why one can apply index theory to geometric and topological questions is that a special geometric situation implies vanishing results for the index. It is very important to develop further instances of such vanishing theorems, in order to widen the scope of the consequences of the index method. Here we present one of these, which is valid in the context of large scale index theory:

Theorem 6.1. *Let M be a complete non-compact connected Riemannian spin manifold. Let $E \to M$ be a flat bundle of Hilbert A-modules for a C^*-algebra A. Assume that the scalar curvature is uniformly positive outside a compact subset.*

Then the large scale index of the Dirac operator twisted with E vanishes.

For $A = \mathbb{C}$, this result has been stated by John Roe [24, 26]. A different proof, which covers the general case, is given by Bernhard Hanke, Daniel Pape and the author in [9, Theorem 3.11].

A concrete application of Theorem 6.1 to compact spin manifolds is the codimension-2 obstruction to positive scalar curvature of Theorem 1.7. In its proof in [9], a gluing and bending construction of an intermediate space gives positive scalar curvature outside of a neighborhood of the hypersurface.

7. The Stolz exact sequence

Stephan Stolz (compare [23, Proposition 1.27]) introduced a long exact sequence that makes systematic the bordism classification of metrics of positive scalar curvature. It is quite similar in spirit to the surgery exact sequence for the classification of closed manifolds.

Convention 7.1. Throughout the remainder of the article, a Riemannian metric on a manifold with boundary is assumed to have product structure near the boundary.

Definition 7.2. Fix a reference space X.

1. The group $\Omega^{\mathrm{spin}}_n(X)$ is the usual spin bordism group, consisting of cycles $f\colon M \to X$, with M a closed n-dimensional spin manifold. The equivalence relation is spin bordism.
2. The *structure group* $\mathrm{Pos}^{\mathrm{spin}}_n(X)$ is the group of bordism classes of metrics of positive scalar curvature on n-dimensional closed spin manifolds with reference map to X. Two such manifolds $(M_i, g_i, f_i\colon M_i \to X)$ are called *bordant* if there is a manifold W with boundary, with metric G of positive scalar curvature and with reference map $F\colon W \to X$ such that its boundary is $M_1 \amalg (-M_2)$ and G, F restrict to the given g_i, f_i at the boundary.

3. Finally, the group $R_n(X)$ is the group of equivalence classes of compact spin manifolds W with boundary, with reference map $f\colon W \to X$ and with a metric g of positive scalar curvature on ∂W. Again, the equivalence relation on such cycles is bordism, where a bordism between (W_1, f_1, g_1) and (W_2, f_2, g_2) is a manifold Y with boundary $\partial Y = W_1 \cup_{\partial W_1} Z \cup_{\partial W_2} -W_2$ (where Z is a spin bordism between W_1 and W_2) together with a continuous map $f\colon Y \to X$ and a positive scalar curvature metric g on Z. Of course, the restriction of f to W_j must be f_j and the restriction of g to ∂W_j must be g_j. It turns out that $R_n(X)$ only depends on $\pi_1(X)$ for $n > 5$.
4. The group structure in each of the three cases is given by disjoint union, and the inverse is obtained by reversing the spin structure and leaving all other data unchanged.
5. There are evident "forget structure" and "take boundary" maps between these groups. Using these, one obtains a long exact sequence, the *Stolz positive scalar curvature exact sequence*

$$\cdots \to R_{n+1}(\pi_1(X)) \to \mathrm{Pos}_n^{\mathrm{spin}}(X) \to \Omega_n^{\mathrm{spin}}(X) \to \dots \tag{7.3}$$

The most useful cases of this sequence arises if $X = M$ and $f = \mathrm{id}\colon M \to M$ or if $X = B\Gamma$ is the classifying space of a discrete group and $f\colon M \to B\Gamma$ induces the identity on the fundamental groups.

To get information about $\mathrm{Pos}_n^{\mathrm{spin}}(M)$ we want to use index theory systematically by mapping in a consistent way to the analytic exact sequence of Nigel Higson and John Roe. This sequence is simply the long exact K-theory sequence of the extension $0 \to C^*\tilde{M}^\Gamma \to D^*\tilde{M}^\Gamma \to D^*\tilde{M}^\Gamma/C^*\tilde{M}^\Gamma \to 0$, where $\tilde{M}$ is the universal covering of M, and $\Gamma = \pi_1(M)$.

Using that $K_*(C^*\tilde{M}^\Gamma) = K_*(C_r^*\Gamma)$ and that $K_{*+1}(D^*\tilde{M}^\Gamma/C^*\tilde{M}^\Gamma) = K_*(M)$, we obtain the following theorem, compare [23, Theorem 1.39]

Theorem 7.4. *Let X be a topological space with Γ-covering $\tilde{X}$. We have a natural canonical commutative diagram (if n is odd proved in detail)*

$$\begin{array}{ccccccc}
\longrightarrow & \Omega_{n+1}^{\mathrm{spin}}(X) & \longrightarrow & R_{n+1}(X) & \longrightarrow & \mathrm{Pos}_n^{\mathrm{spin}}(X) & \longrightarrow \Omega_n^{\mathrm{spin}}(X)\cdots \\
& \downarrow{\scriptstyle \beta} & & \downarrow{\scriptstyle \mathrm{ind}} & & \downarrow{\scriptstyle \rho_\Gamma} & \downarrow{\scriptstyle \beta} \\
\longrightarrow & K_{n+1}(X) & \longrightarrow & K_{n+1}(C_r^*\Gamma) & \longrightarrow & K_{n+1}(D^*\tilde{X}^\Gamma) & \longrightarrow K_n(X)\cdots
\end{array}$$

Here, β is obtained by taking the large scale (equivariant) index of the Dirac operator on the covering of a cycle $f\colon N \to X$ and then use functoriality of large scale index theory to push forward via f_* from $K_*(C^*\tilde{N}^\Gamma)$ to $K_*(C^*\tilde{X}^\Gamma)$. It coincides with the Atiyah orientation as natural transformation from spin bordism to K-homology. Similarly, ρ_Γ is obtained by constructing the structure invariant of the positive scalar curvature metric of the covering of $(N, g, f\colon N \to X)$ and then use naturality to push forward along f_* from $K_*(D^*\tilde{N}^\Gamma)$ to $K_*(D^*\tilde{X}^\Gamma)$.

Finally, ind *assigns to a manifold with boundary and positive scalar curvature at the boundary an Atiyah-Patodi-Singer type index.*

Note that the assertion of Theorem 8.1 is that the (index based) maps all exist, that they are indeed well defined, i.e. invariant under bordism, and that the diagram is commutative. This means that we have to work (for the cycles and for the equivalence relation) throughout with manifolds with boundary. It turns out that large scale index theory can very elegantly and efficiently be used to carry out index theory on manifolds with boundary, as well.

8. Index theory on manifolds with boundary

Our method to do index theory on a manifold with boundary is simply to attach an infinite half-cylinder to the boundary. This produces a manifold without boundary, of course at the expense that the resulting manifold is never compact. However, large scale index theory can deal with such spaces.

To obtain the appropriate information, the construction must take the extra information into account coming from the fact that the metric of the boundary is assumed to have positive scalar curvature. Let us review the construction:

1. We start with a smooth manifold W with boundary, with a Riemannian metric g which has positive scalar curvature near the boundary (and a product structure there, by our general convention). As a metric space, W is assumed to be complete. Moreover, we fix an auxiliary C^*-algebra A and a flat Hilbert A-module bundle E on W (again with product structure near the boundary).
2. We now attach a half-cylinder $\partial W \times [0,\infty)$ to the boundary to obtain W_∞ and extend all the structures over W_∞. We obtain a complete manifold without boundary, with product end $\partial W \times [0,\infty)$.
3. As in Section 3, the Dirac operator D_E produces a bounded operator $\psi(D_E)$ in $D^*(W_\infty; A)$.
4. Now, however, we use the invertibility of D_E on $\partial M \times [0,\infty)$ coming from the Schrödinger-Lichnerowicz formula: for suitable ψ the element $1-\psi(D_E)^2$ does not only lie in $C^*(W_\infty; A)$ but in the smaller ideal $C^*(W \subset W_\infty; A)$. This is by definition generated by all locally compact finite propagation operators T which are *supported near* W, which means that there is $R > 0$ such that $T\phi = 0$ and $\phi T = 0$ whenever ϕ is a compactly supported function with $d(\mathrm{supp}(\phi), W) > R$.
5. Correspondingly, the fundamental class of W_∞ has a canonical lift to a class $[W, g|_{\partial W}]$ in $K_{n+1}(D^*(W_\infty; A)/C^*(W \subset W_\infty; A))$. This class does in general depend on the positive scalar curvature metric on the boundary.
6. As usual, we next define the "large scale Atiyah-Patodi-Singer index" by applying the boundary map of the long exact K-theory sequence, now for the extension

$$0 \to C^*(W \subset W_\infty; A) \to D^*(W_\infty; A) \to D^*(W_\infty; A)/C^*(W \subset W_\infty; A) \to 0,$$

   to obtain $\mathrm{ind}(D_W, g_{\partial W}) \in K_n(C^*(W \subset W_\infty; A)) \cong K_n(C^*(W; A))$. The latter isomorphism is induced by the inclusion $C^*(W; A) \hookrightarrow C^*(W \subset W_\infty; A)$ which just extends the operators by zero. Note that this construction of the index required the invertibility of the operator at the boundary and indeed depends in general on the metric of positive scalar curvature at ∂W.

Note that large scale index theory in the situation we just described produces two invariants which depend on the positive scalar curvature metric on ∂W, namely $\mathrm{ind}(D_W, g_{\partial W}) \in K_n(C^*(W \subset W_\infty; A))$, but also the secondary invariant $\rho(\partial W, g_{\partial W}) \in K_n(D^*(\partial W; A))$. A major result, which we consider a secondary higher Atiyah-Patodi-Singer index theorem, relates these two.

Theorem 8.1. *(compare [23, Theorem 1.22]) Let (W, g_W) be an even dimensional Riemannian spin-manifold with boundary ∂W such that $g_{\partial W}$ has positive scalar curvature. Assume that a group Γ acts isometrically on M. Then*

$$\iota_*(\mathrm{ind}_\Gamma(D_W)) = j_*(\rho(\partial W, g_{\partial W})) \text{ in } K_0(D^*(W)^\Gamma).$$

Here, we use $j\colon D^*(\partial W)^\Gamma \to D^*W^\Gamma$ induced by the inclusion $\partial W \to W$ and $\iota\colon C^*(W)^\Gamma \to D^*(W)^\Gamma$ the inclusion.

Remark 8.2. Above we apply the obvious generalization of the construction of the large scale index of Sections 3 and 8 to an equivariant situation, where subalgebras $D^*(W)^\Gamma$ and $C^*(W)^\Gamma$ generated by invariant operators are used. This works because the Dirac operator then itself is invariant under the group Γ.

Remark 8.3. The heart of the proof of Theorem 8.1 is an explicit secondary index calculation in a model (product) case which is surprisingly intricate.

Remark 8.4. The assertion of Theorem 8.1 should generalize to arbitrary (non-cocompact) spin manifolds, to Hilbert C^*-algebra coefficient bundles and to the K-theory of real C^*-algebras. In a preprint of Zhizhang Xie and Guoliang Yu [35] an argument is sketched which shows how to extend the result to arbitrary dimensions and to real C^*-algebras.

9. Constructions of new classes of metrics of positive scalar curvature

The fundamental idea in the construction of the "geometrically significant" homotopy classes of the space of metrics of positive scalar curvature of Theorem 1.10 is quite old and based on index theory:

Given a closed n-dimensional spin manifold B with $\hat{A}(B) \neq 0$, we know that B does not admit a metric of positive scalar curvature.

Remove an embedded disc from B. The result is a manifold W with boundary $\partial W = S^{n-1}$. Given any metric of positive scalar curvature on W (with product structure near the boundary), the corresponding boundary metric g_1 can not be homotopic to the standard metric on S^{n-1} because then one could glue in the standard disc (with positive scalar curvature) to obtain a metric of positive scalar curvature on B. Now, if g_1 is homotopic to $\psi^* g_{eucl}$ for a non-identity diffeomorphism we can glue the disc back in with ψ to obtain a new manifold B_ψ which is of positive scalar curvature. Note that B_ψ is not necessarily diffeomorphic to B, but using the Alexander trick there is a homeomorphism between B_ψ and B. As the rational Pontryagin classes and therefore the $\hat{A}$-genus are homeomorphism invariant, $\hat{A}(B_\psi) \neq 0$, also B_ψ can not carry a metric of positive scalar curvature.

Observe that exactly the same argument can be applied to a family situation: Let $Y \to S^k$ be a family (i.e. bundle) of manifolds with boundary, with boundary $S^n \times S^k$. Assume there is a family of metrics g_x of positive scalar curvature on Y (product near the boundary). If this family of metrics is homotopic to the constant family consisting of the standard metric (or to a pullback of that one along a family of diffeomorphisms ψ_x) we can glue in $D^{n+1} \times S^k$ to obtain a family of closed manifolds which admits a metric of positive scalar curvature (fiberwise, and then also the total space X admits such a metric). Note that this is only interesting if each g_x is in the component of the standard metric, which we therefore assume.

Alas: if the total space X has non-trivial $\hat{A}$-genus, this is a contradiction (and again, by the homeomorphism invariance and the Alexander trick the argument works modulo diffeomorphism).

Note that this requires two important ingredients:

1. the topological situation with the bundle Y (and X)
2. the geometric input of a family of metrics of positive scalar curvature on Y.

It turns out that already the topological input is surprisingly difficult to get. It means that (after the gluing) we have a fiber bundle $M \to X \to S^k$ of spin manifolds where M does admit a metric of positive scalar curvature, therefore $\hat{A}(M) = 0$, whereas $\hat{A}(X) \neq 0$. Note that this means that the $\hat{A}$-genus is not multiplicative in fiber bundles, even if the base is simply connected (in contrast to the L-genus).

In [12, Theorem 1.4] we use advanced differential topology, in particular surgery theory, Casson's theory of prefibrations and Hatcher's theory of concordance spaces to prove that the required fiber bundles X exist:

Theorem 9.1. *For sufficiently large n, there are $4n$-dimensional smooth closed spin manifolds X with non-vanishing $\hat{A}$-genus fitting into a smooth fiber bundle $F \to X \to S^k$ such that F admits a metric of positive scalar curvature, is highly connected and the bundle contains as subbundle $D^{4n-k} \times S^k$.*

How about the second ingredient, the existence of the family of metrics of positive scalar curvature on $Y = X \setminus D^{4n-k} \times S^k$?

The only tool known which can provide such metrics is the surgery method of Gromov and Lawson. In highly non-trivial work [34] this has been extended by Mark Walsh to families of the kind X as constructed in Theorem 9.1. To apply this, we use the high connectivity and results of Kiyoshi Igusa on Morse theory for fiber bundles [18]. As a consequence we obtain Theorem 1.10.

10. Open problems

The geometry of positive scalar curvature and the development and application of large scale index theory is a vibrant field of research, with a host of important open problems. Many of those were already mentioned above; here we want to highlight them and add a couple of further directions of research.

Gromov-Lawson-Rosenberg conjecture. We should find further obstructions to positive scalar curvature on spin manifolds, in particular for finite fundamental group $(\mathbb{Z}/p\mathbb{Z})^n$ for the so-called toral manifolds. We expect that this will require fundamentally new ideas.

On the other hand, can the class of fundamental groups for which the conjecture holds be described systematically?

Stable Gromov-Lawson-Rosenberg conjecture. The stable Gromov-Lawson-Rosenberg conjecture and its weaker cousin 1.5 which states that "the Rosenberg index sees everything about positive scalar curvature which can be seen using the Dirac operator" follow from the strong Novikov conjecture. It would be spectacular to find counterexamples to either of these

(they are expected to exist, but to find them will of course be very hard). It is necessary to investigate this question further. In this context, the role of the codimension-2 obstruction as discussed in Theorem 1.7 should be understood.

This theorem should extend to the signature operator, which will shed new light on its meaning. Vaguely, we conjecture the following.

Conjecture 10.1. *Let M_1, M_2 be two complete non-compact connected oriented Riemannian manifolds and $f\colon M_1 \to M_2$ a sufficiently well behaved map which is an "oriented homotopy equivalence near infinity".*

Let $E \to M_2$ be a flat bundle of Hilbert A-modules for a C^*-algebra A. Let D_E^{sgn} be the signature operator on M_1 twisted with the flat bundle E, and $D_{f^*E}^{sgn}$ the signature operator on M_2 twisted by f^*E. Then the large scale indices of these two operators should coincide, i.e.

$$f_*(\mathrm{ind}(D_{f^*E}^{sgn})) = \mathrm{ind}(D_E^{sgn}) \in K_*(C^*(M_1; A)).$$

Note that, in this conjecture, one has to work out the precise concept of "sufficiently well behaved" and of "homotopy equivalence at infinity".

Area based large scale geometry. Large scale geometry is based on the metric spaces and distances, viewed from a coarse perspective. Curvature, on the other hand, is a concept based on the bending of surfaces, where scalar curvature looks at the average over all possible surface curvatures through a given point.

This is reflected in the fact that area-enlargeability suffices to obstruct positive scalar curvature (Theorem 1.6). So far, this is not captured well by large scale index theory.

This suggests that a program should be developed for large scale geometry based on 2-dimensional areas instead of lengths. A possible starting point would be to work on a relative of the loop space and carry out the analysis there. This is interesting in its own right, with a host of potential further applications, but seems to require new analytical tools.

Note that the axiomatic abstraction from metric spaces to coarse structures as developed by John Roe [25] does not seem to apply here. Of course, this generalization is interesting in its own right and applications to positive scalar curvature should be developed further.

Coarse Baum-Connes conjecture. If the coarse Baum-Connes conjecture holds for the classifying space of a discrete group, then also the strong Novikov conjecture is true for this group. Moreover, the validity of the coarse Baum-Connes conjecture is a powerful computational tool. On the other hand, there are enigmatic counterexamples due to Guoliang Yu if one drops the "bounded geometry" condition on the space in question.

We expect that many new classes of metric spaces can be found where the coarse Baum-Connes conjecture can be established. But we also feel that the search for counterexamples (of bounded geometry) should be intensified.

Aspherical manifolds. A lot of attention has been given to the special class of aspherical manifolds.

Conjecture 10.2. *Let M be a closed manifold whose universal covering is contractible (i.e. M is* aspherical*). Then M does not admit a metric of positive scalar curvature.*

Often the geometry implies that a manifold is aspherical (e.g. if it admits a metric which is non-positively curved in the sense of comparison geometry). The conjecture states that

in a weak sense this is the only way a manifold can be aspherical. The strong Novikov conjecture for an aspherical spin manifold M implies that $\alpha(M) \neq 0$ because the Dirac operator of a manifold M always represents a non-zero K-homology class in $K_*(M)$, and here $M = B\pi_1(M)$. Of course, we now look for ways to directly use the asphericity in proofs of (special cases) of Conjecture 10.2.

Mapping surgery to analysis to homology. The program to map surgery to analysis has been fully carried out in [23] only for half the dimensions, and only for complex C^*-algebras, based on a delicate explicit index calculation. New developments, in particular the work of Zhizhang Xie and Guoliang Yu [35] extend this to all dimensions with a modified method. It remains to develop the details of this (or an alternative) approach and to carry it over to the more powerful real C^*-algebras.

K-theory of C^*-algebras is a very powerful tool. Most useful, however is its combination with homological tools (in particular Hochschild and cyclic (co)homology). To achieve this systematically and use it for the classification of metrics of positive scalar curvature, we propose a program to not only map the positive scalar curvature sequence to analysis, as described in Section 7, but then to map further to a corresponding long exact sequence of (cyclic) homology groups. There, one would then see primary and secondary numerical invariants of higher index theory.

The primary invariants are well developed. Rather not understood, however, is the theory related to the secondary invariants. Indeed, the relevant algebra D^*M is very large and the usual dense and holomorphically closed subalgebras on which explicit formulas for the Connes-Karoubi Chern character would make sense seem hard to come by. Exactly because of this we feel that the development of such a theory will shed important new light on the power of the secondary invariants of rho-type as proposed here.

Apart from this general program, the theory described above needs to be applied in more concrete situations. The analytic structure set $K_*(D^*M)$, despite its evident potential, so far has only been used in a small number of concrete contexts (compare in particular [15]). This must change before we will have a definite idea of its power.

Minimal surface obstructions to positive scalar curvature. The minimal surface method is the only known tool to obstruct the existence of a metric of positive scalar curvature which works for non-spin manifolds of dimension ≥ 5. So far, it is controversial how to extend the method if the dimension of the manifold in question is larger than 8 (due to singularities which develop in the minimal hypersurfaces one wants to use). Joachim Lohkamp has a program to achieve this.

The minimal surface technique has so far only been used together with the Gauss-Bonnet theorem (via an iterative approach, until the hypersurface is 2-dimensional). Are there other ways to exploit it and combine it with obstructions to positive scalar curvature (Seiberg-Witten, spin Dirac) and what are the relations?

Enlargeability and non-spin manifolds. As just one case of the question whether the known results for spin manifolds carry over to non-spin manifolds consider the following question:

Question 10.3. *Let M be an arbitrary (non-spin) closed n-dimensional manifold with coverings M_ϵ and with maps $f_\epsilon\colon M_\epsilon \to S^n$ which are constant outside a compact subset of M_ϵ, which have non-zero degree and which are ϵ-contracting.*

Can M admit a metric of positive scalar curvature?

Using the minimal surface method, Gromov and Lawson [7, Section 12] have shown that this is not the case if $n \leq 7$.

Topology of the space of metrics of positive scalar curvature. The stable Gromov-Lawson-Rosenberg conjecture shows that there is a stability feature in the topology of the space $\mathrm{Riem}^+(M)$ of metrics of positive scalar curvature: if index theory suggests that it should be non-empty, this might be violated by M itself, but after iterated product with B, eventually it is non-empty. Are there similar stability features concerning the (higher) homotopy groups of $\mathrm{Riem}^+(M)$? It would also be important to develop estimates on the stable range.

The space of metrics of positive scalar curvature and fundamental group. We know well that, for a spin manifold M with a complicated fundamental group Γ, the existence of a metric of positive scalar curvature is not only obstructed by $\hat{A}(M)$, but by $\alpha(M) \in K_*(C^*\Gamma)$, and many elements of $K_*(C^*\Gamma)$ are indeed realized as values of $\alpha(M)$.

Similarly, we should expect that the topology of $\mathrm{Riem}^+(M)$, if non-empty, should be governed by $K_*(C^*\Gamma)$. At the moment, a precise conjecture (e.g. about the homotopy groups) seems too far-fetched. Still, the methods of large scale and higher index theory should be developed to the point that they are available to detect new elements in $\pi_*(\mathrm{Riem}^+(M))$, and one should systematically construct non-trivial examples.

Gauge theory and mirror symmetry

Constantin Teleman

Abstract. Outlined here is a description of *equivariance* in the world of 2-dimensional extended topological quantum field theories, under a topological action of compact Lie groups. In physics language, I am gauging the theories — coupling them to a principal bundle on the surface world-sheet. I describe the data needed to gauge the theory, as well as the computation of the gauged theory, the result of integrating over all bundles. The relevant theories are 'A-models', such as arise from the Gromov-Witten theory of a symplectic manifold with Hamiltonian group action, and the mathematical description starts with a group action on the generating category (the Fukaya category, in this example) which is factored through the topology of the group. Their mirror description involves holomorphic symplectic manifolds and Lagrangians related to the Langlands dual group. An application recovers the complex mirrors of flag varieties proposed by Rietsch.

Mathematics Subject Classification (2010). Primary 57R56, 55N91; Secondary 18D05, 81T13.

Keywords. Gauge theory, holomorphic symplectic space, Toda system, flag variety.

1. Introduction

This paper tells the story of equivariance, under a compact Lie group, in the higher algebra surrounding *topological quantum field theory* (TQFT). Speaking in riddles, if 2-dimensional TQFT is a higher analogue of cohomology (the reader may think of the Fukaya-Floer theory of a symplectic manifold as refining ordinary cohomology), my story of gauged TQFTs is the analogue of equivariant cohomology. The case of finite groups, well-studied in the literature [30], provides a useful and easy reference point, but the surprising features of the continuous case, such as the appearance of holomorphic symplectic spaces and Langlands duality, are missing there.

From another angle, this is a story of the categorified representation theory of a compact Lie group G, with the provision that representations are *topological*: the G-action (on a linear category) factors through the topology of G. One floor below, where the group acts on vector spaces, these would be not the ordinary complex representations of G, but the local systems of vector spaces on the classifying space BG. There is no distinction for a finite group, but in the connected case, BG is simply connected, and we must pass to the derived category to see anything interesting. The same will hold in the categorified story, where simply connected groups will appear to have trivial representation theory, before deriving. This observation suggests a straightforward homological algebra approach to the investigation, worthy of featuring as an example in a graduate textbook. Pursuing that road, however, leads to faulty predictions, even in the simplest case of pure gauge theory of a

Proceedings of the International Congress of Mathematicians, Seoul, 2014

point (topological Yang-Mills theory). One reason for this failure is a curious predilection of interesting TQFTs to break the obvious $\mathbb{Z}$-grading information present, collapsing it to a $\mathbb{Z}/2$ grading, or encoding it in more labored form (as in the Euler field of Gromov-Witten theory [17]). The result is that homological algebra, which localizes the spectrum of a graded ring to its degree zero part, loses relevant information, which needs restoration by ulterior guesswork. In our example, we will see the homological information in the neighborhood of a Lagrangian within a certain holomorphic symplectic manifold, whereas most of the interesting 'physics' happens elsewhere.

The emerging geometric picture for this categorical topological representation theory is surprisingly attractive. Representations admit a character theory, but characters are now coherent sheaves on a manifold related to the conjugacy classes, instead of functions. The manifold in question, the *BFM space* of the Langlands dual Lie group $G^\vee$, introduced in [5], is closely related to the cotangent bundle to the space of conjugacy classes in the complex group $G^\vee_{\mathbb{C}}$. (For SU_2, it is the Atiyah-Hitchin manifold studied in detail in [4].) Multiplicity spaces of G-invariant maps between linear representations are now replaced by multiplicity categories, whose 'dimensions' are the Hom-spaces in the category of coherent sheaves. (In interesting examples, they are the Frobenius algebras underlying 2-dimensional TQFTs.) There is a preferred family of simple representations, which in a sense exhausts the space of representations: they foliate the BFM space. Every such representation is 'symplectically induced' from a one-dimensional representation of a certain Levi subgroup of G: more precisely, it is the Fukaya category of a flag variety of G. This is formally similar to the Borel-Weil construction of irreducible representations of G by holomorphic induction. Recall that in that world there is another kind of "L^2-induction" from closed subgroups, which is right adjoint to the restriction functor. The counterpart of naïve induction also exists in our world, and gives the (curved) *string topologies* [8] of the same flag varieties, instead of their Fukaya categories.

This story might seem a bit unhinged, were it not for the appearance of the governing structure in the work of Kapustin, Rozansky and Saulina [15]. Studied there are boundary conditions in the 3-dimensional TQFT associated to a holomorphic symplectic manifold X, known as Rozansky-Witten theory [23]. Among those are holomorphic Lagrangian submanifolds of X, or more generally, sheaves of categories over such sub-manifolds. (The full 2-category of all boundary conditions does not yet have a precise definition.) The relation to gauge theory is summarized by the observation that gaugeable 2-dimensional field theories are topological boundary conditions for pure 3-dimensional topological gauge theory. The reader may illustrate this with an easy example: the representations of a finite group F are the boundary conditions for pure F-gauge theory in 2 dimensions; yet these representations are exactly the 1-dimensional topological field theories (vector spaces) which admit F-symmetry. Modulo the [15] description of Rozansky-Witten theory, my entire story is underpinned by the following

Meta-Statement. *Pure topological gauge theory in* 3 *dimensions for a compact Lie group G is equivalent to the Rozansky-Witten theory for the BFM space of the Langlands dual Lie group $G^\vee$.*

I shall offer no elucidation of this, beyond its inspirational value; however, strong indications of this statement have been known in the physics literature, at least for special G [3, 19, 27]. Formulating this statement in a mathematically useable way will require an excursion through much preliminary material in §2-5. A small reward will come in §6, where we

illustrate how these ideas can lead to 'real answers'.

A closing warning is that the results in this paper are partly experimental: enough examples have been checked to rule out plausible alternatives, but I do not claim to know proofs in full generality. In fact, the status of Floer-Fukaya theory makes such claims difficult to sustain, and the author has no special expertise on that topic. In topological cases, such as for string topology (Fukaya theory of cotangent bundles), precise statements and proofs are possible (and easy). More generally, the results apply to the abstract setting of differential graded (or A_∞-categories) with topological G-action, the question being to what extent the Fukaya category of a symplectic manifold with Hamiltonian G-action qualifies. (For non-compact manifolds, this depends on the 'wrapping' condition at ∞.) If nothing else, the paper can be read as a template for what a nice world should look like.

2. Topological field theory

Topological field theory, introduced originally by Atiyah[2], Segal [25] and Witten [32], promised to systematize a slew of new 3-manifold invariants. The invariants of a 3-manifold M are thought to arise from *path integrals* over a space of maps from M to a target X. The latter is often a manifold, but in interesting cases, related to *gauge theory*, it is a stack. One example relevant for us will have X a holomorphic symplectic manifold, leading to *Rozansky-Witten theory* [23]. The 2-dimensional version of this notion quickly found application to the counting of holomorphic curves, the Gromov-Witten invariants of a symplectic manifold X: these are controlled by a family of TQFTs parametrized by the even cohomology space $H^{ev}(X)$.

2.1. Extended TQFTs. Both theories above have a bearing on my story, once they are *extended down to points*. In the original definition, a d-dimensional TQFT is a symmetric, strongly monoidal functor form the category whose objects are closed $(d-1)$-manifolds and whose morphisms are compact d-bordisms, to the category $\mathfrak{Vect}$ of complex finite-dimensional vector spaces; the monoidal structures are disjoint union and tensor product, respectively. (Some tangential structure on manifolds is chosen, as part of the starting datum.) Fully extending the theory means extending this functor to one from the *bordism d-category* $Bord_d$, whose objects are points and whose k-morphisms are compact k-manifolds with corners (and some tangential structure), to some de-looping of the category of vector spaces: a symmetric monoidal d-category whose top three layers are complex numbers, vector spaces and linear categories, or a differential graded (dg) version of this. When $d = 2$, which most concerns us, the target is usually the 2-category $\mathfrak{LCat}$ of linear dg categories, linear functors and natural transformations. The reader may consult Lurie [16], references therein and the wide following it inspired, for a precise setting of higher categories.

Example 2.1 (2-dimensional gauge theory with finite gauge group F). This theory is defined for unoriented manifolds; among others, the functor Z_F which sends a point $*$ to the category $\mathfrak{Rep}(F)$ of (finite-dimensional) linear representations of F, the half-circle bordism $\subset\colon \emptyset \to \{*, *'\}$ to the functor $\mathfrak{Vect} \to \mathfrak{Rep}(F) \otimes \mathfrak{Rep}(F)$ sending $\mathbb{C}$ to the (2-sided) regular representation of F, the opposite bordism $\supset\colon \{*, *'\} \to \emptyset$ to the functor $\mathfrak{Rep}(F) \otimes \mathfrak{Rep}(F) \to \mathfrak{Vect}$ sending $V \otimes W$ to the subspace of F-invariants therein. A closed surface gives a number, which is the (weighted) count of principal F-bundles. See

for instance [9] for a uniform construction of the complete functor and generalizations.

The first theorem of [16] is that an such extended TQFT $Z : Bord_d \to ??$ is determined by its value $Z(+)$ on the point, at least in the setting of *framed* manifolds. The object $Z(+)$, which we call the generator of Z, must satisfy some strong (*full dualizability*) conditions, but carries no additional structure, beyond being a member of an ambient d-category.

On the other hand, the ability to pass to surfaces with less structure than a framing on their tangent bundle forces additional structure on the generator $Z(+)$. The point (conceived together with an ambient germ of d-manifold) carries a d-framing, on which the group $\mathrm{O}(d)$ acts. Lurie's second theorem states that, given a tangential structure, encoded in a homomorphism $G \to \mathrm{O}(d)$, factoring the theory Z from $Bord_d$ through the category $Bord_d^G$ of d-folds with G-structure is equivalent to exhibiting $Z(+)$ as a fixed-point for the G-action on the image of TQFTs in the target d-category (more precisely, the sub-groupoid of fully dualizable objects and invertible morphisms).

The best-known case of oriented surfaces, when $G = \mathrm{SO}(2)$, requires a *Calabi-Yau* structure on $Z(+)$. This can be variously phrased: as a trivialization of the *Serre functor*, which is an automorphism of any fully dualizable linear dg category (see Remark 2.3 below); alternatively, as a linear functional on the cyclic homology of $Z(+)$ whose restriction to Hochschild homology $HH_*(Z(+))$ induces a perfect pairing on Hom spaces:

$$\mathrm{Hom}(x,y) \otimes \mathrm{Hom}(y,x) \to \mathrm{Hom}(x,x) \to HH_* \to \mathbb{C}.$$

This case of Lurie's theorem recovers earlier results of Costello, Kontsevich and Hopkins-Lurie [6, 13].

The Hochschild homology $HH_*(Z(+))$ is meaningful in a different guise: it is the space of states $Z(S^1)$ of the theory, for the circle with the radial framing. The circle is pictured here with a germ of surrounding surface, and therefore carries a $\mathbb{Z}$'s worth of framings, detected by a winding number. The Hochschild cohomology HH^* goes with the blackboard framing, and the space for the framing with winding number n is HH^* of the nth power of the Serre functor. (Of course, for oriented theories there is no framing dependence, and these spaces agree.)

2.2. Topological group actions. An important point is that the action of $\mathrm{O}(2)$ (and thus G) on the target category $Z(+)$ is *topological*, or factored through its topology. There are several ways to formulate this constraint, which is vacuous when G is discrete. The favored formulation will depend on the nature of the target category; in the linear case, and when G is connected, we will provisionally settle for the one in Theorem 2.5 below. Combined with Statement 2.9 below, this generalizes an old result of Seidel [26] on Hamiltonian diffeomorphism groups.

Here are some alternative definitions:

1. We can ask for a *local trivialization* of the action in a contractible neighborhood of $1 \in G$, an isomorphism with the trivial action of that same neighborhood (up to coherent homotopies of all orders).
2. Using the action to form a bundle of categories with fiber $Z(+)$ over the classifying stack BG, we ask for an integrable flat connection on the resulting bundle of categories. (Formulating the flatness condition requires some care, in light of the fiberwise automorphisms.)

3. Exploiting the contractibility of the group P_1G of paths starting at $1 \in G$, we can ask for a trivialization of the lifted P_1G-action.

   Now, the action of the based loop group ΩG (kernel of $P_1G \to G$) is already trivial (being factored through $1 \in G$), and the difference of trivializations defines a (topological) representation of ΩG by automorphisms of the identity functor in $Z(+)$.

   The group ΩG has an E_2 structure, seen from its equivalence with the second loop space $\Omega^2 BG$; and the representation on $\mathrm{Id}_{Z(+)}$ is the 2-holonomy, over spheres, of the flat connection in #2. Importantly, it is an E_2 representation.

Remark 2.2. When G is connected, description #3 above captures all the information for the action (up to contractible choices), because the space of trivializations of a trivial topological action of P_1G is contractible.

Example 2.3. A topological action of the circle on a category is given by a group homomorphism from $\mathbb{Z} = \pi_1 S^1 = \pi_0 \Omega S^1$ to the automorphisms of the identity: equivalently, a central (in the category) automorphism of each object. Because there is no higher topology in S^1, this also works when the target is a 2-category, such as the (sub-groupoid of fully dualizable objects in the) 2-category $\mathfrak{2Cat}$. The structural $\mathrm{SO}(2) \subset \mathrm{O}(2)$ action gives an automorphism of each category: this is the Serre functor.

Example 2.4. Endomorphisms of the identity in the linear category $\mathfrak{Vect}$ are the complex scalars, so that linear topological representations of a connected G on $\mathfrak{Vect}$ are 1-dimensional representations of $\pi_0 \Omega G \cong \pi_1 G$. These are the points in the center of the complexified Langlands dual group $G^\vee_{\mathbb{C}}$.

Recall that the endomorphisms of the identity in a category (the center) form the 0^{th} Hochschild cohomology. To generalize the above example to the derived world, we should include the entire Hochschild cochain complex.

Theorem 2.5. *Topological actions of a connected group G on a linear dg-category $\mathfrak{C}$ are captured (up to contractible choices) by the induced E_2 algebra homomorphism from the chains $C_*\Omega G$, with Pontrjagin product, to the Hochschild cochains of $\mathfrak{C}$.* □

Example 2.6. From a continuous action of G on a space X, we get a locally trivial action on the cochains C^*X. Indeed, we get an action of ΩG on the free loop space LX of X. The action is fiber-wise with respect to the bundle $\Omega X \to LX \to X$. Let $C^*\big(X; C_*\tilde{\Omega}X\big)$ be the cochain complex on X with coefficients in the fiber-wise chains for this bundle. With the fiber-wise Pontrjagin product, this is a model for the Hochschild cochains of the algebra $C^*(X)$, and the action of ΩG exhibits the E_2 homomorphism in the theorem.

Remark 2.7. The "E_2" in the statement is not jus a commutativity constraint, but can contain (infinite amounts of!) data; see Lesson 3.2.5.

Remark 2.8. One floor below, for 1-dimensional field theories, the category $Z(+)$ is replaced with a vector space (or a complex), and we recognize #2 above as defining a topological representation of G. The datum in Theorem 2.5 is replaced by an (E_1) algebra homomorphism from the chains C_*G, with Pontrjagin product, to $\mathrm{End}(Z(+))$; there is no connectivity assumption. Climbing to the higher ground of n-categories, we can extract an E_{n+1}-algebra homomorphism from $C_*\Omega^n G$ to the E_n Hochschild cohomology; but this misses the information from the homotopy of G below n.

The following key example captures the relevance of my story to real mathematics. (In fact, it contains *all* examples I know for topological group actions!)

Conjecture 2.9. *Let G act in Hamiltonian fashion action on a symplectic manifold X. Then, G acts topologically on the Fukaya category of X.*

Proof. A Hamiltonian action of G on X defines, in the category of symplectic manifolds and Lagrangian correspondences, an action of the group object T^*G.[1] This makes the Fukaya category of X into a module category over the wrapped Fukaya category $\mathfrak{WF}(T^*G)$. A theorem of Abouzaid [1] identifies the latter with that of $C_*\Omega G$-modules. The tensor structure is identified with the E_2 structure of the Pontrjagin product, by detecting it on generators of the category (the cotangent fibers). The resulting structure is equivalent to the datum in Theorem 2.5. □

Remark 2.10. It may seem strange to state a conjecture and then provide a proof. However, the reader will detect certain assumptions which have not been clearly stated in the conjecture: mainly, functoriality of Fukaya categories under Lagrangian correspondences. If X is non-compact, equivariance of the wrapping condition at ∞ is essential; the statement fails for the *infinitesimally wrapped* Fukaya category of Nadler and Zaslow [20], see below. (Another outline argument is more tightly connected to holomorphic disks and $G_{\mathbb{C}}$-bundles, but that relies on details of the construction of the Fukaya category.)

Remark 2.11. A closely related notion to the one discussed, but distinct from it, is that of an *infinitesimally trivialized* Lie group action. Here, we ask for the action to be differentiable, and the restricted action to the formal group $\hat{G}$ (equivalently, the Lie algebra $\mathfrak{g}$) should be homologically trivialized. An example is furnished by an action of G on a manifold X and the induced action on the algebra $\mathcal{D}(X)$ of differential operators: the Lie action of $\mathfrak{g}$ is trivialized in the sense that it is inner, realized by the natural Lie homomorphism from $\mathfrak{g}$ to the 1st order differential operators. Theorem 2.5 does *not* usually apply to such situations. With respect to the alternative definition #2 above, the relevant distinction is between *flat* and *integrable* connections over BG.

2.3. Gauging a topological theory. Given a guantum field theory and a (compact Lie) group G, physicists normally produce a G-gauged theory in two stages. The theory is first coupled to a 'classical gauge background', a principal G-bundle. (No connection is needed in the case of topological actions.[2]) Then, we 'integrate over all principal bundles' to quantize the gauge theory.

These two distinct stages are neatly spelt out in the setting of extended TQFTs. Lurie's theory already captures the first stage of gauging. Namely, we convert the principal G-bundle into a tangential structure by choosing the trivial homomorphism $G \to \mathrm{O}(2)$. (Of course, we may add any desired tangential structure, such as orientability, by switching to $G \times \mathrm{SO}(2) \to \mathrm{O}(2)$, by projection.) Making $Z(+)$ into a fixed point for the trivial G-action means defining a (topological) G-action on $Z(+)$. This is the input datum for a classically gauged theory.

Quantizing the gauge theory, or integrating over principal G-bundles, is tricky. It is straightforward for finite groups: integration of numbers is a weighted sum, and integration

[1] The moment map $\mu : X \to \mathfrak{g}^*$ appears in the requisite Lagrangian, $\{(g, \mu(gx), x, gx)\} \subset T^*G \times (-X) \times X$.
[2] Flat connections would be needed when G action does not factor through topology, as in B-model theories.

of vector spaces and categories is a finite limit or colimit. (The duality constraints require the limits and colimts to agree; working in characteristic 0 ensures that [9].) For Lie groups G, integration of the numbers requires a fundamental class on the moduli of principal bundles. For instance, the symplectic volume form is relevant to topological Yang-mills theory. A limited K-theoretic fundamental class was defined in [31], and cohomological classes, such as the one relevant to topological Yang-Mills theory, can be extracted from it. But this matter seems worthy of more subtle discussion than space allows here.

In fact, the gauge theory *cannot* always be fully quantized. The generating object for the quantum gauge theory is the invariant category $Z(+)^G$, which agrees with the co-invariant category $Z(+)_G$ under mild assumptions. In the framework of Theorem 2.5, we compute the generator $Z(+)_G$ as a tensor product

$$Z(+)_G = Z(+) \otimes_{C_*\Omega G} \mathfrak{Vect} \tag{2.1}$$

with the trivial representation. The 1-dimensional part of the field theory, and sometimes part of the surface operations, are well-defined; but the complete surface-level operations often fail to be defined. Thus, for the trivial $2D$ theory, $Z(+) = \mathrm{dg}{-}\mathfrak{Vect}$ with trivial G-action, and the fixed-points are local systems over BG. This generates a partially defined $2D$ theory, a version of string topology for the space BG. The space associated to the circle is the equivariant cohomology $H^*_G(G)$ for the conjugation action, and the theory is defined the subcategory of $Bord_2$ where all surfaces (top morphisms) have non-empty output boundaries for each component.

This example can be made more interesting by noting that the trivial action of G on $\mathrm{dg}{-}\mathfrak{Vect}$ has interesting topological deformations, in the $\mathbb{Z}/2$-graded world; the notable one comes from the quadratic Casimir in $H^4(BG)$, and gives topological Yang-Mills theory with gauge group G. When G is semi-simple, this theory is almost completely defined, and the invariants of a closed surface (of genus 2 or more) are the symplectic volumes of the moduli spaces of flat connections. (Further deformations exits, by the entire even cohomology of BG and relate to more general integrals over those spaces.) These should be regarded as twisted Gromov-Witten theories with target space BG. A starting point of the present work was the abject failure of the homological calculation (2.1) in these examples: for topological Yang-Mills theory, (2.1) gives the zero answer when G is simple.

2.4. The space of states. The space(s) of states of the gauged theory are well-defined, independently of good behavior of the fixed-point category $Z(+)^G$. More precisely, each $g \in G$ gives an autofunctor g_* of the category. The Hochshild cochain complexes $HCH^*(g_*; Z(+))$ assemble to a (derived) local system $\mathcal{H}(Z(+))$ over the group G, which is equivariant for the conjugation action, and the space of states for the (blackboard framed) circle in the gauge theory is the equivariant homology $H^G_*(G; \mathcal{H})$. It has a natural E_2 multiplication, using the Pontrjagin product in the group. When $Z(+) = \mathfrak{Vect}$, with the trivial G-action, we recover the string topology space $H^G_*(G)$ of BG by exploiting Poincaré duality on G.[3]

[3]The last space goes with the radially framed circle.

3. The 2-category of Kapustin-Rozansky-Saulina

As the image of the point, an object in the 3-dimensional bordism 3-category, Lurie's generator for pure 3-dimensional gauge theory should have categorical depth 2. My proposal for this generator is a 2-category associated to a certain holomorphic symplectic manifold, to be described in §5.

Fortunately, the existence of the requisite 2-category has already been conjectured, and a proposal for its construction has been outlined in [14, 15]. When X is compact, this 2-category should generate the Rozansky-Witten theory [23] of X. In particular, its Hochschild cohomology, which on general grounds is a 1-category with a braided tensor structure, should be (a dg refinement of) the derived category of coherent sheaves on X described in [24]. Just like Rozansky-Witten theory, the narrative takes place in a differential graded world, and in applications, the integer grading must be collapsed $\mathrm{mod}\ 2$ (the symplectic form needs to have degree 2, if the integral grading is to be kept). To keep the language simple, I will use 'sheaf' for 'complex of sheaves' and write $\mathfrak{Coh}$ for a differential graded version of the category of coherent sheaves, etc.

Remark 3.1. The 2-category may at first appear analogous to the deformation quantization of the symplectic manifold; but that is not so. That analogue — a double categorification — is $\mathfrak{Coh}(X)$ with its braided tensor structure. The category [15] is a 'square root' of that, and I will denote it $\sqrt{\mathfrak{Coh}}(X)$ or $KRS(X)$.

3.1. Simplified description. The following partial description of the KRS 2-category applies to a Stein manifold X, when deformations coming from coherent cohomology vanish.[4] In our example, X will be affine algebraic. Among objects of $\sqrt{\mathfrak{Coh}}(X)$ are smooth holomorphic Lagrangians $L \subset X$; more general objects are coherent sheaves of $\mathcal{O}_L$-linear categories on such L. (The object L itself stands for its dg category $\mathfrak{Coh}(L)$ of coherent sheaves, a generator for the above.) To make this even more precisee, $\sqrt{\mathfrak{Coh}}(X)$ is the sheaf of global sections of a coherent sheaf of $\mathcal{O}_X$-linear 2-categories, whose localization at any smooth L as above is equivalent the 2-category of module categories over the sheaf of tensor categories $(\mathfrak{Coh}(L), \otimes)$ on L; with a bit of faith, this pins down $\sqrt{\mathfrak{Coh}}(X)$, as follows.

For two Lagrangians $L, L' \in X$, $\mathrm{Hom}(L, L')$ will be a sheaf of categories supported on $L \cap L'$, and a $(\mathfrak{Coh}(L), \otimes) - (\mathfrak{Coh}(L'), \otimes)$ bi-module. Localizing at L, we choose a (formal) neighborhood identified symplectically with T^*L, so that we regard (locally) L' as the graph of a differential $d\Psi$, for a *potential* function $\Psi : L \to \mathbb{C}$. Locally where this identification is valid, $\mathrm{Hom}(L, L')$ becomes equivalent to the *matrix factorization* category $MF(L, \Psi)$. (See for instance [21] for a definition of the latter.)

3.2. Lessons. Several insights emerge from this important notion.

1. A familiar actor in mirror symmetry, a complex manifold L with potential Ψ, is really the object in $\sqrt{\mathfrak{Coh}}(T^*L)$ represented by the graph $\Gamma(d\Psi)$, masquerading as a more traditional geometric object. The matrix factorization category $MF(L, \Psi)$ is its Hom with the zero-section. This resolves the contradiction in which the restriction of the category $MF(L, \Psi)$ to a sub-manifold $M \subset L$ is commonly taken to be the matrix factorization category of $\Psi|_M$. That is clearly false in the 2-category of $(\mathfrak{Coh}(L), \otimes)$-

[4] My discussion is faulty in another way, failing to incorporate the Spin structures, which must be carried by the Lagrangians. I am grateful to D. Joyce for flagging their role.

module categories (the result of localizing to the zero-section $L \subset T^*L$). For instance, if the critical locus of Ψ does not meet M, Hom computed in $(\mathfrak{Coh}(L), \otimes)$-modules gives zero. Instead, M must be replaced by the object represented by its co-normal bundle in $\sqrt{\mathfrak{Coh}}(T^*L)$, whose Hom there with $\Gamma(d\Psi)$ computes precisely $MF(M, \Psi|_M)$.

2. The well-defined assignment sends $(\mathfrak{Coh}(L), \otimes)$-module categories to sheaves of categories with Lagrangian support in the cotangent bundle $\hat{T}^*L$, completed at the zero-section. Namely, the Hochschild cohomology of such a category $\mathfrak{K}$ is (locally on L) an E_2-algebra over the second (E_2) Hochschild cohomology of $(\mathfrak{Coh}(L), \otimes)$, which is an E_3 algebra. The spectrum of the latter is $\hat{T}^*L$, with E_3 structure given by the standard symplectic form. This turns $\operatorname{Spec} HH^*(\mathfrak{K})$ into a coherent sheaf with coisotropic support in $\hat{T}^*L$, and $\mathfrak{K}$ sheafifies over it. The *Lagrangian* condition is clearly related to a finiteness constraint, but this certainly shows the need to include singular Lagrangians in the KRS 2-category.
3. The deformation of a $(\mathfrak{Coh}(L), \otimes)$-module category $\mathfrak{M}$ by the addition of a potential ('curving') $\Psi \in \mathcal{O}(L)$ shifts the support of $\mathfrak{M}$ vertically by $d\Psi$ in T^*L. This allows one to move from formal to analytic neighborhoods of L, if the deformation theory under curvings is well-understood. For instance, one can compute the Hom between two objects that do not intersect the zero-section — such as two potentials without critical points — by drawing their intersection into L: $\operatorname{Hom}(\Gamma(d\Phi), \Gamma(d\Psi)) = MF(L, \Psi - \Phi)$.
4. More generally, Hamiltonian vector fields on $\hat{T}^*L$ give the derivations of $\sqrt{\mathfrak{Coh}}(\hat{T}^*L)$ defined from its E_2 Hochschild cohomology. Hamiltonians vanishing on the zero-section preserve the latter, and give first-order automorphisms of $(\mathfrak{Coh}(L), \otimes)$.
5. The KRS picture captures in geometric terms sophisticated algebraic information. For example, the category $\mathfrak{Vect}$ can be given a $(\mathfrak{Coh}(L), \otimes)$-module structure in many more ways in the $\mathbb{Z}/2$ graded world: any potential Ψ with a single, Morse critical point will accomplish that. The location of the critical point $p \in L$ misses an infinite amount of information, which is captured precisely by the graph of $d\Psi$; this is equivalent to an E_2 structure on the evaluation homomorphism $\mathcal{O}_L \to \mathbb{C}_p$ at the residue field (cf. Theorem 2.5).

Parts of this story can be made rigorous at the level of formal deformation theory, see for instance [10], and of course the outline in [14]. Lesson 3 also offers a working definition of the 2-category $\sqrt{\mathfrak{Coh}}(T^*L)$ as that of $(\mathfrak{Coh}(L), \otimes)$-modules, together with all their deformations by curvings. On a general symplectic manifold X, we can hope to patch the local definitions from here.[5] It is not my purpose to supply a construction of $\sqrt{\mathfrak{Coh}}(X)$ here — indeed, that is an important open question — but rather, to indicate enough structure to explain my answer to the mirror of (non-abelian) gauge theory. I believe that one important reason why that particular question has been troublesome is that the mirror holomorphic symplectic manifold, the BFM space of §5, *not* quite a cotangent bundle, so the usual description in terms of complex manifolds with potentials is inadequate.

Remark 3.2. If $X = T^*L$ for a manifold L, and we insist on integer, rather than $\mathbb{Z}/2$-gradings, then the cotangent fibers have degree 2 and all structure in the KRS category

[5] If X is not Stein, deformations will be imposed upon this story by coherent cohomology.

is invariant under the scaling action on T^*L. In that case, we are dealing precisely with $(\mathfrak{Coh}(L), \otimes)$-modules.

3.3. Boundary conditions and domain walls. The Hom category $\mathrm{Hom}(L, L')$ for two Lagrangians $L, L' \subset X$ with finite intersection supplies a 2-dimensional topological field theory for framed surfaces; this follows form its local description by matrix factorizations. Since X itself aims to define a $3D$ (Rozansky-Witten) theory and each of L, L' is a boundary condition for it, one should picture a sandwich of Rozansky-Witten filling between a bottom slice of L and a top one of L'. The formal description is that $L, L' : \mathrm{Id} \to RW_X$ are morphisms from the trivial $3D$ theory Id to Rozansky-Witten theory RW_X, viewed as functors from $Bord_2$ to the 3-category of linear 2-categories, and the category $\mathrm{Hom}(L, L')$ of natural transformations between these morphisms is the generator for this sandwich theory. Geometrically, it is represented by the interval, with RW_X in the bulk and L, L' at the ends, and is also known as the *compactification* of RW_X along the interval, with the named boundary conditions.

Factoring this theory through *oriented* surfaces requires a trace on the Hochschild homology HH_* (cf. §2.1). Now, the canonical description of the only non-zero group, $HH_{\dim L}$, turns out to involve the Spin square roots[6] of the canonical bundles ω, ω' of L, L' on their scheme-theoretic overlap:

$$HH_{\dim L}\,\mathrm{Hom}(L, L') \cong \Gamma\big(L \cap L'; (\omega \otimes \omega')^{1/2}\big). \tag{3.1}$$

A non-degenerate quadratic form on $HH_{\dim L}$ comes from the Grothendieck residue (and the symplectic volume on X). A non-degenerate trace on HH_* will thus be defined by choosing non-vanishing sections of $\omega^{1/2}, \omega'^{1/2}$ on L, L'.

Remark 3.3. A generalization of the notion of boundary condition is that of a *domain wall* between TQFTs. This is an adjoint pair of functors between the TQFTs meeting certain (dualizability) conditions, see [16], §4. A boundary condition is a domain wall with the trivial TQFT. Just as a holomorphic Lagrangian in X can be expected to define a boundary condition for RW_X, a holomorphic Lagrangian correspondence $X \leftarrow C \to Y$ should define a domain wall between RW_X and RW_Y. We shalll use these in §5 and §6, in comparing gauge theories for different groups.

4. The mirror of abelian gauge theory

This interlude recalls the mirror story of torus gauge theory; except for the difficulty mentioned in Lesson 1 of §3.2, this story is well understood and can be phrased as a categorified Fourier-Mukai transform. In fact, in this case we can indicate the other mirror transformation, from the gauged B-model to a family of A-models.

4.1. The $\mathbb{Z}$-graded story. We will need to correct this when abandoning $\mathbb{Z}$-gradings, in light of the wisdom of the previous section; nevertheless the following picture is nearly right.

[6] The *cohomology* is easy to pin down canonically, as the functions on $L \cap L'$.

Proposition 4.1.

(i) *Topological actions of the torus T on the category $\mathfrak{Vect}$ are classified by points in the complexified dual torus $T^\vee_{\mathbb{C}}$.*

(ii) *A topological action of T on a linear category $\mathfrak{C}$ is equivalent to a quasi-coherent sheafification of $\mathfrak{C}$ over $T^\vee_{\mathbb{C}}$.*

Proof. Both statements follow from Theorem 2.5, considering that the group ring $C_*(\Omega T)$ is quasi-isomorphic to the ring of algebraic functions on $T^\vee_{\mathbb{C}}$, and that a category naturally sheafifies over its center, the zeroth Hochschild cohomology. □

There emerges the following 0^{th} order approximation to abelian gauged mirror symmetry: if X is a symplectic manifold with Hamiltonian action of T, and $X^\vee$ is a mirror of X — in the sense that $\mathfrak{Coh}(X^\vee)$ is equivalent to the Fukaya category $\mathfrak{F}(X)$ — then the group action on X is mirrored into a holomorphic map $\pi : X^\vee \to T^\vee_{\mathbb{C}}$. This picture could be readily extracted from Seidel's result, [26].

Proposition 4.1 interprets the mirror map $X^\vee \to T^\vee_{\mathbb{C}}$ as a *spectral decomposition* of the category $\mathfrak{F}(X)$ into irreducibles $\mathfrak{Vect}_\tau$. One of the motivating conjectures of this program gives a geometric interpretation of this spectral decomposition, in terms of the original manifold X and the moment map $\mu : X \to \mathfrak{t}^*$.

Conjecture 4.2 (Torus symplectic quotients). *The multiplicity of $\mathfrak{Vect}_\tau$ in $\mathfrak{F}(X)$ is the Fukaya category of the symplectic reduction of X at the point $\operatorname{Re}\log\tau \in \mathfrak{t}^*$, with imaginary curving (B-field) $\operatorname{Im}\log\tau$.*

Remark 4.3. This is, for now, meaningless over singular values of the moment map, where there seems to be no candidate definition for the Fukaya category of the quotient.

Remark 4.4. The conjecture relies on using the *unitary mirror* of X, constructed from Lagrangians with unitary local systems. Otherwise, in the toric case, the algebraic mirror $X^\vee$ is $T^\vee_{\mathbb{C}}$, obviously having a point fiber over every point in $T^\vee_{\mathbb{C}}$; yet the symplectic reduction is empty for values outside the moment polytope. That polytope is precisely the cut-off prescribed for the mirror by unitarity.

Example 4.5 (Toric varieties). The following construction of mirrors for toric manifolds, going back to the work of Givental and Hori-Vafa, illustrates both the conjecture and the need to correct the picture by moving to the KRS category.

Start with the mirror of $X = \mathbb{C}^N$, with standard symplectic form, as the space $T^\vee_{\mathbb{C}} := (\mathbb{C}^\times)^N$ with potential $\Psi = z_1 + \dots z_N$. Here, $T^\vee$ is the dual of the diagonal torus acting on X, and the mirror map $X^\vee \to T^\vee_{\mathbb{C}}$ is the identity.[7] For a sub-torus $i : K \hookrightarrow T$, the mirror of the symplectic reduction $X_q := \mathbb{C}^N /\!/_q K$ at $q \in \mathfrak{k}^*$ is the (torus) fiber $X^\vee_q$ of the dual surjection $i^\vee : T^\vee_{\mathbb{C}} \twoheadrightarrow K^\vee_{\mathbb{C}}$, with restricted super-potential Ψ. The parameter q lives in the small quantum cohomology of X. We see here the familiar, but faulty restriction to the fiber of the matrix factorization category $MF(T^\vee_{\mathbb{C}}, \Psi)$ of Lesson 3.2, #1. The problem is glaring, because the original MF category is null.

The mirror $X^\vee_q$ projects isomorphically to the kernel $S^\vee_{\mathbb{C}}$ of $i^\vee$; this is the map π mirror to the action of $S = T/K$ on X.

[7] This is readily obtained from the SYZ picture, using coordinate tori as Lagrangians; the unitary mirror is cut off by $|z_k| < 1$.

4.2. Fourier transform. As can be expected in the abelian case, the spectral decomposition of Proposition 4.1 is formally given by a Fourier transform. Specifically, there is a 'categorical Poincaré line bundle'

$$\mathfrak{P} \to BT_{\mathbb{C}} \times T^{\vee}_{\mathbb{C}},$$

with an integrable flat connection along BT. (Of course, $\mathfrak{P}$ is the universal one-dimensional topological representation of T, and its fiber over $\tau \in T^{\vee}_{\mathbb{C}}$ is $\mathfrak{Vect}_{\tau}$.) Given a category $\mathfrak{C}$ with topological T-action, we form the bundle $\mathrm{Hom}(\mathfrak{P}, \mathfrak{C})$ and integrate along $BT_{\mathbb{C}}$ to obtain the spectral decomposition of $\mathfrak{C}$ laid out over $T^{\vee}_{\mathbb{C}}$.

Remark 4.6 (B to A). The interest in this observation stems from a related Fourier transformation, giving a "B to A" mirror symmetry. There is another Poincaré bundle $\mathfrak{Q} \to BT_{\mathbb{C}} \times T^{\vee}_{\mathbb{C}}$, with flat structure this time along $T^{\vee}_{\mathbb{C}}$. It may help to exploit flatness and descend to $B(T_{\mathbb{C}} \times \pi_1(T)^{\vee})$, in which case $\mathfrak{Q}$ is the line $\mathfrak{Vect}$ with action of the group $T \times \pi_1(T)^{\vee}$, defined by the Heisenberg $\mathbb{C}^{\times}$-central extension. (The extension is a multiplicative assignment of a line to every group element, and the action on $\mathfrak{Vect}$ tensors by that line.)

Fourier transform converts a category $\mathfrak{C}$ with (non-topological!) T-action into a local system $\tilde{\mathfrak{C}}$ of categories over $T^{\vee}_{\mathbb{C}}$. The fiber of $\tilde{\mathfrak{C}}$ over 1 is the fixed-point category $\mathfrak{C}^T$, and the monodromy action of $\pi_1(T^{\vee})$ comes from the natural action thereon of the category $\mathfrak{Rep}(T)$ of complex T-representations. For example, when $\mathfrak{C} = \mathfrak{Coh}(X)$, the (dg) category of coherent sheaves on a complex manifold with holomorphic T-action, $\mathfrak{C}^T$ is, almost by definition, the category of sheaves on the quotient stack $X/T_{\mathbb{C}}$. The analogue of Conjecture 4.2 is completely obvious here.

I do not know a non-abelian analogue of this "B to A" story.

4.3. The $\mathbb{Z}/2$-graded story. In light of Lesson 3.2.1 and Example 4.5, the only change needed to reach the true story is to replace the $(\mathfrak{Coh}(T^{\vee}_{\mathbb{C}}), \otimes)$-module category $\mathfrak{Coh}(X^{\vee})$, determined from $\pi : X^{\vee} \to T^{\vee}_{\mathbb{C}}$, by an object in the KRS category of $T^*T^{\vee}_{\mathbb{C}}$: the category with T-action sees precisely the germ of a KRS object near the zero-section.

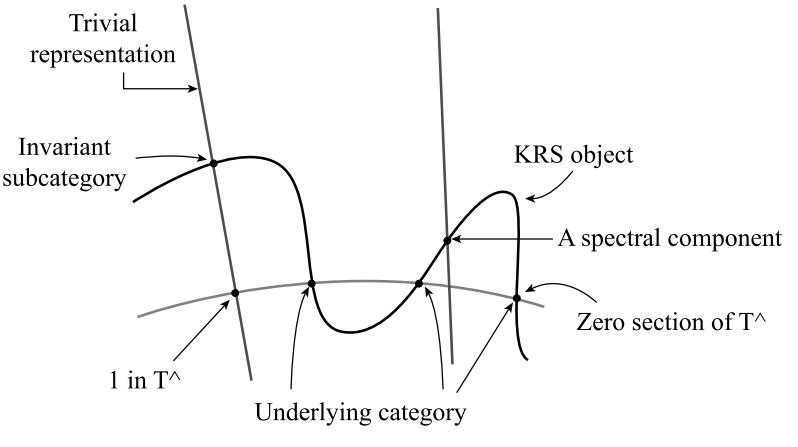

Figure 4.1. Pictorial representation of $\sqrt{\mathfrak{Coh}}(T^*T^{\vee}_{\mathbb{C}})$

This enhancement of information relies upon knowing not just the Fukaya category $\mathfrak{F}(X)$ with its torus action, but all of its curvings with respect to functions lifted from the mirror map $\pi : X^\vee \to T^\vee_{\mathbb{C}}$. However, we can expect in examples that a meaningful geometric construction of the mirror would carry that information. For instance, in Example 4.5, we replace $(X^\vee_q, \Psi|_{X^\vee_q})$ and its map to $S^\vee_{\mathbb{C}}$ by the graph of $d\Psi|_{X^\vee_q}$ in $T^*S^\vee_{\mathbb{C}}$; this is the result of intersecting the graph of $d\Psi$ with the cotangent space at $q \in K^\vee_{\mathbb{C}}$.

Figure 4.1 attempts to capture the distinction between $(\mathfrak{Coh}T^\vee_{\mathbb{C}}, \otimes)$-modules and their KRS enhancement. The squiggly line stands for (the support of) a general object; its germ at the zero-section is the underlying category, with topological T-action. In that sense, the zero-section represents the regular representation of T (its Hom category with any object recovers the underlying category.) The invariant category is the intercept with the trivial representation, the cotangent space at $1 \in T^\vee_{\mathbb{C}}$; other spectral components are intercepts with vertical axes. We see that the invariant subcategory is computed 'far' from the underlying category, and a homological calculation centered at the zero-section will fail.

5. The non-abelian mirror $BFM(G^\vee)$

For torus actions, the insight was that gauging a Fukaya category $\mathfrak{F}(X)$ amounted to enriching it from a $\mathfrak{Coh}(T^\vee_{\mathbb{C}})$ module to an object in $\sqrt{\mathfrak{Coh}}(T^*T^\vee_{\mathbb{C}})$. In a cotangent bundle, this promotion may seem modest. A non-abelian Lie group G will move us to a more sophisticated holomorphic algebraic manifold which is *not* a cotangent bundle. Let T be a maximal torus of G, W the Weyl group and B, B_+ two opposite (lower and upper triangular) Borel subgroups, N, N_+ their unipotent radicals; Fraktur letters will stand for the Lie algebras and $^\vee$ will indicate their counterparts in the Langlands dual Lie group $G^\vee$.

5.1. The home of $2D$ gauge theory. The space $BFM(G)$ was introduced and studied by Bezrukavnikov, Mirkovic and Finkelberg [5] in general, but special instances were known in many guises. Here are several descriptions. Call $T^*_{\mathrm{reg}}G_{\mathbb{C}} \subset T^*G_{\mathbb{C}}$ the Zariski-open subset comprising the *regular* cotangent vectors (centralizer of minimal dimension, the rank of G).

Theorem 5.1. *The following describe the same holomorphic symplectic manifold, denoted $BFM(G)$.*

(i) *The spectrum of the complex equivariant homology $H^{G^\vee}_*(\Omega G^\vee)$, with Pontrjagin multiplication.*

(ii) *The holomorphic symplectic reduction of $T^*_{\mathrm{reg}}G_{\mathbb{C}}$ by conjugation under $G_{\mathbb{C}}$.*

(iii) *The affine resolution of singularities of the quotient $T^*T_{\mathbb{C}}/W$, obtained by adjoining the functions $(e^\alpha - 1)/\alpha$. (α ranges over the roots of $\mathfrak{g}$, $e^\alpha - 1$ is the respective function on $T_{\mathbb{C}}$ and the denominator α is the linear function on $\mathfrak{t}^*$.)*

(iv) *$BFM\big(\mathrm{SU}_n\big)$ is the moduli space of SU_2 monopoles of charge n, and is a Zariski-open subset of the Hilbert scheme of n points in $T^*\mathbb{C}^\times$ [4].*

(v) $BFM(T) = T^*T_{\mathbb{C}}$

Remark 5.2. The moment map zero-fiber for the conjugation $G_{\mathbb{C}}$-action on $T^*_{\mathrm{reg}}G_{\mathbb{C}}$ is the (regular) *universal centralizer* $\mathcal{Z}_{\mathrm{reg}} = \{(g, \xi) \,|\, g\xi g^{-1} = \xi, \xi \text{ is regular}\}$. $\mathcal{Z}_{\mathrm{reg}}$ is smooth, and $BFM(G) = \mathcal{Z}_{\mathrm{reg}}/G_{\mathbb{C}}$, with stabilizer of constant dimension and local slices. This is the only one of the descriptions that makes the holomorphic symplectic structure evident.

The space $BFM(G^\vee)$ inherits two projections from $T^*_{\mathrm{reg}}G_{\mathbb{C}} : \pi_v$, to the space $(\mathfrak{g}^\vee)^*_{\mathbb{C}}/G^\vee_{\mathbb{C}} \cong \mathfrak{t}_{\mathbb{C}}/W$ of co-adjoint orbits, and π_h, to the conjugacy classes in $G^\vee_{\mathbb{C}}$. Both are Poisson-integrable with Lagrangian fibers. The projection π_v will have the more obvious meaning for gauge theory, capturing the $H^*(BG)$-module structure on fixed-point categories. The projection π_h is closely related to the restriction to T (and to the *string topology* of flag varieties.)

The symplectic structure on $BFM(G^\vee)$ relates to its nature as (an uncompletion of) the second Hochschild cohomology of the E_2-algebra $H_*(\Omega G)$.[8] In fact, $BFM(G)$ contains the zero-fiber of π_v, $Z := \mathrm{Spec}H_*(\Omega G)$, as a smooth Lagrangian; it comes from the part of $\mathcal{Z}_{\mathrm{reg}}$ with nilpotent ξ (cf. Remark 5.2).

Theorem 2.5 and Lesson 3.2.2 sheafify categories with topological G-action over the formal neighborhood of Z. However, it is the entire space $BFM(G^\vee)$ which is the correct receptacle for G-gauge theory: gauged TQFTs are objects in the 2-category $\sqrt{\mathfrak{Coh}}(BFM(G^\vee))$. Clearly, that requires a rethinking of the notion: the definition of 'topological category with G-action' as in §2 would complete the BFM space at the exceptional Lagrangian Z. Loosely speaking, we need to know a theory together with all its deformations of the group action.

The Lagrangian Z replaces the zero-section from the torus case, and plays the role of the regular representation of G: $\mathrm{Hom}(Z, L)$ gives the underlying category of the representation L. The formal calculation is $\mathrm{Hom}_{C_*\Omega G}(C_*\Omega G; L) = L$, if we use Theorem 2.5 to model representations. Figure 5.1 below sketches $BFM(\mathrm{PSU}_2)$.

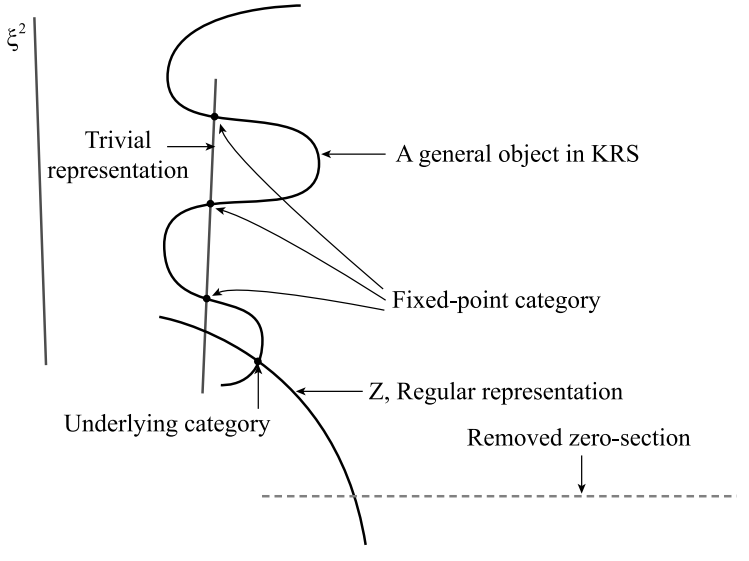

Figure 5.1. BFM space of PSU_2; the fiber of π_h at 1 is $Z \cup$trivial representation

5.2. Induction by String topology. No map relates $BFM(T^\vee) = T^*T^\vee_{\mathbb{C}}$ and $BFM(G^\vee)$, because of the blow-up, but a holomorphic Lagrangian correspondence is defined from the

[8] Of course, the E_2 structure is trivial over the complex numbers and the algebra is quasi-isomorphic to its underlying dg ring of chains.

branched cover

$$BFM(G^\vee) \longleftarrow BFM(G^\vee) \times_{\mathfrak{t}_\mathbb{C}/W} \mathfrak{t}_\mathbb{C} \longrightarrow T^*T^\vee_\mathbb{C}. \tag{5.1}$$

The right map is neither proper not open.[9] A holomorphic Lagrangian correspondences could give a pair of adjoint functors between the respective $\sqrt{\mathfrak{Coh}}$ 2-categories, thus a domain wall between T- and G- gauge theories (cf. §3.3). This is indeed the case, and we can identify the functors.

Theorem 5.3. *The correspondence* (5.1) *matches an adjoint pair of restriction-induction functors between categorical T- and G-representations. Induction from a category $\mathfrak{C}$ with topological T-action is effected by* string topology with coefficients *of the flag variety G/T:*

$$\mathrm{Ind}(\mathfrak{C}) = C_*\Omega G \otimes_{C_*\Omega T} \mathfrak{C}.$$

Restriction is the obvious functor. □

Remark 5.4.

(i) An alternative (slightly worse) description of induction is given by the category of (derived) global sections $\mathrm{R}\Gamma\big(G/T; \tilde{\mathfrak{C}}\big)$ for the associated local system $\tilde{\mathfrak{C}}$ of categories.

(ii) Neither description is quite correct. Just as the BFM spaces carry more information than the category and the action, so does induction.

(iii) For example, inducing from the representation $\mathfrak{Vect}_\tau$, for a point $\tau \in T^\vee_\mathbb{C}$ which is *not* central in G, by either method above, will appear to give zero. (This is what a homological algebra calculation of the curved string topology of G/T for a non-trivial curving $\tau \in H^2(G/T; \mathbb{C}^\times)$ gives.) However, geometric induction gives the fiber of $\pi_v^{-1}(\tau)$. The puzzle is resolved by noting that none of those fibers meet the regular representation Z, so the underlying categories are null. We are letting G act on categories without objects, and growing wiser.

(iv) The 'naïvely induced' representations can serve to probe the entire BFM space by abelianization. It is therefor not *conceptually* more difficult to understand non-abelian gauged mirrors than abelian ones. However, the symplectically induced representations of the next section are much nicer.

5.3. Alternative model for induction. I close with a new model for the correspondence (5.1), useful in a later mirror calculation. Call $\mathfrak{b}_{+,\mathrm{reg}} \subset \mathfrak{b}_+$ the open subset of regular elements. Identify $\mathfrak{b}_+ = \big(\mathfrak{g}_\mathbb{C}/\mathfrak{n}_+\big)^*$, B_+-equivariantly; the last space matches the fibers of the bundle, over $B_+ \subset G_\mathbb{C}$, of co-normals to the N_+-translation orbits. Using this to define the left map below and projection on the right gives a holomorphic Lagrangian correspondence

$$\begin{array}{ccc} & \dfrac{B_+ \times \mathfrak{b}_{+,\mathrm{reg}}}{B_+} & \\ \swarrow & & \searrow \\ T^*_{\mathrm{reg}} G_\mathbb{C} /\!/_{\mathrm{ad}} B_+ & & T^*T_\mathbb{C} \end{array}$$

[9] Z maps to $1 \in T^\vee$, but most of the zero-section in $T^*T^\vee_\mathbb{C}$ is missed by the map.

having divided by the conjugation action of $B_+^\vee$. We can also divide out by B_+ in the defining correspondence for $BFM(G)$,

$$BFM(G) \longleftarrow \mathcal{Z}_{\mathrm{reg}}/B_+ \longrightarrow T^*_{\mathrm{reg}}G_{\mathbb{C}}/\!/_{\mathrm{ad}}B_+.$$

The composition of these two can be shown to yield (5.1) (for the group G).

6. Mirrors of flag varieties

I will now explain the place of flag varieties in the mirror view of gauge theory. Lifting to the torus-equivariant picture will recover a construction of K. Rietsch [22].

6.1. Flag varieties as domain walls. Let $L \subset G$ be a Levi subgroup, centralizer of a dominant weight $\lambda : \mathfrak{l} \to \mathrm{i}\mathbb{R}$. The flag variety $X = G/L$ is a symplectic manifold with Hamiltonian G-action (the co-adjoint orbit of λ), and as such it should have a mirror holomorphic Lagrangian in $BFM(G^\vee)$. This will be true, but we forgot some structure relevant to gauge theory. Namely, we can use G/L to *symplectically induce* categorical representations from L to G.

A categorical representation $\mathfrak{C}$ of L gives the local system of categories $\tilde{\mathfrak{C}} = G \times_L \mathfrak{C} \to X$, and we can construct the Fukaya category of X with coefficients in $\tilde{\mathfrak{C}}$. (Objects would be horizontal sections of objects over Lagrangians, and Floer complexes can be formed in the usual way from the Hom-spaces over intersections.) In fact, the weight λ (or rather, its exponential e^λ in the center of $L_{\mathbb{C}}^\vee$) defines a topological representation $\mathfrak{Vect}_\lambda$ of L, and we can think of the ordinary Fukaya category $\mathfrak{F}(X, \lambda)$ as the symplectic induction from the latter. The precise meaning is that deforming λ in $\mathfrak{Vect}_\lambda$ achieves the same effect as the matching deformation of the symplectic form. An imaginary variation of λ (movement in the unitary group $L^\vee$) has the effect of adding a unitary B-field twist to the Fukaya category.

Remark 6.1. Left adjoint to the symplectic induction functor SInd_L^G is a *symplectic restriction* from G to L. This is not the ordinary (forgetful) restriction, which instead is adjoint to string topology induction (§5). For example, when $L = T$, the spectral decomposition under T of the symplectic restriction of $\mathfrak{C}$ would extract the multiplicities of the $\mathfrak{F}(X, \tau)$ in $\mathfrak{C}$, rather than those of the $\mathfrak{Vect}_\tau$.

This pair of functors is a new *domain wall* between pure 3-dimensional G- and L-gauge theories. On the mirror side, we can hope to represent a domain wall by a holomorphic Lagrangian correspondence between $BFM(L^\vee)$ and $BFM(G^\vee)$. We will be fortunate to identify this correspondence with an open embedding.

To recover the mirror of X in its various incarnations (as a symplectic manifold, or a G-equivariant symplectic one) we must apply boundary conditions to the two gauge theories, aiming for the 'sandwich picture' of a $2D$ TQFT, as in §3.3. For example, to find the underlying symplectic manifold (X, λ), we must apply the representation $\mathfrak{Vect}_\lambda$ of L and the regular representation Z of G. I shall carry out this (and a more general) exercise in the final section.

The study of symplectically induced representations can be motivated by the following conjecture, the evident non-abelian counterpart of Conjecture 4.2 (with the difference that it seems much less approachable).

Conjecture 6.2. *For a Hamiltonian G-action on the compact symplectic manifold X and a regular value μ of the moment map, the Fukaya category $\mathfrak{F}(X//G)$, reduced at the orbit of μ (and with unitary B-field $\mathrm{i}\nu$) is the multiplicity in $\mathfrak{X}$ of the representation symplectically induced from $\mathfrak{Vect}_{\mu+i\nu}$.*

6.2. The Toda isomorphism. The following isomorphism of holomorphic symplectic manifolds is mirror to symplectic induction. It fits within a broad range of related results ('Whittaker constructions') due to Kostant. Its relation to Fukaya categories of flag varieties is mysterious, and now only understood with reference to the appearance of the Toda integrable system in the Gromov-Witten theory of flag varieties [11, 12]. From that point of view, the isomorphism enhances the Toda system by supplying the conjugate family of commuting Hamiltonians, pulled back from conjugacy classes in the group, rather than orbits in the Lie algebra.

The mirror picture of G-gauge theory involves the Langlands dual group $G^\vee$ of G, but the notation is cleaner with G. With notation as in §5, call $\chi : \mathfrak{n} \to \mathbb{C}^\times$ the regular character (unique up to $T_{\mathbb{C}}$-conjugation) and consider the *Toda space*, the holomorphic symplectic quotient of $T^*G_{\mathbb{C}}$

$$T(G) := (N, \chi)\backslash\backslash T^*G_{\mathbb{C}}//(N, \chi)$$

under the left×right action of N, reduced at the point $(\chi, \chi) \in \mathfrak{n}^* \oplus \mathfrak{n}^*$.

Theorem 6.3. *We have a holomorphic symplectic isomorphism*

$$T(G) = (N, \chi)\backslash\backslash T^*G_{\mathbb{C}}//(N, \chi) \cong T^*_{\mathrm{reg}}G_{\mathbb{C}}//_{\mathrm{Ad}}G_{\mathbb{C}} = BFM(G)$$

induced from the presentation of the two manifolds as holomorphic symplectic reductions of the same manifold $T^*_{\mathrm{reg}}G_{\mathbb{C}}$.

Proof. The $N \times N$ moment fiber in $T^*G_{\mathbb{C}} \cong G_{\mathbb{C}} \times \mathfrak{g}^*_{\mathbb{C}}$ (by left trivialization) is

$$\mathcal{T} := \{(g, \xi) \in G_{\mathbb{C}} \times \mathfrak{g}^*_{\mathbb{C}} \,|\, \pi(\xi) = \pi(g\xi g^{-1}) = \chi\},$$

where $\pi : \mathfrak{g}^*_{\mathbb{C}} \to \mathfrak{n}^*$ is the projection. As $\pi^{-1}(\chi)$ consists of regular elements, we may use $T^*_{\mathrm{reg}}G_{\mathbb{C}}$ instead. Now, N acts freely on $\pi^{-1}(\chi)$, with Kostant's global slice, so the $N \times N$ action on $\mathcal{T}$ is free also and $T(G) = N\backslash\mathcal{T}/N$ is a manifold.

The moment map fibers $\mathcal{T}$ and $\mathcal{Z}_{\mathrm{reg}}$ (for the Ad-action of $G_{\mathbb{C}}$) provide holomorphic Lagrangian correspondences

$$\begin{array}{ccccc} & \mathcal{T} & & \mathcal{Z}_{\mathrm{reg}} & \\ \swarrow & & \searrow \quad \swarrow & & \searrow \\ T(G) & & T^*_{\mathrm{reg}}G_{\mathbb{C}} & & BFM(G) \end{array} \tag{6.1}$$

whose composition $\mathcal{T} \times_{T^*_{\mathrm{reg}}G_{\mathbb{C}}} \mathcal{Z}_{\mathrm{reg}}$, I claim, induces an isomorphism. Actually, the clean correspondence must mind the fact that the two actions on T^*G, of $N \times N$ and G, respectively, have in common the conjugation action of N (sitting diagonally in $N \times N$): so we must really factor through $T^*_{\mathrm{reg}}G_{\mathbb{C}}//_{\mathrm{Ad}}(N)$, within which the co-isotropics $\mathcal{T}/_{\mathrm{Ad}}N$ and $\mathcal{Z}_{\mathrm{reg}}/_{\mathrm{Ad}}N$ turn out to intersect transversally.

We check that the composition in (6.1) induces a bijection on points: preservation of the Poisson structure then supplies the Jacobian criterion. Choose $(g, \xi) \in \mathcal{T}$; then, $\xi, g\xi g^{-1} \in$

$\pi^{-1}(\chi)$ are in the same $G_{\mathbb{C}}$-orbit in $\mathfrak{g}^*_{\mathbb{C}}$. Kostant's slice theorem ensures that the two elements are then Ad-related by a unique $\nu \in N$, $\nu g \xi (\nu g)^{-1} = \xi$. There is then, up to right action of N, a unique $(g', \xi') \in \mathcal{Z}_{\mathrm{reg}}$ in the $N \times N$-orbit of (g, ξ). We thus get an injection $T(G) \hookrightarrow BFM(G)$. To see surjectivity, conjugate a chosen $(h, \eta) \in \mathcal{Z}_{\mathrm{reg}}$ to bring η into $\pi^{-1}(\chi)$. The result is in $\mathcal{T}$ (and is again unique up to N-conjugation). □

Remark 6.4. The space $T(G)$ has a hyperkähler structure; it comes from a third description, as a moduli space of solutions to Nahm's equations. This is closely related to a conjectural derivation of my mirror conjecture (6.5) below from Langlands (electric-magnetic) duality in 4-dimensional $N = 4$ Yang-Mills theory. (I am indebted to E. Witten for this explanation.)

6.3. The mirror of symplectic induction. Inclusion of the open cell $N \times w_0 \cdot T_{\mathbb{C}} \times N \subset G_{\mathbb{C}}$ leads to a holomorphic symplectic embedding $T^*T_{\mathbb{C}} \subset T(G)$. Sending a co-tangent vector to its co-adjoint orbit projects $T(G)$ to $\mathfrak{g}^*_{\mathbb{C}}//G^{ad}_{\mathbb{C}}$, and the functions on the latter space lift to the commuting Hamiltonians of the Toda integrable system; so the theorem completes the picture by providing a complementary set of Hamiltonians lifted from the conjugacy classes of G.

More generally, if $L \subset G$ is a Levi subgroup, with representative $w_L \in L$ of its longest Weyl element, and with unipotent group $N_L = N \cap L_{\mathbb{C}}$, then χ restrict to a regular character of N_L and the inclusion

$$N \times_{N_L} w_0 w_L^{-1} \cdot L_{\mathbb{C}} \times_{N_L} N \subset G_{\mathbb{C}}$$

determines an open embedding $T(L) \subset T(G)$. The following is, among others, a character formula for induced representations. It relies on too many wobbly definitions to be called a theorem, but assuming it is meaningful, its truth can be established form existing knowledge.

Conjecture 6.5. *Via the Toda isomorphism, the embedding $T(L^\vee) \subset T(G^\vee)$ is mirror to symplectic induction from L to G, representing the flag variety G/L as a domain wall between L- and G-gauge theories.*

Example 6.6. With the torus $L = T$, a one-dimensional representation of T is described by a point $q \in T^\vee$, represented in $\sqrt{\mathfrak{Coh}}(T^*T^\vee)$ by the cotangent space at q. Its image under the Toda isomorphism, a Lagrangian leaf $\Lambda(q) \subset BFM(G)$, is the symplectically induced representation, or the G-equivariant Fukaya category of the flag variety G/T with quantum parameter q. The analogue of the character is the structure sheaf $\mathcal{O}_{\Lambda(q)}$, whose algebra of global sections is the G-equivariant quantum cohomology of G/T [11].

Remark 6.7. It is difficult to prove the conjecture without a precise definitions (of equivariant Fukaya categories with coefficients and of the KRS 2-category). Nevertheless, accepting that $BFM(G^\vee)$ as the correct mirror of G-gauge theory, the conjecture follows from known results about the equivariant quantum cohomology of flag varieties [7, 11, 18]. The latter describe $qH^*_G(G/L)$ as a module over $H^*(BG) = \mathbb{C}[\mathfrak{g}]^G$, the algebra of Toda Hamiltonians, induced from the projection π_v. The symplectic condition turns out to pin the map uniquely.

6.4. Foliation by induced representations. Recall (Example 2.4) the one-dimensional representations of a Levi subgroup $L \subset G$, corresponding to the points in the center of $L^\vee_{\mathbb{C}}$. Let us call them *cuspidal*: they are not symplectically induced from a smaller Levi subgroup. (Such a symplectic induction produces representation of rank equal to the Euler characteristic of the flag variety.) The following proposition suggests that these induced representations are better suited to spectral theory that the naïvely induced ones of §5.

Theorem 6.8. *The space $BFM(G^\vee)$ is smoothly foliated by symplectic inductions of cuspidal representations: each leaf comes from a unique cuspidal representation of a unique Levi subgroup L, with $T \subset L \subset G$.*

Proof. The leaves are the fibers of $N\backslash\mathcal{T}^\vee/N \to N\backslash G^\vee_{\mathbb{C}}/N$, and induction on the semi-simple rank reduces us to checking that the part of $\mathcal{T}^\vee$ which does *not* come from any $T(L^\vee)$, for a proper $L \subset G$, lives over the center of $G^\vee_{\mathbb{C}}$.

Omit $^\vee$ from the notation and choose $(g, \xi) \in \mathcal{T}$. From $G_{\mathbb{C}} = \coprod_w N \cdot wT_{\mathbb{C}} \cdot N$, we may take $g \in wT_{\mathbb{C}}$ for some $w \in W$. Split $\mathfrak{g}^*_{\mathbb{C}} = \mathfrak{n}^* \oplus \mathfrak{t}^*_{\mathbb{C}} \oplus \mathfrak{n}^*_+$; then,

$$\begin{aligned} \xi &= \chi + \eta + \nu, && \text{for some } \eta \in \mathfrak{t}_{\mathbb{C}}, \nu \in \mathfrak{n}^*_+ \\ g\xi g^{-1} &= \chi + w(\eta) + \nu', && \text{for some } \nu' \in \mathfrak{n}^*_+ \end{aligned}$$

whence we see that w sends each simple negative root either to a simple negative root, or to a positive root. If $w = 1$, then $g \in T_{\mathbb{C}}$ centralizes $\chi \pmod{\mathfrak{b}^*_+}$ and thus lies in the center of $G_{\mathbb{C}}$. Otherwise, I claim that $w = w_0 w_L^{-1}$, for the Levi L whose negative simple roots stay negative. Equivalently, the unique simple root system of $\mathfrak{g}$ comprising the simple negative roots of L and otherwise only positive roots, is the w_L-transform of the positive root system. This can be seen by choosing a point $\zeta + \varepsilon$, with ζ generic on the L-fixed face of the dominant Weyl chamber, and ε a dominant regular displacement: $w_L(\zeta + \varepsilon)$ must be in the dominant chamber of the new root system. □

Example 6.9 ($G = \mathrm{SU}_2$). The dual complex group is $G^\vee_{\mathbb{C}} = \mathrm{PSL}_2(\mathbb{C})$, whose BFM space is the blow-up of $\mathbb{C} \times \mathbb{C}^\times/\{\pm 1\}$ at $(0, 1)$, with the proper transform of the zero-section $\{0\} \times \mathbb{C}^\times/\{\pm 1\}$ removed. This is the Atiyah-Hitchin manifold studied in [4]. The $\mathbb{Z}/2$-action identifies (ξ, z) with $(-\xi, z^{-1})$. Projection to the line of co-adjoint orbits is given by the Toda Hamiltonian ξ^2.

The Toda inclusion of $T^*T^\vee_{\mathbb{C}} \cong \mathbb{C} \times \mathbb{C}^\times$ sends a point (u, q) to

$$\xi^2 = u^2 - q, \qquad \frac{z + z^{-1}}{4} = \frac{u^2}{q} - \frac{1}{2}$$

(A match of signs is required between z and ξ.) The induced leaves of constant q are given by

$$\xi = q\frac{\sqrt{z} - \sqrt{z}^{-1}}{2},$$

after lifting to the coordinates $\xi, \sqrt{z}$ for the double-cover maximal torus in SL_2. We recognize here the (graph of the differentiated potential in the) S^1-equivariant mirror of the flag variety $\mathbb{P}^1$.

The one remaining leaf in $BFM(\mathrm{PSU}_2)$ is the trivial representation of SU_2; it is the proper transform of $T^*_1\mathbb{C}^\times/\{\pm 1\}$, the image in $\mathbb{C} \times \mathbb{C}^\times/\{\pm 1\}$ of) the cotangent fiber at 1. If we switch instead to $\mathrm{PSU}(2)$, the new BFM space (on the Langlands dual side) is a double cover of the former, and there is a new cuspidal leaf over the central point $(-\mathrm{I}_2) \in \mathrm{SU}_2$, corresponding to the sign representation of $\pi_1\mathrm{PSU}_2$.

6.5. Torus-equivariant flag varieties. Restricting the G-action to T, the flag manifold G/L is a transformation from L-gauge theory to T-gauge theory, given by composition of the symplectic induction and string topology domain walls:

$$T(L^\vee) \xrightarrow{\text{SInd}} T(G^\vee) \xrightarrow[\text{Toda}]{\sim} BFM(G) \xrightarrow{\text{ST}} BFM(T^\vee) = T^*T^\vee_{\mathbb{C}} \tag{6.2}$$

The equivariant mirror is a family of $2D$ TQFTs, which can be defined, for instance, by a family of complex manifolds with potentials parametrized by the Lie algebra $\mathfrak{t}_{\mathbb{C}}$. This family reflects the $H^*(BT)$-module structure on equivariant quantum cohomology. When $\mathfrak{F}(G/L)$ has been represented by an object $\Lambda \in \sqrt{\mathfrak{Coh}}(T^*T^\vee_{\mathbb{C}})$, the family comes from the projection of $T^*T^\vee_{\mathbb{C}}$ to the cotangent fiber, and the TQFTs are the fibers of Λ over $\mathfrak{t}_{\mathbb{C}}$, the Hom categories with the constant sections of $T^*T^\vee_{\mathbb{C}}$.

To recover this family of mirrors from the double domain wall (6.2), we must use it to pair two Lagrangians, in $T(L^\vee)$ and in $T^*T^\vee_{\mathbb{C}}$. The Lagrangians are

- the Lagrangian leaf $\Lambda(q) \subset BFM(L^\vee)$ over a point q in the center of $L^\vee_{\mathbb{C}}$, describing a cuspidal representation of L (q is also the quantum parameter for G/L);
- the constant Lagrangian section S_ξ of $T^*T^\vee_{\mathbb{C}}$, with fixed value $\xi \in \mathfrak{t}_{\mathbb{C}}$.

Note that S_ξ is the differential of a multi-valued character $\xi \circ \log : T^\vee_{\mathbb{C}} \to \mathbb{C}$.

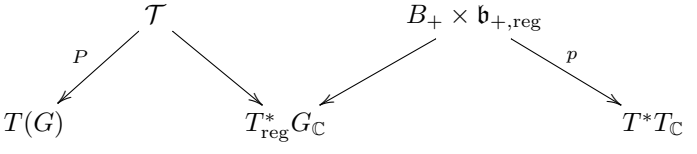
Remark 6.10. The relevant TQFT picture is a sandwich with triple-decker filling: the base slice is the representation $\mathfrak{Vect}_q$ of L corresponding to $\Lambda(q)$, a boundary condition for L-gauge theory. The filling of the sandwich is a triple layer of L, G, T gauge theories, separated by the SInd and string topology domain walls in (6.2). The sandwich is topped with the slice S_ξ, a boundary condition for T-gauge theory. Its underlying representation category is null, if $\xi \neq 0$; S_ξ is a deformation of the regular representation of T by the multi-valued potential $\xi \circ \log$.

6.6. Rietsch mirrors. Building on ideas of Peterson and earlier calculations of Givental-Kim, Ciocan-Fontanine, Kostant and Mihalcea [7, 11, 12, 18], Rietsch [22] proposed torus-equivariant complex mirrors for all flag varieties G/L.

Let us recover these from my story by computing the answer outlined above. Recall (§5.3) the Lagrangian correspondence

$$T^*T_{\mathbb{C}} \leftarrow B_+ \times \mathfrak{b}_{+,\text{reg}} \to T^*_{\text{reg}}G_{\mathbb{C}},$$

appearing in the alternate model for the string topology induction. Compose this with the Toda construction to define the following holomorphic Lagrangian correspondence between $T(G)$ and $BFM(T) = T^*T_{\mathbb{C}}$:

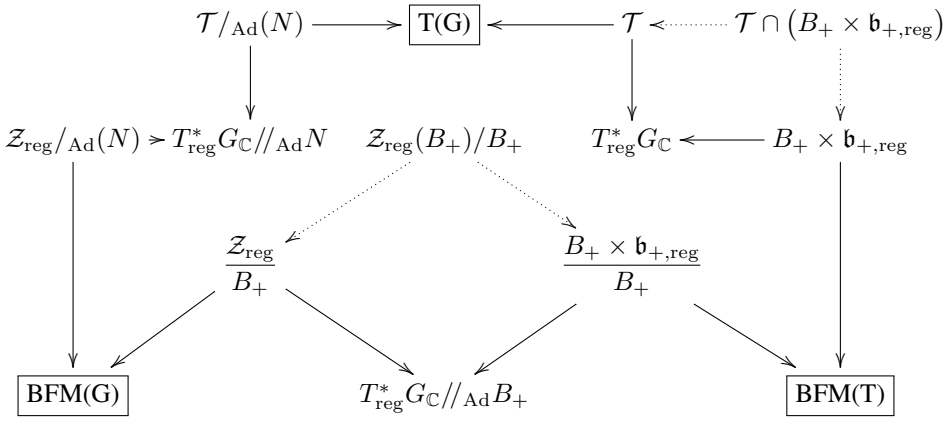


(6.3)

Proposition 6.11. *Correspondence* (6.3) *is the composition* $\text{ST} \circ \text{Toda}$ *of* (6.2).

Sketch of proof. In the jagged triangle of correspondences below, the left edge is the Toda isomorphism, the right edge the correspondence (6.3) and the bottom edge the string topology domain wall. The long, counterclockwise way from top to right involves division by the

complementary subgroups N and B_+ of $G_{\mathbb{C}}$; so it seems reasonable that the composition should agree with the undivided correspondence (6.3) on the right edge:



The argument exploits the regularity of the Lie algebra elements. The intersection in the upper right corner comprises the pairs $(b, \beta) \in B_+ \times \mathfrak{b}_+$ with b centralizing $\beta \in E + \mathfrak{t}_{\mathbb{C}}$. ($E = \chi$ under $\mathfrak{n}_+ \cong \mathfrak{n}^*$.) That is a slice for the conjugation B_+-action on the regular centralizer $\mathcal{Z}_{\mathrm{reg}}(B_+)$ in B_+, which makes clear the isomorphism with the fiber product in the center the triangle; and the map is compatible with the Toda isomorphism on the left edge. □

We now calculate the pairing $S_\xi \subset T(L^\vee)$ and $\Lambda(q) \subset T^*T^\vee_{\mathbb{C}}$ by the correspondence (6.3) for the dual group $G^\vee$. We do so by computing in $T^*_{\mathrm{reg}}G^\vee_{\mathbb{C}}$

$$\mathrm{Hom}\left(p^{-1}S_\xi, P^{-1}\Lambda(q)\right).$$

The two Lagrangians meet over the intersection

$$B^\vee_+ \cap \left(N^\vee \cdot w_0 w_L^{-1} L^\vee_{\mathbb{C}} \cdot N^\vee\right) \subset G^\vee_{\mathbb{C}}.$$

Lift $\xi \circ \log$ to $B^\vee_+$ by p; over $B^\vee_+$, $p^{-1}S_\xi$ is the conormal bundle to $B^\vee_+ \subset G^\vee_{\mathbb{C}}$ shifted by the graph of $d(\xi \circ \log)$. (The shifted bundle is well-defined, independently of any local extension of the function $\xi \circ \log$.)

The Lagrangian $P^{-1}\Lambda(q)$ lives over the open set $N^\vee \cdot w_0 w_L^{-1} L^\vee_{\mathbb{C}} \cdot N^\vee$ in $G^\vee_{\mathbb{C}}$, where it is the shifted co-normal bundle to the submanifold

$$M := N^\vee \cdot w_0 w_L^{-1} q \cdot N^\vee \cong \frac{N^\vee \times N^\vee}{\mathrm{diag}(N^\vee \cap L^\vee_{\mathbb{C}})},$$

shifted into $\mathcal{T}$ by the graph of the differential of the following function f:

$$f : n_1 \cdot w_0 w_L^{-1} l \cdot n_2 \mapsto \chi(\log n_1 + \log n_2).$$

Now, $B^\vee_+$ and M meet transversally in $G^\vee_{\mathbb{C}}$, in a manifold isomorphic to a Zariski-open in the flag variety $G^\vee/L^\vee$; this is the $\mathcal{R}_{w_0,w_L}$ of [22]-. Transversality permits us to dispense

with the conormal bundles, and identify $\mathrm{Hom}(S_\xi, \Lambda(q))$ with the pairing, in the cotangent bundles, between graphs of the restricted functions to $B_+^\vee \cap M$

$$\mathrm{Hom}_{T^*(B_+^\vee \cap M)}\left(\Gamma(d(\xi \circ \log)), \Gamma(df)\right);$$

this is the matrix factorization category $MF\big(B_+^\vee \cap M; f - \xi \circ \log\big)$. This is the Rietsch mirror of G/L.

The last mirror comes with a volume form, which defines the trace on HH_*. In the Lagrangian correspondence, we need instead a half-volume form on each leaf. The two leaves S_ξ and $\Lambda(q)$ do in fact carry natural half-volumes, translation-invariant for the groups (B and $N \times N$) and along the cotangent fibers. Rietsch's volume form on the mirror $\mathcal{R}_{w_0,w_L}$ comes from the product of these half-volumes.

Acknowledgements. The author thanks the MSRI for its hospitality during the writing of this paper. The work was partially supported by NSF grant DMS-1007255. I thank M. Abouzaid, D. Ben-Zvi, K. Fukaya, K. Hori, A. Kapustin, A. Neitzke, C. Woodward for helpful comments and conversation, and am especially indebted to E. Witten for explaining the relation to 4-dimensional gauge theory and the Nahm equations. Many thanks are due to the Geometry group at UT Austin for the invitation to lecture there, where a primitive version of this material was first outlined [28]; for later developments, see [29].
