Model theory of difference fields and applications to algebraic dynamics

Zoé Chatzidakis

Abstract. This short paper describes some applications of model theory to problems in algebraic dynamics.

Mathematics Subject Classification (2010). Primary 03C60; Secondary 12H10, 14GXX.

Keywords. Model theory, difference fields, canonical base property.

1. Introduction

A few years ago, Hrushovski noticed that the model theory of difference fields could give a new proof of a result of M. Baker on algebraic dynamics. Baker's result deals with endomorphisms of $\mathbb{P}^1$ defined over a function field K, and shows that under certain conditions, the endomorphism of $\mathbb{P}^1$ is isomorphic (over some algebraic extension of K) to one defined over the constant field k of K. He answered thus a question of Szpiro and Tucker. Nothing was known for varieties of higher dimension. We started working on this together, were able to answer a question of Baker (1.7 in [1]) in case of function fields of characteristic 0, and got a descent result in some special cases: there is a bijective rational map from our original algebraic dynamics (V, ϕ) to one defined over the smaller field. Because our tools are difference fields, the maps we obtain are in general only birational isomorphisms and not isomorphisms when the dimension of the underlying variety is > 1. These results appeared in [4] and [5].

It turns out that another model-theoretic tool, the Canonical Base Property, a property enjoyed by existentially closed difference fields, allows one to obtain a fairly strong result in a more general context. Explaining what is now known is the object of section 4 of this paper.

Section 2 recalls some of the now classical results of the model theory of difference fields, as well as some more recent ones (e.g., 2.12). In section 3, we explain briefly the connection between our algebraic dynamics (V, ϕ) (where ϕ is rational dominant, not necessarily a morphism) and difference fields. In section 4, we introduce the Canonical Base Property, some of its history, give some of its consequences, and explain briefly the strategy to show that existentially closed fields of arbitrary characteristic enjoy it. Section 5 puts everything together.

Proceedings of the International Congress of Mathematicians, Seoul, 2014

2. Difference fields and their model theory

2.1. Basic definitions. A difference ring is a ring R with a distinguished endomorphism σ. A *difference* field is a difference ring which is a field (note that the endomorphism will necessarily be injective). A difference ring becomes naturally a structure of the language $\mathcal{L} = \{+, -, \cdot, \sigma, 0, 1\}$, where $+, -, \cdot$ are interpreted as the usual binary operations, 0 and 1 are the usual constants, and σ is interpreted by the endomorphism. The difference ring is *inversive* if the endomorphism is onto. Every difference ring R has a unique up to R-isorphism *inversive closure*, or *inversive hull*, i.e., an inversive difference ring containing it, and which R-embeds into every inversive difference field containing R.

The *difference polynomial ring in the variables* $Y = (Y_1, \ldots, Y_n)$ *over* R, denoted $R[Y]_\sigma$, is the polynomial ring $R[\sigma^j(Y_i) \mid 1 \leq i \leq n, j \geq 0]$, endowed with the natural extension of σ defined by sending $\sigma^j(Y_i)$ to $\sigma^{j+1}(Y_i)$ for each i and j.

If K is a field, then zero-sets of elements of $K[Y_1, \ldots, Y_n]_\sigma$ generate the closed sets of a topology on K^n, and this topology is Noetherian. It is very similar to the Zariski topology. I will call the closed sets of this topology *σ-closed*.

All these results and more can be found in Richard Cohn's book [7].

2.2. The model theory of existentially closed difference fields. A difference field K is *existentially closed* if every finite system of difference equations with coefficients in K which has a solution in a difference field containing K, has a solution in K. Note that an existentially closed difference field is necessarily inversive and algebraically closed. Every difference field embeds into an existentially closed one, and the existentially closed difference fields form an elementary class, with theory usually called ACFA. These fields were first investigated in the 90's by Macintyre, Van den Dries and Wood, see [12]. An indepth study, concentrating on geometric stability properties of these fields was then started by Hrushovski and myself, later joined by Peterzil [3, 6]. I will now recall some of the classical results.

The theory ACFA expresses the following properties of the $\mathcal{L}$-structure K:

– K is algebraically closed, $\sigma \in \mathrm{Aut}(K)$;

– If U, V are irreducible (algebraic) varieties, with $U \subset V \times V^\sigma$, and such that U projects dominantly onto V and V^σ, then there is a such that $(a, \sigma(a)) \in U$. [Here V^σ denotes the variety obtained by applying σ to the defining equations of V.]

2.3. Notation. $\mathbb{N}$ denotes the set of non-negative integers. We will work in a large sufficiently saturated existentially closed difference field $\mathcal{U}$. If E is a field, then E^{alg} denotes the (field-theoretic) algebraic closure of E. If E is a difference subfield of $\mathcal{U}$, and a a tuple in $\mathcal{U}$, then $E(a)_\sigma$ denotes the difference field generated by a over E, i.e. $E(a)_\sigma = E(\sigma^i(a) \mid i \in \mathbb{N})$, and $E(a)_{\sigma^{\pm 1}}$ its inversive hull $E(a)_{\sigma^{\pm 1}} = E(\sigma^i(a) \mid i \in \mathbb{Z})$.

2.4. Some properties of ACFA and of its models. Most of the results here appear in [13] or in [3]. ACFA does not eliminate quantifiers, the problem coming from the fact that an automorphism of a field E needs not extend uniquely to the algebraic closure E^{alg} of E. However, this is the only obstacle, and one obtains that if E is an algebraically closed difference field, then ACFA $\cup$ qfDiag(E) is complete (Here qfDiag(E) denotes the quantifier-free diagramme of E in the language $\mathcal{L}(E)$ obtained by adjoining constant symbols for the elements of E). This last result has several important consequences:

(1) Completions of ACFA are obtained by describing the action of the automorphism on

the algebraic closure of the prime field. This implies that ACFA is decidable.

(2) If E is a difference subfield of a model $\mathcal{U}$ of ACFA, and a, b are tuples in $\mathcal{U}$, then $tp(a/E) = tp(b/E)$ if and only if there is an E-isomorphism $E(a)_\sigma^{alg} \to E(b)_\sigma^{alg}$ which sends a to b.

(3) If $A \subset \mathcal{U}$, then the model-theoretic algebraic closure $\mathrm{acl}(A)$ of A is the smallest inversive algebraically difference field containing A. The definable closure of A, $\mathrm{dcl}(A)$, is usually much larger than the inversive difference field generated by A: it is the subfield of $\mathrm{acl}(A)$ fixed by the elements of $\mathrm{Aut}(\mathrm{acl}(A)/A)$ which commute with σ.

(4) Let $S \subset \mathcal{U}^n$ be definable. Then there is a set $W \subset \mathcal{U}^{n+m}$ defined by difference equations such that the projection π on the first n coordinates defines a finite-to-one map from W onto S.

One can also show that any completion of the theory ACFA is supersimple (of SU-rank ω), and that it eliminates imaginaries. An important definable subset of $\mathcal{U}$, is the *fixed field*

$$\mathrm{Fix}(\sigma) := \{a \in \mathcal{U} \mid \sigma(a) = a\}.$$

It is a pseudo-finite field, and its induced structure is that of a pure field. It is also stably embedded, and therefore, if $S \subset \mathrm{Fix}(\sigma)^n$ is definable in $\mathcal{U}$ with parameters from $\mathcal{U}$, then it is of the form $S' \cap \mathrm{Fix}(\sigma)^n$, where S' is definable in the langauge of rings with parameters from $\mathrm{Fix}(\sigma)$.

In positive characteristic p, there are other definable automorphisms, which are built up using the definable Frobenius automorphism $\mathrm{Frob} : x \mapsto x^p$ and its powers Frob_q. More precisely, if $\tau = \sigma^n \mathrm{Frob}^m$, where $n \geq 1$, $m \in \mathbb{Z}$, then $\mathrm{Fix}(\tau)$ is a pseudo-finite field, stably embedded; the induced structure is that of a pure field if $n = 1$, but involves the automorphism σ if $n > 1$. We will also call $\mathrm{Fix}(\tau)$ a fixed field. One has the following result:
(1.12 in [3]) *Let τ be as above, (K, σ) a model of ACFA, and consider its reduct the difference field (K, τ). Then $(K, \tau) \models$ ACFA.*

2.5. Independence and SU-rank. As the theory is supersimple, every type is ranked by the rank SU, a rank based on forking (or non-independence). In what follows, A, B, C are subsets of $\mathcal{U}$, a is a tuple of elements of $\mathcal{U}$, and E is a difference subfield of $\mathcal{U}$.

Independence of A and B over C, denoted $A \downarrow_C B$, is characterized by the linear disjointness of the fields $\mathrm{acl}(CA)$ and $\mathrm{acl}(CB)$ over $\mathrm{acl}(C)$. A set D definable over E has finite SU-rank iff every tuple $a \in D$ has finite SU-rank over E, and then

$$\mathrm{SU}(D) = \sup\{\mathrm{SU}(a/E) \mid a \in D\}.$$

One shows easily the following:

- $\mathrm{SU}(a/E) = 0$ if and only if $a \in \mathrm{acl}(E)$.
- $\mathrm{SU}(a/E) \leq 1$ if and only if for every $B \supset E$, either a and B are independent over E, or $a \in \mathrm{acl}(B)$.
- If $\mathrm{tr.deg}(E(a)_\sigma/E) < \infty$, and F is a difference field containing E, then $a \downarrow_E F$ if and only if $\mathrm{tr.deg}(E(a)_\sigma/E) = \mathrm{tr.deg}(F(a)_\sigma/F)$.
- If $\mathrm{tr.deg}(E(a)_\sigma/E) < \infty$, then $\mathrm{SU}(a/E) \leq \mathrm{tr.deg}(E(a)_\sigma/E)$.

- $\mathrm{SU}(a/E) < \omega$ if and only if $\mathrm{tr.deg}(E(a)_\sigma/E) < \infty$.

If $\mathrm{SU}(a/E) < \omega$, then $tp(a/E)$ can be *analysed* in terms of types of SU-rank 1, and so types of SU-rank 1 determine the properties of $tp(a/E)$. This will be explained below in the paragraph on semi-minimal analyses. First, a few definitions:

Definition 2.6. Let T be a supersimple theory which eliminates imaginaries, $\mathbb{U}$ a sufficiently saturated model of T, and $S \subset \mathbb{U}^n$, $P \subset \mathbb{U}^m$ subsets which are invariant under $\mathrm{Aut}(\mathbb{U}/A)$ for some small subset A of $\mathbb{U}$. E.g. S is A-definable, or is a union of realisations of types over A.

(1) S is *one-based* if whenever $a_1,\ldots,a_\ell \in S$ and $B \supset A, C = \mathrm{acl}(Aa_1\ldots,a_\ell) \cap \mathrm{acl}(AB)$, then $(a_1,\ldots,a_\ell)$ and B are independent over C.

(2) A partial type is *one-based* if the set of its realisations is one-based.

(3) S is *internal to* P, resp. *almost-internal to* P, if for some finite set B, we have $S \subset \mathrm{dcl}(ABP)$, resp. $S \subset \mathrm{acl}(ABP)$.

(4) (difference field context) S is *qf-internal to* P if for some finite set B, if $a \in S$, then there is some tuple b of elements of P such that a is in the inversive difference field generated by ABb.

(5) If p, q are types, we say that p is internal, almost-internal, qf-internal, to q, if the set of realisations of p is internal, almost-internal, qf-internal, to the set of realisations of q.

The following is one of the major results in the model theory of difference fields, and is often called the *dichotomy theorem*:

Theorem 2.7 ([3, 6]). *Let q be a type of SU-rank 1 in a model $\mathcal{U}$ of ACFA. Then either q is one-based, or it is almost internal*[1] *to the generic type of $\mathrm{Fix}(\tau)$, where $\tau = \sigma$ if the characteristic is 0, and in positive characteristic, τ is of the form $\sigma^n\mathrm{Frob}^m$ for some $n \geq 1$, $m \in \mathbb{Z}$ relatively prime to n. Moreover, if the characteristic is 0 and q is one-based, then q is stable stably embedded.*

So, Theorem 2.7 tells us that if a type of SU-rank 1 is not one-based, then it is almost internal to $\mathrm{Fix}(\tau)$ for some definable τ. The property of being one-based is very strong, since it gives a criterion for independence. It also forbids the existence of two distinct group laws, such as in fields. Hrushovski and Pillay ([11]) showed that stable one-based groups of finite rank are particularly nice, and their result generalises partially to our context, as follows:

Theorem 2.8. *Let G be an algebraic group definable in a model $\mathcal{U}$ of ACFA, et let B be a quantifier-free definable subgroup of $G(\mathcal{U})$ which is one-based, and defined over some $E = \mathrm{acl}(E)$. Let X be a quantifier-free definable subset of B^n. Then X is a Boolean combination of cosets of E-definable subgroups of B^n.*

In particular, if Y is a subvariety of G^n, then $Y \cap B^n$ is a finite union of translates of quantifier-free definable subgroups of B^n.

If $\mathcal{U}$ has characteristic 0, the result extends to arbitrary definable group G and definable subsets X of B^n: they are Boolean combination of translates of definable subgroups of B^n, and these subgroups are defined over E.

[1] The original formulation is: non-orthogonal to

The following gives a useful characterization of types of SU-rank 1 which are almost-internal to $\mathrm{Fix}(\sigma)$:

Theorem 2.9. *Let $\mathcal{U}$ be a model of ACFA, $E = \mathrm{acl}(E)$ a difference subfield of $\mathcal{U}$ and b a tuple in $\mathcal{U}$, with SU$(b/E) = 1$. Then $tp(b/E)$ is almost-internal to the generic type of $\mathrm{Fix}(\sigma)$ if and only if*

$$\mathrm{tr.deg}(E(b)_\sigma/E) = 1 \text{ and } \{[E(b, \sigma^\ell(b)) : E(b)] \mid \ell \in \mathbb{Z}\} \text{ is bounded.}$$

2.10. Some consequences of the dichotomy. The fact that definable sets which are orthogonal to the fixed fields are one-based, is at the core of several applications to number theory, by Hrushovski ([9]) and by Scanlon ([17–19]). I will explain how its use gives a new proof of the conjecture of Manin-Mumford. Recall first the

Conjecture of Manin-Mumford. *Let A be an abelian variety defined over a number field k, and let $X \subset A$ be a subvariety. Then the Zariski closure of $X(k^{alg}) \cap \mathrm{Tor}(A)(k^{alg})$ is a finite union of translates of abelian subvarieties of A by torsion points.*

This conjecture, as well as several strengthenings (A a commutative algebraic group, k an arbitrary field, with similar conclusions) have been proved using different methods. The one by Hrushovski deals with an arbitrary commutative algebraic group G defined over a number field. One important point is that the torsion subgroup lives in the semi-abelian quotient of the group, and he shows that the number of components of the Zariski closure of $\mathrm{Tor}(G) \cap X$ is bounded by the number of components of the Zariski closure of $\mathrm{Tor}(H) \cap \pi(X)$, where H is the quotient of G by its maximal vector subgroup, and $\pi : G \to H$ is the natural map. Results of Mumford, together with a characterization by Hrushovski of one-based subgroups of abelian varieties or of $\mathbb{G}_m$, allow him to show that there is some $\sigma \in \mathrm{Aut}(\mathbb{Q})$ such that the torsion subgroup of G is contained in a quantifier-free definable subgroup B of G, which defines a one-based group in any existentially closed difference field containing $(\bar{\mathbb{Q}}, \sigma)$. This, together with 2.8 and a simple argument, give the result. Bounds on the complexity of the difference equations defining B give bounds on the number of cosets involved in the description.

The applications by Scanlon have a similar flavour.

2.11. The classical semi-minimal analysis. A standard result on supersimple theories states that if $tp(a/E)$ has finite SU-rank, then there are SU-rank 1 types $p_1, \ldots, p_n$, and tuples $a_1, \ldots, a_n$ such that $\mathrm{acl}(Ea) = \mathrm{acl}(Ea_1 \ldots, a_n)$, and for each i, $tp(a_i/Ea_{i-1})$ is almost-internal to p_i. Such a sequence $a_1, \ldots, a_n$ is called a *semi-minimal analysis of* $tp(a/E)$.

It may happen that one can choose the a_i's such that each $tp(a_i/E)$ is almost-internal to p_i; in that case, notice that $tp(a/E)$ is almost internal to the set S of realisations of the p_i's. This is a strong condition on $tp(a/E)$, and we will say in this case that $tp(a/E)$ is *almost-internal* [to types of rank 1].

One can refine the semi-minimal analysis a little and impose that the a_i's are in $\mathrm{dcl}(Ea)$, and that the types $tp(a_i/\mathrm{acl}(Ea_{i-1}))$ are internal to p_i, for all i. But, as mentioned above, in the case of difference fields, the definable closure is too large to hope obtain precise results on definable sets. After some work, and precise analysis of what internality to a fixed field

means, one obtains the following result:

Proposition 2.12 ([5, 2.13]). *Let E be an inversive difference field, a a tuple in $\mathcal{U}$ such that $\sigma(a) \in E(a)^{alg}$.*

(1) *Then there are $a_1, \ldots, a_n = a \in E(a)_\sigma$, such that, setting $A_i = E(a_{i-1})_\sigma$ for each i (with $a_0 = \emptyset$), $tp(a_i/A_i)$ satisfies one of the following:*

   (i) *$tp(a_i/A_i)$ is algebraic;*
   (ii) *$tp(a_i/A_i)$ is one-based;*
   (iii) *$tp(a_i/A_i)$ is qf-internal to $\mathrm{Fix}(\tau)$ for some $\tau = \mathrm{Frob}^m\sigma^n$.*

(2) *Furthermore, let $\ell \geq 1$ be an integer, $(\mathcal{U}', \sigma')$ a model of ACFA, and $f : (E(a)_\sigma, \sigma^\ell) \to (\mathcal{U}', \sigma')$ an embedding of difference fields. Then, if $a_1, \ldots, a_n$ are as in (1), we have similar results holding in $\mathcal{U}'$: $tp^{\mathcal{U}'}(f(a_i)/f(A_i))$ is algebraic in case* (i)*, one-based in case* (ii)*, and qf-internal to $\mathrm{Fix}(\tau^\ell)$ in case* (iii)*.*

The content of this proposition is very strong. Note that in particular it implies that whether the tuple a is "one-based over E" depends only on its quantifier-free type over E, not on the particular embedding of $E(a)_\sigma$ into a model of ACFA. This result decomposes the extension $E(a)_\sigma/E$ into a tower of field extensions, each one of a certain kind.

3. Difference fields and algebraic dynamics

Definition 3.1. An *algebraic dynamics* defined over a field K is given by a pair (V, ϕ) consisting of a (quasi-projective) variety defined over K, together with a rational dominant map $\phi : V \to V$.

Remarks 3.2. In the literature, ϕ is often assumed in addition to be a morphism. Moreover, one also often imposes that the morphism be *polarized*, i.e., that there is an ample vector bundle $\mathfrak{L}$ on V and an integer $q > 1$ such that $\phi^*\mathfrak{L} \simeq \mathfrak{L}^{\otimes q}$. These hypotheses have strong consequences which we will discuss later.
If L is a field extension of K, an algebraic dynamics (V, ϕ) gives naturally rise to one defined over L, by viewing V as defined over L. We will constantly use this remark, and always consider them as algebraic dynamics over a large ambient algebraically closed field $\mathcal{U}$ (while they may be defined over smaller subfields).
If V is not absolutely irreducible, it may become reducible when viewed over L, and for this reason **we will always assume that our varieties are absolutely irreducible**.

Definition 3.3. If (V, ϕ) and (W, ψ) are algebraic dynamics, a *morphism* $(V, \phi) \to (W, \psi)$ is a rational map $f : V \to W$ such that $f \circ \phi = \psi \circ f$. It is *dominant* if $f : V \to W$ is dominant.

(3.4) Let (V, ϕ) be as above, and consider the function field $K(V)$ of V. The map ϕ then yields an endomorphism ϕ^* of $K(V)$, which leaves K fixed, and is defined by $f \mapsto f \circ \phi$, for $\phi \in K(V)$ (We view the elements of $K(V)$ as partial functions on $V(K)$ taking their values in K).
The *degree* of the morphism ϕ is $\deg(\phi) = [K(V) : \phi^*K(V)]$

Another equivalent way of translating algebraic dynamics into the difference field context, is the following: let a be a generic of V over K, and define an endomorphism σ of $K(a)$ by letting σ be the identity on K, and setting $\sigma(a) = \phi(a)$. If $f : (V, \phi) \to (W, \psi)$ is a dominant morphism, then $b = f(a)$ will be a generic of W, and we will have $\sigma(b) = \psi(b)$. Thus dominant morphisms of algebraic dynamics correspond to inclusions of difference fields.

3.5. Applying the semi-minimal analysis. Applying 2.12, there are tuples $a_1, \ldots, a_n = a \in K(a)$, such that for each i, $\sigma(a_i) \in K(a_i) \subset K(a_{i+1})$, and $tp(a_i/K(a_{i-1}))$ is either algebraic, or qf-internal to $\mathrm{Fix}(\tau)$, or one-based.

These tuples a_i give rise to a fibration of (V, ϕ), namely, if V_i is the algebraic locus of a_i over K, ϕ_i the rational endomorphism of V_i such that $\sigma(a_i) = \phi_i(a_i)$ and $g_i : V_i \to V_{i-1}$ the rational map induced by the inclusion $K(a_{i-1}) \subset K(a_i)$, we obtain

$$(V, \phi) \xrightarrow{g_n} (V_{n-1}, \phi_{n-1}) \xrightarrow{g_{n-1}} \cdots \xrightarrow{g_2} (V_1, \phi_1).$$

Note that the fibers of these maps are not themselves algebraic dynamics: indeed, the map σ transports the fiber $f_n^{-1}(a_{n-1})$ to $f_n^{-1}(\sigma(a_{n-1})) = f_n^{-1}(\phi_{n-1}(a_{n-1}))$.

3.6. Internality to the fixed field $\mathbf{Fix}(\boldsymbol{\sigma})$. Assume that $tp(a_i/K(a_{i-1}))$ is internal to $\mathrm{Fix}(\sigma)$, and that $K(a_i)$ intersects the separable closure $K(a_{i-1})^s$ of $K(a_{i-1})$ in $K(a_{i-1})$. Then, over some L containing $K(a_{i-1})$ and linearly disjoint from $K(a_i)$ over $K(a_{i-1})$, there is a tuple b such that $L(a_i) = L(b)$ and $\sigma(b) = b$. This implies that $L(a_i) = L(\sigma(a_i))$. If $i = 1$, then we get that ϕ_1 is a birational map, i.e., has degree 1. If $i \geq 2$, we obtain that ϕ_i induces a birational map between $g_i^{-1}(a_{i-1})$ and $g_i^{-1}(\sigma(a_{i-1}))$, and we have $\deg(\phi_i) = \deg(\phi_{i-1})$.

3.7. Algebraic extensions. Note that if a_j is algebraic over $K(a_{j-1})$, then also $\deg(\phi_j) = \deg(\phi_{j-1})$.

4. The Canonical base property

This property was originally a property of compact complex manifolds, which was isolated (independently) by Campana and Fujiki. Work of Moosa and Pillay provided a translation of this property in model-theoretic terms ([13] and [15]); Pillay and Ziegler ([16]) showed that various enriched fields enjoy it. This property will be later called the Canonical Base Property, CBP for short, by Moosa and Pillay who investigate it further in [14], and ask several questions.

Definition 4.1. Let T be a theory which eliminates imaginaries, $\mathbb{U}$ a saturated model of T, $A \subset \mathbb{U}$ and a a tuple in $\mathbb{U}$, $p(x) = tp(a/A)$.

(1) If T is stable and p is stationary, then p is definable, that it, for every formula $\varphi(x, y)$, there is a formula $d_\varphi(y)$ (with parameters in A) such that for every tuple b in A (of the correct arity), $\mathbb{U} \models d_\varphi(b)$ if and only if $\varphi(x, b) \in p$. Furthermore, these definitions define a (consistent and complete) type over $\mathbb{U}$. The *canonical base* of p is the smallest definably closed subset of $\mathcal{U}$ over which one can find parameters for all the formulas $d_\varphi(y)$ (in other words, contains the code of all sets defined by the $d_\varphi(y)$). It is denoted by $\mathrm{Cb}(p)$ or $\mathrm{Cb}(a/A)$, and is contained in A.

(2) If T is unstable, but simple, then the definition of canonical base is more involved, see e.g. Wagner's book [20], as it is defined in terms of extension base. It is easier to define the algebraic closure of the canonical base, denoted $\overline{\mathrm{Cb}}(p)$ or $\overline{\mathrm{Cb}}(a/A)$: it is the smallest algebraically closed subset B of A such that a and A are independent over B. If T is supersimple, then $\overline{\mathrm{Cb}}(p)$ will be contained in the algebraic closure of finitely many realisations of p, and so will have finite SU-rank if p has. Note that this definition also makes sense for infinite tuples, and we will often use it for the infinite tuple enumerating the algebraic closure of a finite tuple.

Example 4.2. Consider the theory ACF of algebraically closed fields, say of characteristic 0 for simplicity, and let $\mathbb{U}$ be a large algebraically closed field, $A \subset \mathbb{U}$ a subfield, and a a tuple in $\mathbb{U}$. Assume that $A(a)$ is a regular extension of A, and consider the algebraic locus V of a over A. Then $\mathrm{Cb}(a/A)$ is simply the field of definition of V.

Example 4.3. Let a be a tuple in $\mathcal{U}$, E a difference subfield of $\mathcal{U}$. If X is a tuple of indeterminates of the same size as a, then one can consider the ideal I of $E[X]_\sigma$ of difference polynomials which vanish at a. As in classical geometry, this ideal has a smallest (difference) field of definition, i.e., there is a unique smallest difference subfield E_0 of E such that I is generated by its intersection with $E_0[X]_\sigma$. Then $\overline{\mathrm{Cb}}(a/E) = \mathrm{acl}(E_0)$.

Definition 4.4. Let T be a supersimple theory which eliminates imaginaries. We say that T has the *Canonical Base Property*, or ***CBP***, if whenever A and B are algebraically closed sets such that $\mathrm{SU}(A/A \cap B) < \omega$ and $B = \overline{\mathrm{Cb}}(A/B)$, then $tp(B/A)$ is almost-internal (to types of SU-rank 1).

4.5. Comments.

(1) Let $C = A \cap B$, and a, b finite tuples such that $A = \mathrm{acl}(Ca)$, $B = \mathrm{acl}(Cb)$. Then $\mathrm{SU}(A/C) = \mathrm{SU}(a/C)$. The notion of almost-internality is by definition preserved under passage to the algebraic closure, so there are a set $D = \mathrm{acl}(D)$ containing A and independent from B over A, and tuples $b_1, \ldots, b_n$ with $\mathrm{SU}(b_i/D) = 1$, such that $\mathrm{acl}(DB) = \mathrm{acl}(Db_1 \ldots b_n)$.

(2) The definition in the stable case deals with finite tuples a and b, assumes that $\mathrm{Cb}(a/b) = b$, and deduces that $tp(b/a)$ is internal to types of rank 1.

(3) If $tp(A/C)$ is one-based, then ... by definition of one-basedness, we know that A and B are independent over their intersection, and therefore $B = C$. To say it in another fashion: if $tp(a/E)$ is one-based, and B contains E, then $\overline{\mathrm{Cb}}(a/B) \subset \mathrm{acl}(Ea)$.

(4) Hrushovski, Palacin and Pillay give in [10] an example of an ω-stable theory of finite rank which does not have the CBP. This example is built up from the theory ACF of algebraically closed fields.

Theorem 4.6 (Pillay-Ziegler [16]).

(1) *The theory of differentially closed fields of characteristic* 0 *has the CBP* (*version for stable theories*).

(2) *The elementary theory of an existentially closed difference field of characteristic* 0 *has the CBP.*

Pillay and Ziegler have some additional partial results concerning types of rank 1 in separably closed fields, but not the full and hoped for result. Their proof uses jet spaces, and generalises only partially to positive characteristic, because of possible inseparability problems. In order to show that the result holds for existentially closed fields of arbitrary characteristic, one needs to show a decomposition result:

Theorem 4.7 (1.16 in [2]). *Let T be a supersimple theory, $\mathbb{U}$ a large model of T, A, B and $C = A \cap B$ algebraically closed subsets of $\mathbb{U}$ such that $\mathrm{SU}(A/C) < \omega$ and $B = \overline{\mathrm{Cb}}(A/B)$. Then there are $a_1, \ldots, a_n \in A$, types $p_1, \ldots, p_n$ of SU-rank 1 (maybe over some larger base set D which is independent from AB over C), such that $\mathrm{acl}(Ca_1 \ldots, a_n) = \mathrm{acl}(CA)$; and each $tp(a_i/C)$ has a semi-minimal analysis in which all components are almost-internal to the set of realisations of the $\mathrm{Aut}(\mathbb{U}/C)$-conjugates of p_i.*
Furthermore, each of the types p_i is non-one-based.

From this, one shows easily that it suffices to show the CBP for types whose semi-minimal analysis only involves one fixed non-one-based type of rank 1. In the particular case of existentially closed difference fields of positive characteristic p, we must therefore look at types analysable in terms of $\mathrm{Fix}(\tau)$, for the various possible τ. When $\tau = \sigma$, one shows the following:

Lemma 4.8. *Let a be a finite tuple in $\mathcal{U}$, of finite SU-rank over $E = \mathrm{acl}(E)$, and assume that the semi-minimal analysis of $tp(a/E)$ only involves $\mathrm{Fix}(\sigma)$-almost-internal types. Then there is a tuple $b \in E(a)_{\sigma^{\pm 1}}$ such that $E(a)_{\sigma^{\pm 1}}$ is separably algebraic over $E(b)$.*

Inspection of the proof of Pillay-Ziegler then shows that there is no problem when $\tau = \sigma$: their proof goes through verbatim. Working in the reduct $(\mathcal{U}, \tau)$ then allows to obtain the results for all types analysable in $\mathrm{Fix}(\tau)$. Using the dichotomy Theorem 2.7, this finishes the proof of

Theorem 4.9 (3.5 in [2]). *Existentially closed difference fields of any characteristic have the CBP.*

The CBP has several interesting consquences, which I will now list. Relative versions of these results exist.

Theorem 4.10 (References are to [2]). *Let T be a supersimple theory with the CBP, $\mathbb{U}$ a saturated model, and $A, B, C = A \cap B$ algebraically closed subsets of $\mathbb{U}$, with $\mathrm{SU}(A/C)$ finite.*

(1) (2.1) *If $B = \overline{\mathrm{Cb}}(A/B)$, then $tp(B/C)$ is almost-internal.*

(2) (2.2) *More generally, if $tp(B/A)$ is almost-internal, then so is $tp(B/C)$.*

(3) (2.4) *There is some $D = \mathrm{acl}(D)$ with $C \subseteq D \subseteq A$ such that whenever $E = \mathrm{acl}(E)$ is such that $tp(A/E)$ is almost-internal, then $E \subseteq D$.*

(4) (2.5) *If $B = \overline{\mathrm{Cb}}(A/B)$ and D is such that $tp(A/D)$ is almost-internal, then so is $tp(AB/D)$.*

(5) (2.10) *Let a_1, a_2, b_1, b_2 be tuples of finite SU-rank, $\mathcal{S}$ a set of types of SU-rank 1 and assume that*

- *$tp(b_2)$ is almost-internal to types in $\mathcal{S}$,*
- *$\mathrm{acl}(b_1) \cap \mathrm{acl}(b_2) = \mathrm{acl}(\emptyset)$,*

– $a_1 \downarrow_{b_1} b_2$ *and* $a_2 \downarrow_{b_2} b_1$,

– $a_2 \in \mathrm{acl}(a_1 b_1 b_2)$.

Then there is $e \subset \mathrm{dcl}(a_2 b_2)$ *such that* $tp(a_2/e)$ *is almost-internal to types in* $\mathcal{S}$ *and* $e \downarrow b_2$. *In particular, if* $tp(a_2/b_2)$ *is hereditarily orthogonal to all types in* $\mathcal{S}$, *then* $a_2 \in \mathrm{acl}(eb_2)$.

4.11. Comments. Here is an easy consequence of item (1): assume that $tp(A/C)$ is not almost-internal, has finite SU-rank, and that $A \cap B = C$. Then A and B are independent over C.
Item (4) answers a question of Moosa and Pillay ([14]).
Item (5) is a *descent result*, and is (together with 2.12) the main ingredient of the applications to algebraic dynamics by Hrushovski and myself. After some work, and use of Proposition 2.12, one refines the descent result 4.10(5) to obtain the following:

Theorem 4.12 (4.11 in [2]). *Let* K_1, K_2 *be fields intersecting in* k, *for* $i = 1, 2$, *and with algebraic closures intersecting in* k^{alg}, *let* V_i *be an absolutely irreducible variety and* $\phi_i : V_i \to V_i$ *a dominant rational map defined over* K_i. *Assume that* K_2 *is a regular extension of* k, *and that there is an integer* $r \geq 1$ *and a dominant rational map* $f : V_1 \to V_2$ *such that* $f \circ \phi_1 = \phi_2^{(r)} \circ f$. *Then there is a variety* V_0 *and a dominant rational map* $\phi_0 : V_0 \to V_0$, *all defined over* k, *a dominant map* $g : V_2 \to V_0$ *such that* $g \circ \phi_2 = \phi_0 \circ g$, *and* $\deg(\phi_0) = \deg(\phi_2)$.

5. Applications of the CBP to algebraic dynamics

The original result of Matthew Baker. Let k be a field, C a curve over k, and $K = k(C)$. Let $\phi : \mathbb{P}^1 \to \mathbb{P}^1$ be defined over K, and of degree $d \geq 2$. One can define a logarithmic height function on the points of $\mathbb{P}^1(K)$, called the Weil height, and which I will denote by h. For details, please see [1]. If $K = k(t)$, then the Weil height of a point $P \in \mathbb{P}(K)$ is simply the minimal degree of polynomials needed to represent the point P. One then defines the canonical height $\hat{h}(P)$ as:

$$\hat{h}(P) = \lim_{n \to \infty} h(\phi^{(n)}(P))/d^n.$$

[Here $\phi^{(n)}$ denotes the iteration n times of the map ϕ.] One verifies that $\hat{h}(\phi(P)) = d\hat{h}(P)$; moreover, there is a constant $C > 0$, such that for any point P, one has $|\hat{h}(P) - h(P)| < C$. Clearly, any *preperiodic point* P (i.e., such that for some integers $m > n$ one has $\phi^{(m)}(P) = \phi^{(n)}(P)$) must have $\hat{h}(P) = 0$. Baker's theorem shows that these are the only ones, unless, over some finite extension of K one has $(\mathbb{P}^1, \phi) \simeq (\mathbb{P}^1, \psi)$ for some ψ defined over k:

Theorem 5.1 ([1]). *Let* $k \subset K$ *and* ϕ *be as above. Assume that for no finite algebraic extension of* K', *there is an* $M \in \mathrm{PGL}_2(K')$ *such that* $M^{-1}\phi M$ *is defined over* k. *Then a point* $P \in \mathbb{P}^1(K)$ *satisfies* $\hat{h}(P) = 0$ *if and only if it is preperiodic.*

He shows moreover that there is a positive ϵ which bounds below the canonical height of non-preperiodic points of $\mathbb{P}^1(K)$.

5.2. The analogue for higher dimensional varieties. The setting: Let V be a quasi-projective variety defined over K, $\phi : V \to V$ a dominant rational map of degree $d \geq 2$. Once fixed an embedding of V into projective space, the Weil heights of points of $V(K)$ exist as before. (But to obtain the canonical height, additional conditions are necessary.) We assume that for some N, the points $P \in V(K)$ such that all $\phi^{(n)}(P)$, $n \geq 0$, have height $\leq N$, form a Zariski dense subset of V.

The hope: (V, ϕ) is isomorphic to some (W, ψ) defined over k.

5.3. The observation which makes things work. The following observation, due to Szpiro, is what allows model theory to play a role, since it gives a certain configuration which one can exploit.

Given some integer N, the points of $V(K)$ which have Weil height $\leq N$, form what we will call a *limited set*, i.e., there is some algebraic set U defined over k, a constructible map $\pi : U \to V$ (defined over K), such that $\pi(U(k))$ contains all points of $V(K)$ of Weil height $\leq N$, and π is injective on $U(k)$ (see e.g. section 3 of [4]). Consider the following sets:

$$V_0 = \pi(U(k));\ V_n = \bigcap_{0 \leq j \leq n} \phi^{-(j)}(V_0).$$

So, a point P will be in V_n if and only if each of $P, \phi(P), \ldots, \phi^{(n)}(P)$ has Weil height $\leq N$.

The map ϕ induces a (partially defined) constructible map ϕ^* on U. Namely, if $Q \in U(k)$, and $\phi\pi(Q) \in V_0$, then $\phi^*(Q)$ is defined by $\pi\phi^*(Q) = \phi\pi(Q)$. Assume that for the number N above, the sets V_n are Zariski dense in V. We now look at U_n, the Zariski closure of $\pi^{-1}(V_n) \cap U(k)$. These sets form a decreasing chain of Zariski closed infinite subsets of U, which must therefore stabilise at some integer n. Let $\tilde{U} \subset U_n$ be the union of all irreducible components W of U_n such that $\pi(W(k))$ is Zariski dense in V. Then, the constructible ϕ^* induces a permutation of the irreducible components of $\tilde{U}$ of maximal dimension, and for some $r \geq 1$, the constructible map $(\phi^*)^{(r)}$ yields a rational dominant endomap ψ of some irreducible component W of $\tilde{U}$ of maximal dimension. Note that $\pi(W(k))$ is still Zariski dense in V, but that π sends (W, ψ) to $(V, \phi^{(r)})$. It turns out that this is sufficient to obtain some results, using Theorem 4.12.

Theorem 5.4 ([5, 3.2], [2, 4.12]). *With assumption as in 5.2, let $\mathcal{U}$ be a model of ACFA containing K, and a a generic point of V over K satisfying $\sigma(a) = \phi(a)$.*

(1) *Assume that the semi-minimal analysis of $tp(a/K)$ does not involve $\mathrm{Fix}(\sigma)$. Then there is a bijective morphism $g : (V, \phi) \to (V_0, \phi_0)$ for some (V_0, ϕ_0) defined over k. In characteristic 0, this g is a birational isomorphism.*

(2) *In the general case, there is a dominant rational map $(V, \phi) \to (V, \phi_0)$ where (V, ϕ_0) is defined over k, and $\deg(\phi) = \deg(\phi_0)$.*

Sketch of Proof. I will use (the proof of) 4.11 in [2], and follow its notation. By the above discussion 5.3, we know that there is some algebraic dynamics (V_1, ϕ_1) defined over k, and which dominates $(V, \phi^{(r)})$ for some $r \geq 1$. Let $\mathcal{U}$ be a model of ACFA containing K, let a_2 be a generic of V satisfying $\sigma(a_2) = \phi(a_2)$. Applying 4.11 of [2] (with $K_1 = k$, $K_2 = K$ and $(V_2, \phi_2) = (V, \phi)$), there is $a_3 \in K(a_2)$ such that $\sigma(a_3) \in k(a_3)$. If V_0 is the algebraic locus of a_3 over k, and $\phi_0 \in k(V_0)$ is such that $\phi_0(a_3) = \sigma(a_3)$, then $\deg(\phi) = \deg(\phi_0)$, and there is a rational dominant map $(V, \phi) \to (V_0, \phi_0)$. This gives (2).

The proof of 4.11 in [2] shows that $tp(a_2/K(a_3)_{\sigma^{\pm 1}})$ is almost-internal to $\mathrm{Fix}(\sigma)$. Hence, in case (1), it must be algebraic. Thus $K(a_2)$ is a finite algebraic extension of $K(a_3)$. Let $\alpha \in K(a_2)$ be defined by $K(\alpha) = K(a_2) \cap K(a_3)^s$, so that $K(a_2)/K(\alpha)$ is purely inseparable.

Now, recall from the proof of 4.11 that there is some generic a_1 of V_1 over K, such that $a_2 \in K(a_1)$. Then $k(a_1)$ and $K(a_3)$ are linearly disjoint over $k(a_3)$, and because $K(\alpha)/K(a_3)$ is separable and $K(a_2) \subset K(a_1)$, it follows that $K(\alpha) = K(\beta)$ for some $\beta \in k(a_1)$. Then $\beta \in k(a_3)^s$. As $\sigma(a_2) \in K(a_2)$, we have $\sigma(\alpha) \in K(\alpha)$, hence $\sigma(\beta) \in k(\beta)$. Let $\tilde{V}$ be the algebraic locus of β over k, and $\tilde{\phi} \in k(\tilde{V})$ such that $\sigma(\beta) = \tilde{\phi}(\beta)$, g the rational map $V \to \tilde{V}$ such that $g(a_2) = \beta$. Then g is generically bijective, and sends (V, ϕ) to $(\tilde{V}, \tilde{\phi})$. In characteristic 0, we may take $\alpha = a_2$, and g is then birational. This finishes the proof of (1). □

5.5. Comments. The fact that we work with function fields only tells us about the generic behaviour of the algebraic dynamics, and does not allow us to show full isomorphisms, only birational isomorphisms.

Remark 5.6. If in addition to the hypotheses of 5.2, one assumes that the map ϕ is a polarised morphism with associated constant $q > 1$, then the conclusion of 5.4(1) holds, so that we get the full result. This follows from an observation made without proof in [4]. The proof I sketch below is due to Hrushovski.

Proof. First, note that the hypotheses imply, by a result of Fakhruddin [8], that we may assume that $V \subset \mathbb{P}^N$ for some N, and that the morphism ϕ on V is the restriction to V of a morphism $\psi : \mathbb{P}^N \to \mathbb{P}^N$. Suppose that the conclusion of 5.4(1) does not hold, and let $\mathcal{U}$ be a model of ACFA containing K.

Let $g : (V, \phi) \to (V_0, \phi_0)$ be given by 5.4, with $\deg(\phi) = \deg(\phi_0)$, let $a = a_2 \in \mathcal{U}$ be a generic of V satisfying $\sigma(a_2) = \phi(a_2)$ and let $a_3 = g(a_2)$ (a generic of V_0 satisfying $\sigma(a_3) = \phi_0(a_3)$). Equality of the degrees of ϕ and ϕ_0 implies that the restriction of ϕ to $S = g^{-1}(a_3)$ is an isomorphism. The variety $S' = \phi(S)$ equals S^σ, and therefore $\deg(S') = \deg(S)$. We will show the following:

If S is a subvariety of V, and $\deg(S) = \deg(\phi(S))$ (as subvarieties of $\mathbb{P}^N$), then the degree of the map ϕ restricted to S is $q^{\dim(S)}$.

Let $r = \dim(S)$, and let $L_1, \ldots, L_r$ be generic hyperplanes. Then $\deg(S') = S' \cdot L_1 \cdot \cdots \cdot L_r$, and also equals $|S' \cap L_1 \cap \cdots \cap L_r|$, the number of points of $S' \cap L_1 \cap \cdots \cap L_r$ counted with multiplicities. Pulling back by ϕ, we get

$$\begin{aligned}\deg(S) &= \deg(S')\deg(\phi|S) = |\phi^{-1}(S') \cap \phi^{-1}(L_1) \cap \cdots \cap \phi^{-1}(L_r)| \\ &= S \cdot qL_1 \cdots qL_r = q^r \deg(S)\end{aligned}$$

(here we use $\phi^* L_i = qL_i$). As $\deg(S) = \deg(S')$, the restriction of ϕ to S has degree q^r.

As $\phi|S$ is birational and therefore of degree 1, we must have $r = 0$. This implies that S is finite, i.e., that a_2 is algebraic over $K(a_3)$, and we conclude as in 5.4(1). □

Acknowledements. The author thanks MSRI for its support during the spring 2014.

Logic and operator algebras

Ilijas Farah

Abstract. The most recent wave of applications of logic to operator algebras is a young and rapidly developing field. This is a snapshot of the current state of the art.

Mathematics Subject Classification (2010). 03C20, 03C98, 03E15, 03E75, 46L05, 46L10.

Keywords. Classification of C*-algebras, tracial von Neumann algebras, logic of metric structures, Borel reducibility, ultraproducts.

1. Introduction

The connection between logic and operator algebras in the past century was sparse albeit fruitful. Dramatic progress has brought set theory and operator algebras closer together over the last decade. A number of long-standing problems in the theory of C*-algebras were solved by using set-theoretic methods, and solutions to some of them were even shown to be independent from ZFC. There is much to be said about these developments (as witnessed in three almost disjoint recent survey papers [30, 45, 96]), but that is not what this paper is about. New applications of logic to operator algebras are being found at such a pace that any survey is bound to become obsolete within a couple of years. Instead of presenting an encyclopaedic survey, I shall proceed to describe the current developments (many of them from the unpublished joint work, [33, 34]) and outline some possible directions of research. The choice of the material reflects my interests and no attempt at completeness has been made. Several results proved by operator algebraists without using logic that have logical content are also included.

'Logic' in the title refers to model theory and (mostly descriptive) set theory, with a dash of recursion theory in a crucial place.

2. Operator algebras

Let $\mathcal{B}(H)$ denote the Banach algebra of bounded linear operators on a complex Hilbert space H equipped with the operation * of taking the adjoint. A *C*-algebra* is a Banach algebra with involution which is *-isomorphic to a subalgebra of $\mathcal{B}(H)$ for some H. Notably, all algebraic isomorphisms between C*-algebras are isometries. All C*-algebras considered here will be unital, unless otherwise specified. A *von Neumann algebra* is a unital subalgebra of $\mathcal{B}(H)$ which is closed in the weak operator topology. An algebra isomorphic to a von

Proceedings of the International Congress of Mathematicians, Seoul, 2014

Neumann algebra is called a *W*-algebra*. Standard terminology from operator theory is imported into operator algebras, and in particular positivity of self-adjoint operators plays an important role.

I only have something to say about those von Neumann algebras that have a trace. A *normalized trace* (on a von Neumann algebra or a unital C*-algebra) is a unital positive functional such that $\tau(ab) = \tau(ba)$ for all a and b. We shall only consider unital algebras and normalized traces. A trace on a von Neumann algebra is automatically continuous in the weak operator topology. A tracial infinite-dimensional von Neumann algebra with a trivial center is a *II_1 factor*. The terminology comes from von Neumann's type classification, in which the unique I_n factor is $M_n(\mathbb{C})$; we shall not consider other types of factors.

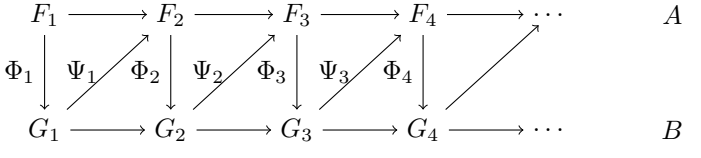
If τ is a trace on an operator algebra A then the ℓ_2-norm $\|a\|_2 = \tau(a^*a)^{1/2}$ turns A into a pre-Hilbert space. The algebra A is represented on this space by the left multiplication; this is the *GNS representation* corresponding to τ. If A is a C*-algebra, then the weak closure of the image of A is a tracial von Neumann algebra. If A is simple and infinite-dimensional, this algebra is a II_1 factor. A GNS representation can be associated to an arbitrary positive unital functional (*state*).

The category of abelian C*-algebras is equivalent to the category of locally compact Hausdorff spaces and the category of abelian von Neumann algebras with a distinguished trace is equivalent to the category of measure algebras. Because of this, these two subjects are considered to be noncommutative (or quantized) topology and measure theory, respectively.

There is only one (obvious, spatial) way to define the tensor product of von Neumann algebras. A C*-algebra A is *nuclear* if for every C*-algebra B there is a unique C*-norm on the algebraic tensor product of A and B. The importance of this notion is evident from a variety of its equivalent characterizations (see [11]), one of them being Banach-algebraic amenability. Although by a result of Junge and Pisier (see [11]) there is finite subset $F \Subset \mathcal{B}(H)$ such that no nuclear C*-algebra includes F, these algebras are ubiquitous in a number of applications.

For more on C*-algebras and von Neumann algebras see [8, 11, 55].

2.1. Intertwining. A *metric structure* is a complete metric space (A, d) equipped with functions $f\colon A^n \to A$ and predicates $p\colon A^n \to \mathbb{R}$, all of which are assumed to be uniformly continuous on d-bounded sets. Consider two separable complete metric structures A and B. Assume we have partial isometric homomorphisms $\Phi_n\colon F_n \to G_n$, $\Psi_n\colon G_n \to F_{n+1}$ for $n \in \mathbb{N}$ such that $F_n \subseteq F_{n+1} \subseteq A$ and $G_n \subseteq G_{n+1} \subseteq B$ for $n \in \mathbb{N}$ and $\bigcup_n F_n$ and $\bigcup_n G_n$ are dense in A and B respectively. Furthermore assume that in the following diagram



the n-th triangle commutes up to 2^{-n}. Then $\Phi\colon \bigcup_n F_n \to B$ defined by $\Phi(a) = \lim_n \Phi_n(a)$ and $\Psi\colon \bigcup_n G_n \to A$ defined by $\Psi(b) = \lim_n \Psi_n(b)$ are well-defined isometric homomorphisms. Their continuous extensions to A and B are respectively an isomorphism from A onto B and vice versa.

Variations of this method for constructing isomorphisms between C*-algebras comprise *Elliott's intertwining argument*. In *Elliott's program* for classification of separable, nuclear, unital and simple C*-algebras maps Φ_n and Ψ_n are obtained by lifting morphism between the K-theoretic invariants (so-called *Elliott invariants*) of A and B. The first result along these lines was the Elliott–Bratteli classification of separable AF algebras (i.e., direct limits of finite-dimensional C*-algebras) by the ordered K_0. Remarkably, for A and B belonging to a rather large class of nuclear C*-algebras this method shows that any morphism between Elliott invariants lifts to a morphism between the algebras. Elliott conjectured that the separable, nuclear, unital and simple algebras are classified by K-theoretic invariant known as the Elliott invariant. This bold conjecture was partially confirmed in many instances. See [77] for more on the early history of this fascinating subject.

Examples of separable, nuclear, unital and simple C*-algebras that limit the extent of Elliott's classification program were given in [78] and [90]. Algebras defined in [90] have a remarkable additional property. Not only do the nonisomorphic algebras A and B have the same Elliott invariant, but in addition they cannot be distinguished by any homotopy-invariant continuous functor. We shall return to these examples in §4.3. The revised Elliott program is still one of the core subjects in the study of C*-algebras (see [25]).

2.2. Strongly self-absorbing (s.s.a.) algebras. An infinite-dimensional C*-algebra is *UHF* (uniformly hyperfinite) if it is an infinite tensor product of full matrix algebras $M_n(\mathbb{C})$. If A is UHF, then every two unital copies of $M_n(\mathbb{C})$ in it are unitarily conjugate and therefore every endomormphism of A is a point-norm limit of inner automorphisms. The *generalized natural number* of A has as its 'divisors' all n such that $M_n(\mathbb{C})$ embeds unitally into A. Glimm proved that this is a complete isomorphism invariant for the separable UHF algebras.

If A is UHF then it has a unique trace τ. The tracial von Neumann algebra corresponding to the τ-GNS representation of A (§2) is the *hyperfinite II_1 factor, R*, and it does not depend on the choice of A. It is the only injective II_1 factor and it has played a key role in the classification of injective factors [19].

Two *-homomorphisms Φ and Ψ from A into B are *approximately unitarily equivalent* if there is a net of inner automorphisms α_λ, for $\lambda \in \Lambda$, of B such that

$$\lim_\lambda \alpha_\lambda \circ \Phi(a) = \Psi(a)$$

for all $a \in A$ (convergence is taken in the operator norm for C*-algebras and in the ℓ_2-norm for tracial von Neumann algebras). If $A \otimes B \cong A$ we say that A is *B-absorbing* and if $A \otimes A \cong A$ then we say that A is *self-absorbing*. Here and in what follows, we will often be providing two definitions at once, one for von Neumann algebras and another for C*-algebras. The difference comes in the interpretation of $\otimes$, either as the von Neumann (spatial) tensor product $\bar{\otimes}$ or as the C*-algebra minimal (spatial) tensor product $\otimes$. *McDuff* factors are the R-absorbing II_1 factors. A separable C*-algebra D is *strongly self-absorbing* (s.s.a.) [92] if there is an isomorphism $\Phi\colon D \to D \otimes D$ and map $\mathrm{id} \otimes 1_D : D \to D \otimes D$ is approximately unitarily equivalent to Φ. The definition of strongly self-absorbing is modified to II_1 factors following the convention stated above, by replacing $\|\cdot\|$ with $\|\cdot\|_2$ and $\otimes$ with $\bar{\otimes}$.

The hyperfinite factor R is the only s.s.a. tracial von Neumann algebra with separable predual (Stefaan Vaes pointed out that this was essentially proved in [19, Theorem 5.1(3)]). A UHF algebra A is s.s.a. if and only if it is self-absorbing. However, the latter notion is in general much stronger. For any unital C*-algebra A the infinite tensor product $\bigotimes_{\mathbb{N}} A$ is

self-absorbing but not necessarily s.s.a. Every s.s.a. C*-algebra D is simple, nuclear and unital [23].

Three s.s.a. algebras are particularly important. The *Jiang–Su* algebra $\mathcal{Z}$ is an infinite-dimensional C*-algebra which is indistinguishable from $\mathbb{C}$ by its Elliott invariant. Conjecturally, $\mathcal{Z}$-absorbing infinite-dimensional separable, nuclear, unital and simple algebras are classifiable by their Elliott invariant. The Cuntz algebra $\mathcal{O}_2$ is the universal algebra generated by two partial isometries with complementary ranges. The Cuntz algebra $\mathcal{O}_\infty$ is the universal unital C*-algebra generated by partial isometries v_n, for $n \in \mathbb{N}$, with orthogonal ranges. The first step in the Kirchberg–Phillips classification of purely infinite separable, nuclear, unital and simple algebras was Kirchberg's result that every such algebra is $\mathcal{O}_\infty$-absorbing and that $\mathcal{O}_2$ is A-absorbing for every separable, nuclear, unital and simple algebra (see [77]).

3. Abstract classification

A *Polish space* is a separable, completely metrizable topological space. A subset of a Polish space is *analytic* if it is a continuous image of some Polish space. Essentially all classical classification problems in mathematics (outside of subjects with a strong set-theoretic flavour) can be modelled by an analytic equivalence relation on a Polish space. Moreover, the space of classifying invariants is also of this form, and computation of the invariant is usually given by a Borel measurable map. This is indeed the case with C*-algebras and the Elliott invariant [43].

If E and F are equivalence relations on Polish spaces, E is *Borel-reducible* to F, $E \leq_B F$, if there exists a Borel-measurable $f\colon X \to Y$ such that $x \mathrel{\mathrm{E}} y$ if and only if $f(x) \mathrel{\mathrm{E}} f(y)$. One can interpret this as stating that the classification problem for E is not more difficult than the classification problem for F. Following Mackey, an equivalence relation E Borel-reducible to the equality relation on some Polish space is said to be *smooth*. By the *Glimm–Effros* dichotomy the class of non-smooth Borel-equivalence relations has an initial object [52], denoted E_0. It is the tail equality relation on $\{0,1\}^{\mathbb{N}}$. While the Glimm–Effros dichotomy was proved by using sophisticated tools from effective descriptive set theory, the combinatorial core of the proof can be traced back to work of Glimm and Effros on representations of locally compact groups and separable C*-algebras. See [47, 57] for more on (invariant) descriptive set theory.

When is an equivalence relation classifiable? Many non-smooth equivalence relations are considered to be satisfactorily classified. An example from the operator algebras is the Elliott–Bratteli classification of separable AF algebras by countable abelian ordered groups. A rather generous notion is being 'classifiable by countable structures.' Hjorth's theory of turbulence [54] provides a powerful tool for proving that an orbit equivalence relation is not classifiable by countable structures.

Sasyk and Törnquist have proved that every class of injective factors that was not already satisfactorily classified is not classifiable by countable structures [80, 81]. By combining results of [24, 44, 48, 71, 79], one proves that the following isomorphism relations are Borel-equireducible.

(a) Isomorphism relation of separable C*-algebras.

(b) Isomorphism relation of Elliott–classifiable separable, nuclear, unital and simple algebras.

(c) Isometry relation of separable Banach spaces.

(d) Affine homeomorphism relation of metrizable Choquet simplices.

(e) Isometry relation of Polish spaces.

Each of these equivalence relations (as well as the isometry of a class of separable metric structures of any given signature) is Borel-reducible to an orbit equivalence relation of a Polish group action [24].

Being Borel-reducible to an orbit equivalence relation is, arguably, the most generous definition of being concretely classifiable. Conjecturally, E_1, the tail-equivalence relation on $[0,1]^{\mathbb{N}}$, is an initial object among Borel equivalence relations not Borel-reducible to an orbit equivalence relation [58]. Notably, the isomorphism of separable Banach spaces is the $\leq_B$-terminal object among analytic equivalence relations [46].

The answer to the question 'When is an equivalence relation classifiable' is frequently of somewhat sociological nature. It is notable that the isomorphism relation of abelian unital C*-algebras (generally considered intractable) is Borel-reducible to the isomorphism relation of Elliott-classifiable AI algebras (for which there is a satisfactory classification relation). Also, as pointed out by David Fremlin, most analysts find that normal operators are satisfactorily classified up to conjugacy by the spectral theorem, although they are not classifiable by countable structures.

Nevertheless, the theory of Borel-reducibility is a great example of a situation in which logic provides concrete obstructions to sweeping conjectures. For example, the classification of countable abelian torsion free groups of rank $n+1$ is strictly more complicated than the classification of countable abelian torsion free groups of rank n for every n [89]. (Notably, the proof of this result uses *Popa superrigidity* of II_1 factors, [75].) This theory was recently successfully applied to (non)classification of automorphisms of group actions on operator algebras ([59], automorphisms of C*-algebras [60, 64] and subfactors [9].

A partial Borel-reducibility diagram of classification problems in operator algebras is given in Figure 3.1. For an explanation of terminology see [30, §9]. I am indebted to Marcin Sabok for pointing out that the isomorphism of countable structures of any signature is Borel-reducible to the isomorphism relation of separable AF algebras [15].

Borel-reduction of equivalence relations as defined above does not take into the account the functorial nature of the classification of C*-algebras. Some preliminary results on Borel functorial classification were obtained by Lupini.

4. Model-theoretic methods

Until recently there was not much interaction between model theory and operator algebras (although model theory was fruitfully applied to the geometry of Banach spaces, (see [53]). Recent emergence of the logic of metric structures [5], originally introduced only for bounded metric structures, created new opportunities for such interactions. It was modified to allow operator algebras in [36].

4.1. Logic of metric structures. Model theory can roughly be described as the study of axiomatizable classes of structures and sets definable in them. Axiomatizable properties can be expressed in syntactic terms, but they are also characterized by preservation under ultraproduts and ultraroots (see §6). A category $\mathcal{C}$ is *axiomatizable* if there exists a first-

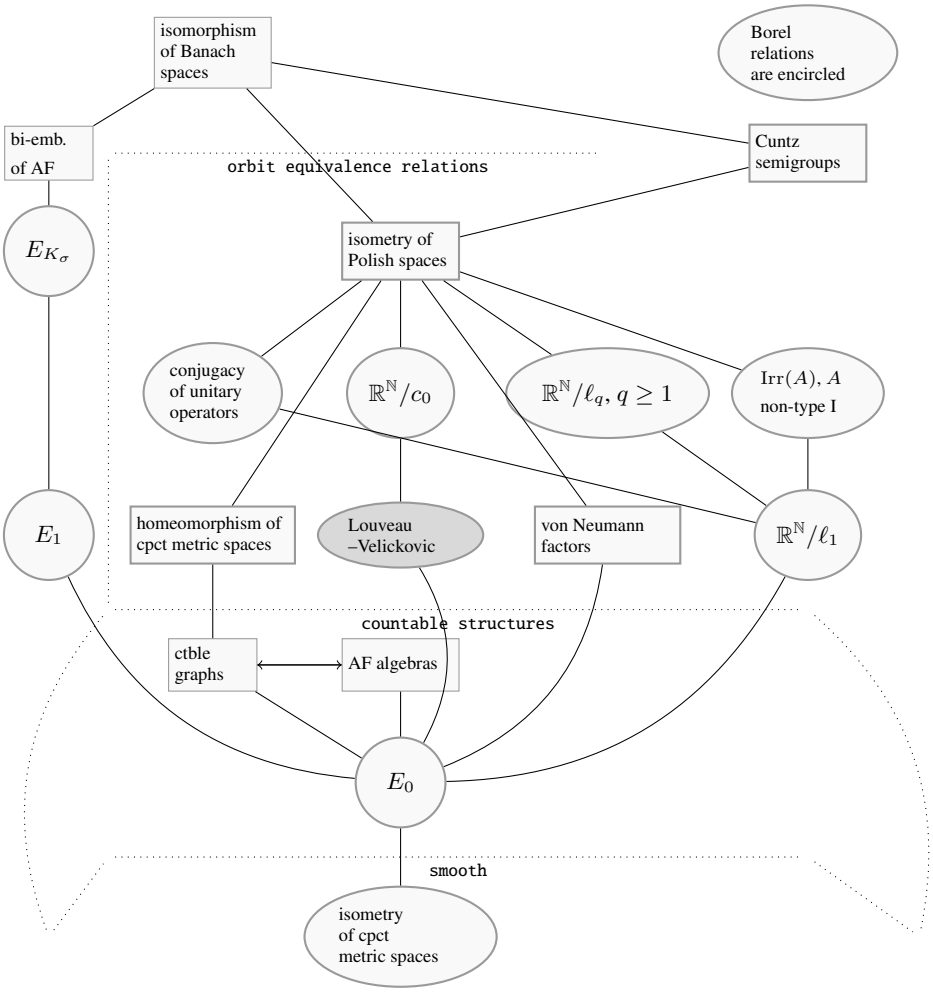


Figure 3.1.

order theory $\mathbf{T}$ such that the category $\mathfrak{M}(\mathcal{C})$ of all models of $\mathbf{T}$ is equivalent to the original category.

Classical model theory deals with discrete structures, and its variant suitable for metric structures as defined in §2.1 was introduced in [5]. In this logic interpretations of formulas are real-valued, propositional connectives are real-valued functions, and quantifiers are $\sup_x$ and $\inf_x$. Each function and predicate symbol is equipped with a modulus of uniform continuity. This modulus is a part of the language. If the diameter of the metric structures is fixed, then every formula has its own modulus of uniform continuity, respected in all relevant metric structures. Formulas form a real vector space equipped with a seminorm, $\|\phi(\bar{x})\| = |\sup \phi(\bar{a})^A|$ where the supremum is taken over all metric structures A of the given language and all tuples $\bar{a}$ in A of the appropriate type. Formulas are usually required to have range in $[0, \infty)$ (or $[0, 1]$ in the bounded case) but allowing negative values results in equivalent logic; see also [4]. The *theory* of a model is the kernel of the functional $\phi \mapsto \phi^A$,

where ϕ ranges over all sentences (i.e., formulas with no free variables) of the language. This kernel uniquely defines the functional, which can alternatively be identified with the theory. The weak*-topology on this space is also known as the *logic topology*. If the language is countable then the space of formulas is separable and the spaces of theories and types (see §4.4) are equipped with compact metric topology.

Two metric structures are *elementarily equivalent* if their theories coincide. A formula is *existential* if it is of the form $\inf_{\bar{x}} \phi(\bar{x})$ for some quantifier-free formula $\phi(\bar{x})$. The *existential theory* of A is $\mathrm{Th}_\exists(A) = \{\psi \in \mathrm{Th}(A) : \psi \text{ is existential}\}$.

There are several equivalent ways to adapt the logic of metric structures to operator algebras and to unbounded metric structures in general [3, 36]. Axiomatizability is defined via equivalence of categories as above, but model $M(A)$ associated with A has more (albeit artificial) structure. It is equipped with *domains of quantification*, bounded subsets of A on which all functions and predicates are uniformly continuous (with a fixed modulus of uniform continuity) and over which quantification is allowed. It is the existence of category $\mathfrak{M}(\mathcal{C})$, and not its particular choice, that matters.

In the simplest version of $M(A)$ quantification is allowed only over the (operator norm) n-balls of the algebra. The notion of *sorts* over which one can quantify corresponds to those functors from the model category into metric spaces with uniformly continuous functions that commute with ultraproducts (see [36, 2]). For example, $M(A)$ can be taken to consist of all matrix algebras $M_n(A)$ for $n \in \mathbb{N}$, as well as completely positive, contractive maps between them and finite-dimensional algebras. This is important because nuclearity is equivalently characterized as the CPAP, the *completely positive approximation property* (see [11] and [12]).

C*-algebras are axiomatized as Banach algebras with an involution that satisfy the *C*-equality*, $\|aa^*\| = \|a\|^2$, by the Gelfand–Naimark and Segal (GNS mentioned earlier) theorem. Abelian C*-algebras are obviously axiomatized by $\sup_{x,y} \|xy - yx\|$ and non-abelian C*-algebras are slightly less obviously axiomatized by $\inf_{\|x\|\le 1} |1 - \|x\|| + \|x^2\|$ (a C*-algebra is nonabelian if and only if it contains a nilpotent element).

The proof that the tracial von Neumann algebras with a distinguished trace are also axiomatizable ([36], first proved in [6]) goes deeper and uses Kaplansky's Density Theorem. Again, quantification is allowed over the (operator norm) unit ball and the metric is the ℓ_2 metric $\|a\|_2 = \tau(a^*a)^{1/2}$. The operator norm is not continuous with respect to the ℓ_2 metric and it therefore cannot be added to II_1 factors as a predicate.

There are elementarily equivalent but nonisomorphic separable unital AF algebras. This is proved by using descriptive set theory. The association $A \mapsto \mathrm{Th}(A)$ is Borel, and hence the relation of elementary equivalence is smooth (§3). The category of AF algebras is equivalent to the category of their ordered K_0 groups. By the Borel version of this result and the fact that the isomorphism of dimension groups is not smooth the conclusion follows.

The following proposition is taken from [34].

Proposition 4.1.

(1) *For every separable, nuclear, unital and simple C*-algebra there exists an elementarily equivalent, separable, non-nuclear, C*-algebra.*

(2) *The reduced group C*-algebra of the free group with infinitely many generators $C^*_r(F_\infty)$ is not elementarily equivalent to a nuclear C*-algebra.*

Instead of providing a genuine obstruction, this proposition precipitated some of the most interesting progress in the field.

Here is a simple but amusing observation. The *Kadison–Kastler* distance between subalgebras of $\mathcal{B}(H)$ is the Hausdorff (norm) distance between their unit balls. For every sentence ϕ the map $A \mapsto \phi^A$ is continuous with respect to this metric. Therefore the negation of an axiomatizable property is stable under small perturbations of an algebra (see [18] and references thereof for more on perturbations of C*-algebras).

4.2. Elementary submodels. If A is a submodel of B, it is said to be an *elementary submodel* if $\phi^A = \phi^B \restriction A^n$ for every n and every n-ary formula ϕ. The Downwards Löwenheim–Skolem theorem implies that every model has a separable elementary submodel. Its C*-algebraic variant is known as 'Blackadar's method' and is used to provide separable examples from known nonseparable examples (see [8, II.8.5] and [72]).

Proposition 4.2. *Assume A is a C*-algebra and B is its elementary submodel. Then B is a C*-algebra with the following properties.*

(1) *Every trace of B extends to a trace of A.*

(2) *Every ideal of B is of the form $I \cap B$ for some ideal I of A.*

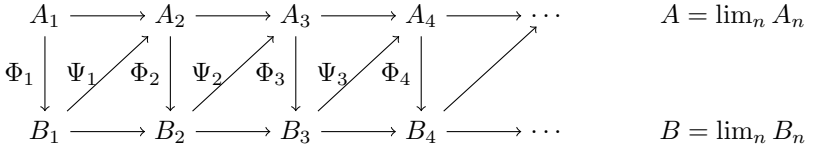
(3) *Every character of B extends to a character of A.*

(4) *If A is nuclear so is B.*

In particular, B is monotracial and/or simple if and only if A has these properties. It should be noted that neither of these properties is axiomatizable, because neither of them is preserved under taking ultrapowers (see [76] for the nonaxiomatizability of having a unique trace and §6 for the ultrapowers).

A drastic example of a property that does not persist to elementary submodels is given in Theorem 8.1.

4.3. Intertwining again. We return to Elliott's intertwining argument (§2.1):



If the maps Φ_n are expected to converge to an isomorphism, it is necessary that they approximate elementary maps. For a formula $\phi(\bar{x})$ and a tuple $\bar{a}$ in the domain of Φ_n one must have $\phi(\bar{a})^A = \lim_n \phi(\Phi_n(\bar{a}))^B$. Even more elementarily, the algebras A and B ought to be elementarily equivalent (no pun intended). Every known counterexample to Elliott's program involves separable, nuclear, unital and simple algebras with the same Elliott invariant, but different theories. For example, the radius of comparison was used in [91] to distinguish between continuum many nonisomorphis separable, nuclear, unital and simple algebras with the same Elliott invariant, and it can be read off from the theory of an algebra [34].

This motivates an outrageous conjecture, that the following question has a positive answer.

Question 4.3. *Assume that separable, nuclear, unital and simple algebras A and B have the same Elliott invariant and are elementarily equivalent. Are A and B necessarily isomorphic?*

Since being $\mathcal{Z}$-stable is axiomatizable (see §6.1), the revised Elliott conjecture that all $\mathcal{Z}$-stable separable, nuclear, unital and simple algebras are classified by their Elliott invariant is a special case of a positive answer to Question 4.3. All known nuclear C*-algebras belong to the so-called *bootstrap class*, obtained by closing the class of type I algebras under operations known to preserve nuclearity (see [8]). An (expected) negative answer to Question 4.3 would require new examples of separable, nuclear, unital and simple algebras. Can model-theoretic methods provide such examples?

4.4. Omitting types. Let $\mathbb{F}_n$ be the set of formulas whose free variables are included in $\{x_1, \dots, x_n\}$. An *n-type* is a subset $\mathbf{t}$ of $\mathbb{F}_n$ such that for every finite $\mathbf{t}_0 \Subset \mathbf{t}$ and for every $\varepsilon > 0$ there are a C*-algebra A and n-tuple $\bar{a}$ in the unit ball of A such that $|\phi(\bar{a})| < \varepsilon$ for all $\phi \in \mathbf{t}_0$. By applying functional calculus one sees that this definition is equivalent to the apparently more general standard definition ([5]) in which types consist of arbitrary closed conditions. An n-type $\mathbf{t}$ is *realized* by n-tuple $\bar{a}$ in the unit ball of A if $\phi(\bar{a})^A = 0$ for all ϕ in $\mathbf{t}$. It is *omitted* in A if it is not realized by any n-tuple in A_1. Łoś's theorem implies that every type is realized in an ultraproduct; we shall return to this in §6.0.1 but presently we are concerned with omitting types.

The omitting types theorem of classical ('discrete') model theory [67] provides a simple condition for omitting a type in a model of a given theory. A predicate p is *definable* if for every $\varepsilon > 0$ there exists a formula $\phi(\bar{x})$ which up to ε approximates the value of p. A type is definable if the distance function to its realization in a saturated model (§6.0.1, §7.1) is definable. By the omitting types theorem of [5] a type is omissible if and only if it is not definable, with the additional stipulation that it be *complete* (i.e., maximal under the inclusion). While a definable type is never omissible even if it is incomplete, Ben Yaacov has isolated types that are neither definable nor omissible. His example was simplified by T. Bice.

Theorem 4.4 ([39]).

(1) *There is a theory $\mathbf{T}$ in a separable language such that the set of types omissible in some model of $\mathbf{T}$ is a complete Σ^1_2 set.*

(2) *There are a complete theory $\mathbf{T}$ in a separable language and a countable set $\mathbf{P}$ of types such that for every finite $\mathbf{P}_0 \Subset \mathbf{P}$ there exists a model M of $\mathbf{T}$ that omits all types in $\mathbf{P}_0$, but no model of $\mathbf{T}$ omits all types in $\mathbf{P}$.*

Therefore the question of whether a type is omissible in a model of a given metric theory is by (1) far from being Borel or even analytic and therefore intractable, and by (2) separately omissible types over a complete theory are not necessarily jointly omissible. Both results stand in stark contrast to the situation in classical model theory.

The idea that the omitting types theorem can be used in the study of C*-algebras emerged independently in [14] and [83]. A sequence $\mathbf{t}_n$, for $n \in \mathbb{N}$, of m-types is *uniform* if there are formulas $\phi_j(\bar{x})$ for $j \in \mathbb{N}$ with the same modulus of uniform continuity such that $\mathbf{t}_n = \{\phi_j(\bar{x}) \geq 2^{-n} : j \in \mathbb{N}\}$ for every n. In this situation, the interpretation of the infinitary formula $\phi(\bar{x}) = \inf_j \phi_j(\bar{x})$ is uniformly continuous in every model (with a fixed modulus of uniform continuity) and moreover $\sup_{\bar{x}} \phi(\bar{x})^A = 0$ if and only if A omits all $\mathbf{t}_n$.

Nuclearity, simplicity, as well as many other important non-axiomatizable properties of C*-algebras (including nuclear dimension or decomposition rank $\leq n$; see [99]) are characterized by omitting a uniform sequence of types. The classical theory of omitting types

applies to such types unchanged: a uniform sequence of types is omissible in a model of a complete theory $\mathbf{T}$ if and only if none of the types is isolated [39]. As an extra, this characterization shows that one can find a separable elementary submodel of a nonnuclear algebra that is itself nonnuclear by assuring that it includes a tuple that realizes the relevant type

4.5. Strongly self-absorbing algebras II. These algebras have remarkable model-theoretic properties. Every s.s.a. algebra D is a *prime model* of its theory (it elementarily embeds into every other model of its theory) and every unital morphism of D into another model of its theory is elementary (§4.2).

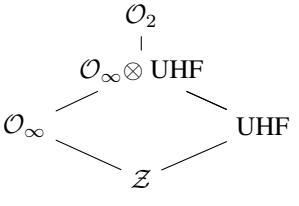
Proposition 4.5. *If D and E are s.s.a. algebras then the following are equivalent.*

(1) *E is D-*absorbing*: $E \otimes D \cong E$.*

(2) *D is isomorphic to a subalgebra of E.*

(3) $\mathrm{Th}_\exists(D) \subseteq \mathrm{Th}_\exists(E)$.

The implications from (1) to (2) and from (2) to (3) are always true, but both converses fail in general. S.s.a. algebras are as rare as they are important and the following diagram represents all known s.s.a. algebras, given in the order defined by either clause of Proposition 4.5.



Finding an s.s.a. algebra other than the ones in the diagram would refute the revised Elliott program.

5. Tracial von Neumann algebras

Many of the pathologies that plague (or enrich, depending on the point of view) the theory of C*-algebras are not present in von Neumann algebras.

By a result of McDuff, the relative commutant of a II_1 factor in its ultrapower is trivial, nontrivial and abelian, or the factor tensorially absorbs R (see Proposition 6.1). Each of these three classes is nonempty, and there is presently no other known method for distinguishing theories of II_1 factors (see [37]).

The hyperfinite II_1 factor R is a canonical object and every embedding of R into a model of its theory is elementary (§4.5). However, there are embeddings between models of the theory of R that are not elementary (i.e., the theory of R is not *model-complete*), and in particular this theory does not allow the elimination of quantifiers [31, 51]. This may be an indication that we do not have the right language for the theory of II_1 factors. The obstruction for the elimination of quantifiers extracted in [31] from [56] is removed by adding a predicate for the unitary conjugacy relation. As this is a definable relation, adding such predicate

affects only syntactical structure of the language. It is not clear whether adding finitely, or even countably, many such predicates could make the theory of R model-complete. This may suggest that the theory of R is as complicated as the first-order arithmetic or ZFC.

Given a II_1 factor M and a projection p in M, are M and its corner pMp elementarily equivalent? By the Keisler–Shelah theorem, this is equivalent to asking whether these algebras have isomorphic ultrapowers. A positive answer would imply that all free group factors $L(F_n)$, for $n \geq 2$, are elementarily equivalent, giving a 'poor man's' solution to the well-known problem whether the free group factors are isomorphic (see [22]). On the other hand, a negative answer would provide a continuum of distinct theories of II_1 factors that are corners of $L(F_2)$. A deeper analysis of the model theory of II_1 factors is likely to involve Voiculescu's free probability.

In recent years theories of C*-algebras and von Neumann algebras are increasingly considered as inseparable. Some of the most exciting progress on understanding tracial C*-algebras was initiated in [68]. We shall return to this in §6.1, but see also [12].

6. Massive algebras I: Ultraproducts

We now consider algebras that are rarely nuclear and never separable, but are nevertheless indispensable tools in the study of separable nuclear algebras.

Ultraproducts emerged independently in logic and in functional analysis (more precisely, in the theory of II_1 factors) in the 1950's (see the introduction to [88]). If (A_n, d_n), for $n \in \mathbb{N}$, are bounded metric structures of the same signature and $\mathcal{U}$ is an ultrafilter on $\mathbb{N}$, then the *ultraproduct* $\prod_{\mathcal{U}} A_n$ is defined as follows. On the product structure $\prod_n A_n$ consider the quasi-metric

$$d_{\mathcal{U}}((a_n),(b_n)) = \lim_{n\to\mathcal{U}} d_n(a_n, b_n).$$

Since every function symbol f has a fixed modulus of uniform continuity, it defines a uniformly continuous function on the quotient metric structure $\prod_n A_n/\sim_{d_{\mathcal{U}}}$. This structure is the *ultraproduct* of A_n, for $n \in \mathbb{N}$, associated to the ultrafilter $\mathcal{U}$. It is denoted by $\prod_{\mathcal{U}} A_n$.

In the not necessarily bounded case one replaces $\prod_n A_n$ with $\{(a_n) \in \prod_n A_n : a_n$ belong to the same domain of quantification$\}$. With our conventions, in the operator algebra case this is the ℓ_∞-product usually denoted $\prod_n A_n$. The nontrivial fact that an ultrapower of tracial von Neumann algebras is a tracial von Neumann algebra is an immediate consequence of the axiomatizability.

The usefulness of ultraproducts draws its strength largely from two basic principles. The first one is *Łoś's theorem*, stating that for any formula $\phi(\bar{x})$ we have

$$\phi(\bar{a})^{\prod_{\mathcal{U}} A_n} = \lim_{n\to\mathcal{U}} \phi(\bar{a}_n)^{A_n}.$$

This in particular implies that the diagonal embedding of A into its ultrapower is elementary (§4.2), and therefore the theory is preserved by taking ultrapowers. The second principle will be discussed in §6.0.1.

This may be a good place to note two results in abstract model theory that carry over to the metric case [5]. A category $\mathbb{K}$ with an appropriately defined ultraproduct construction is closed under the elementary equivalence if and only if it is closed under isomorphisms, ultraproducts, and ultraroots (i.e., $A^{\mathcal{U}} \in \mathbb{K}$ implies $A \in \mathbb{K}$). By the Keisler–Shelah theorem, two models are elementarily equivalent if and only if they have isomorphic ultrapowers. Both results require considering ultrafilters on arbitrarily large sets (see [86]).

The fact that it is easier to prove that an ultraproduct of C*-algebras is a C*-algebras than that an ultraproduct of tracial von Neumann algebras is a tracial von Neumann algebra is reflected in the fact that it is easier to prove that the C*-algebras are axiomatizable than that the tracial von Neumann algebras are axiomatizable.

All ultrafilters considered here concentrate on $\mathbb{N}$ and are nonprincipal. It is not possible to construct such an ultrafilter in ZF alone, as a (rather weak) form of the Axiom of Choice is required for its construction. However, results about separable C*-algebras and separably acting II_1 factors proved using ultrafilters can be proved without appealing to the Axiom of Choice, by standard absoluteness arguments.

An ultrapower of an infinite-dimensional, simple, unital C*-algebra is by Łoś's theorem unital. It is, however, nonseparable, not nuclear, and it is simple only under exceptional circumstances. This shows that none of these three properties is axiomatizable (cf. Proposition 4.1). Nevertheless, separable, nuclear, unital and simple C*-algebras can be constructed by using the Henkin construction and omitting types theorem ([39], see §4.4).

6.0.1. Countable saturation. We define the second important property of massive algebras. If a type (see §4.4) is allowed to contain formulas with parameters from an algebra A we say that it is a type *over* A.

An algebra A is *countably saturated* if every countable type $\mathbf{t}(\bar{x})$ over A is realized in A if and only if it is consistent. (These algebras are sometimes said to be $\aleph_1$*-saturated*. The latter terminology is more conveniently extended to higher cardinalities.) Every ultrapower associated to a nonprincipal ultrafilter on $\mathbb{N}$ is countably saturated. A weakening of countable saturation suffices for many purposes (see §7), and we shall return to full saturation in §7.1.

6.1. Relative commutants. In the theory of operator algebras even more important than the ultrapower itself is the *relative commutant* of the algebra inside the ultrapower,

$$A' \cap A^{\mathcal{U}} = \{b \in A^{\mathcal{U}} : ab = ba \text{ for all } a \in A\}.$$

The current prominence of ultrapowers as a tool for studying separable algebras can be traced back to McDuff ([70]) and the following proposition (generalized to s.s.a. algebras in [92]).

Proposition 6.1. *If D is strongly self-absorbing and A is separable, then A is D-absorbing if and only if D embeds into $A' \cap A^{\mathcal{U}}$.*

The nontrivial, converse, implication uses the following (a lemma in model theory that I learned from Wilhelm Winter) proved using the intertwining argument.

Lemma 6.2. *If $A \subseteq B$ are separable metric structures and $B^{\mathcal{U}}$ has a sequence of isometric automorphisms α_n such that $\lim_n \alpha_n(a) = a$ for all $a \in A$ and $\lim_n \operatorname{dist}(\alpha_n(b), A) = 0$ for all $b \in B$, then A and B are isometrically isomorphic.*

Noting that all nonprincipal ultrafilters on $\mathbb{N}$ 'look the same' and in particular that the choice of $\mathcal{U}$ in Proposition 6.1 is irrelevant as long as it is a nonprincipal ultrafilter on $\mathbb{N}$, one may ask the following.

Question 6.3. *If M is a separable metric structure, does the isomorphism type of $M^{\mathcal{U}}$ (and $M' \cap M^{\mathcal{U}}$, if M is a Banach algebra) depend on $\mathcal{U}$ at all?*

If M is a Hilbert space or a measure algebra, then a simple argument (using Maharam's theorem in the latter case) gives a negative answer. Also, Continuum Hypothesis (CH) im-

plies negative answer to both questions for an arbitrary separable M (see §7.1). Therefore, the question is whether CH can be removed from this proof.

Question 6.3 for relative commutants was asked by McDuff [70] and Kirchberg ([61]) in the case of McDuff factors and C*-algebras, respectively. In [49] it was proved that, under some additional assumptions on M, CH is equivalent to the positive answer to either of these questions! This was achieved by using only results from classical ('discrete') model theory. By using the logic of metric structures and Shelah's non-structure theory, the full result was proved in [35] and [41].

Theorem 6.4. *Assume CH fails. If M is a separable C*-algebra or a McDuff factor with a separable predual, then M has $2^{2^{\aleph_0}}$ nonisomorphic ultrapowers and $2^{2^{\aleph_0}}$ nonisomorphic relative commutants associated to nonprincipal ultrafilters on $\mathbb{N}$.*

Let's zoom out a bit. A complete first-order theory $\mathbf{T}$ has the *order property* if there exist $n \geq 1$ and a $2n$-ary formula $\phi(\bar{x}, \bar{y})$ such that for every m there is a model $\mathfrak{M}$ of $\mathbf{T}$ which has a 'ϕ-chain' of length at least m. A *ϕ-chain* is a sequence $\bar{x}_i, \bar{y}_i$, for $i \leq m$, such that

$$\phi(\bar{x}_i, \bar{y}_j) = 0 \text{ if } i \leq j \text{ and } \phi(\bar{x}_i, \bar{y}_j) = 1 \text{ if } i > j.$$

This is the metric version of one of the important non-structural properties of theories in Shelah's stability theory ([85] and [35]). The theory of any infinite-dimensional C*-algebra and of any II_1 factor has the order property. This is proved by continuous functional calculus and by utilizing noncommutativity, respectively. However, the theories of abelian tracial von Neumann algebras do not have the order property, essentially by applying Maharam's theorem on measure algebras.

Theorem 6.5. *Suppose that A is a separable structure in a separable language.*

(1) *If the theory of A does not have the order property then all of its ultrapowers associated to nonprincipal ultrafilters on $\mathbb{N}$ are isomorphic.*

(2) *If the theory of A has the order property then the following are equivalent:*

   (a) *A has fewer than $2^{2^{\aleph_0}}$ nonisomorphic ultrapowers associated with nonprincipal ultrafilters on $\mathbb{N}$.*

   (b) *all ultrapowers of A associated to nonprincipal ultrafilters on $\mathbb{N}$ are isomorphic.*

   (c) *the Continuum Hypothesis holds.*

6.2. Model theory of the relative commutant. The notion of a relative commutant does not seem to have a useful generalization in the abstract model theory and its model-theoretic properties are still poorly understood.

While the structure of relative commutants of II_1 factors in their ultrapowers provides the only known method for distinguishing their theories, every infinite-dimensional separable C*-algebra has a nontrivial relative commutant in its ultrapower ([61], also [35]). The relative commutant of the Calkin algebra (§7) in its ultrapower is trivial [61] and the relative commutant of $\mathcal{B}(H)$ may or may not be trivial, depending on the choice of the ultrafilter [40].

It is not difficult to see that the existential theory of $A' \cap A^{\mathcal{U}}$ depends only on the theory of A. However, a result of [61] implies that there is a separable C*-algebra A elementarily

equivalent to $\mathcal{O}_2$ such that $A' \cap A^{\mathcal{U}}$ and $\mathcal{O}_2 \cap \mathcal{O}_2^{\mathcal{U}}$ have different $\forall\exists$-theories. (An $\forall\exists$-*sentence* is one of the form $\sup_{\bar{x}} \inf_{\bar{y}} \phi(\bar{x}, \bar{y})$ where ϕ is quantifier-free.) In the following all ultrafilters are nonprincipal ultrafilters on $\mathbb{N}$.

Proposition 6.6. *Assume A is a separable C*-algebra.*

(1) *For all $\mathcal{U}$ and $\mathcal{V}$, the algebras $A' \cap A^{\mathcal{U}}$ and $A' \cap A^{\mathcal{V}}$ are elementarily equivalent.*

(2) *For every separable $C \subseteq A' \cap A^{\mathcal{U}}$ we have $\mathrm{Th}_\exists(A' \cap C' \cap A^{\mathcal{U}}) = \mathrm{Th}_\exists(A' \cap A^{\mathcal{U}})$.*

(3) *If D is a separable unital subalgebra of $A' \cap A^{\mathcal{U}}$ then there are $\aleph_1$ commuting copies of D inside $A' \cap A^{\mathcal{U}}$.*

An entertaining proof of (1) can be given by using basic set theory. Collapse $2^{\aleph_0}$ to $\aleph_1$ without adding reals. Then $\mathcal{U}$ and $\mathcal{V}$ are still ultrafilters on $\mathbb{N}$ and one can use saturation to find an isomorphism between the ultrapowers that sends A to itself. The theories of two algebras are unchanged, and therefore by absoluteness the result follows. Clause (3) is an immediate consequence of (2) and it is a minor strengthening of a result in [61].

When A is not $\mathcal{Z}$-stable, the relative commutant of A can have characters even if it is simple ([62]). In the case when algebra A is nuclear and $\mathcal{Z}$-stable, $A' \cap A^{\mathcal{U}}$ inherits some properties from A. For example, each of the traces on $A' \cap A^{\mathcal{U}}$ extends to a trace on $A^{\mathcal{U}}$ by [68] (cf. Proposition 4.2). The relative commutants of s.s.a. algebras are well-understood; the following was proved in [33].

Proposition 6.7. *If D is a s.s.a. algebra and $\mathcal{U}$ is a nonprincipal ultrafilter on $\mathbb{N}$, then $D' \cap D^{\mathcal{U}}$ is an elementary submodel of $D^{\mathcal{U}}$. Moreover, CH implies that these two algebras are isomorphic.*

6.3. Expansions and traces. If a metric structure A is expanded by adding a new predicate τ, its ultrapower $A^{\mathcal{U}}$ expands to the ultrapower of the expanded structure $(A, \tau)^{\mathcal{U}}$ which still satisfies Łoś's theorem and is countably saturated.

If A is a unital tracial C*-algebra then its traces form a weak*-compact convex subset $T(A)$ of the dual unit ball. For $\tau \in T(A)$ denote the tracial von Neumann algebra associated with the τ-GNS representation (§2) by N_τ. If A is simple and infinite-dimensional and τ is an extremal trace then N_τ is a factor, and if A is in addition nuclear and separable then N_τ is isomorphic to the hyperfinite factor R. This is because A is nuclear if and only if its weak closure in every representation is an injective von Neumann algebra, and R is the only injective II_1 factor with a separable predual. The following was proved in [68] and improved to the present form in [62].

Proposition 6.8. *If A is separable and $\tau \in T(A)$, then the quotient map from $A' \cap A^{\mathcal{U}}$ to $N_\tau' \cap (N_\tau)^{\mathcal{U}}$ is surjective.*

If $b \in A^{\mathcal{U}}$ is such that its image is in the commutant of N_τ', then by countable saturation one finds a positive element c of norm 1 such that $\tau(c) = 0$ and $c(a_n b - b a_n) = (a_n b - b a_n)c = 0$ for all a_n in a fixed countable dense subset of A. The fact that the type of such c is consistent follows from the fact that the image of b is in N_τ'. Then $(1-c)b(1-c)$ is in $A' \cap A^{\mathcal{U}}$ and it has the same image under the quotient map as b.

Proposition 6.8 precipitated remarkable progress on understanding tracial C*-algebras, the most recent results of which are [69] and [82].

7. Massive algebras II: Coronas

Another class of massive C*-algebras (with no analogue in von Neumann algebras) has special relevance to the study of separable algebras. If A is a non-unital C*-algebra, the *multiplier algebra* of A, $M(A)$, is the noncommutative analogue of the Čech–Stone compactification of a locally compact Hausdroff space. It is the surjectively universal unital algebra containing A as an essential ideal. The *corona* (or *outer multiplier*) algebra of A is the quotient $M(A)/A$. Some examples of coronas are the Calkin algebra $\mathcal{Q}(H)$ (the corona of the algebra of compact operators) and the *asymptotic sequence algebra* $\ell_\infty(A)/c_0(A)$ for a unital A. The latter algebra, as well as the associated *central sequence algebra* $A' \cap \ell_\infty(A)/c_0(A)$ are sometimes used in classification of C*-algebras instead of the metamathematically heavier ultrapowers and the corresponding relative commutants. While Łoś's theorem miserably fails for the asymptotic sequence algebra, all coronas and corresponding relative commutants share some properties of countably saturated algebras. The simplest of these properties is being SAW*: for any two orthogonal separable subalgebras A and B of a corona there exists a positive element c such that $ca = a$ for all $a \in A$ and $cb = 0$ for all $b \in B$.

7.0.1. Quantifier-free saturation. An algebra C is *quantifier-free saturated* if every countable type over C consisting only of quantifier-free formulas is consistent if and only if it is realized in C. An algebra C is *countably degree-1 saturated* if every countable type over C consisting only of formulas of the form $\|p\|$, where p is a *-polynomial of degree 1, is consistent if and only if it is realized in C. A dummy variable argument shows that the degree-2 saturation is equivalent to quantifier-free saturation. By refining an argument introduced by Higson, the following was proved in [32].

Theorem 7.1. *If A is a corona of a separable non-unital C*-algebra, or a relative commutant of a separable subalgebra of such corona, then A is countably degree-1 saturated.*

A very interesting class of countable degree-1 saturated C*-algebras was isolated in [94].

7.0.2. A sampler of properties of countable degree-1 saturated algebras. Assume C is countably degree-1 saturated (the results below also apply to tracial von Neumann algebras, and in this case (1), (3) and (5) do not even require countable degree-1 saturation).

(1) C has SAW* as well as every other known countable separation property [32].

(2) A separable algebra A is isomorphic to a unital subalgebra of C if and only if $\mathrm{Th}_\exists(A) \subseteq \mathrm{Th}_\exists(C)$.

(3) A representation of a group Γ in A is a homomorphism $\pi\colon \Gamma \to (\mathrm{GL}(A), \cdot)$. It is *unitarizable* if there is an invertible $h \in A$ such that $h^{-1}\pi(g)h$ is a unitary for all $g \in \Gamma$. Conjecturally unitarizability of all uniformly bounded representations of a group Γ on $\mathcal{B}(H)$ is equivalent to the amenability of Γ (see [74]). If Γ is a countable amenable group, then every uniformly bounded representation π of Γ in C is unitarizable [17].

(4) C is not isomorphic to the tensor product of two infinite-dimensional algebras ([26] for the ultraproducts of II_1 factors and [50] for the general result). Therefore an ultrapower or a corona is never isomorphic to a nontrivial tensor product and the separability assumption is needed in Proposition 6.1.

(5) ('Discontinuous functional calculus.') If a is a normal operator, then by the *continuous functional calculus* for every continuous complex-valued function g on the spectrum,

$\mathrm{sp}(a)$, of a the naturally defined $g(a)$ belongs to the abelian algebra generated by a.

Proposition 7.2. *Assume C is countably degree-1 saturated and $B \subseteq \{a\}' \cap C$ is separable, $U \subseteq \mathrm{sp}(a)$ is open, and $g\colon U \to \mathbb{C}$ is a bounded continuous function. Then there exists $c \in C \cap C^*(B,a)'$ such that for every $f \in C_0(\mathrm{sp}(a))$ we have*

$$cf(a) = (gf)(a).$$

If moreover g is real-valued then c can be chosen to be self-adjoint.

The 'Second Splitting Lemma' ([10, Lemma 7.3]) is a special case of the above when C is the Calkin algebra, $a = h_0$ is self-adjoint, and the range of g is $\{0,1\}$.

7.0.3. Failure of saturation. While the asymptotic sequence algebras, as well as some abelian coronas, are fully countably saturated [42], this is not true for sufficiently noncommutative coronas. By a K-theoretic argument N. C. Phillips constructed two unital embeddings of the CAR algebra into the Calkin algebra $\mathcal{Q}(H)$ that are approximately unitarily equivalent, but not conjugate by a unitary ([32, §4]). This gives a countable quantifier-free type over $\mathcal{Q}(H)$ that is consistent but not realized. Even coronas of separable abelian C*-algebras provide a range of different saturation properties (see [42]).

7.1. Automorphisms. A metric model A is *saturated* if every type over A whose cardinality is smaller than the *density character* $\chi(A)$ of A (i.e., the smallest cardinality of a dense subset) which is consistent is realized in A. The Continuum Hypothesis (CH) implies that all countably saturated models of cardinality $2^{\aleph_0}$ are saturated. A transfinite back-and-forth argument shows that any two elementarily equivalent saturated models of the same density character are isomorphic and that a saturated model A has $2^{\chi(A)}$ automorphisms. By a counting argument, most of these automorphisms are outer and moreover nontrivial when 'trivial automorphism' is defined in any reasonable way; see [20] for a (lengthy) discussion. This explains the effectiveness of CH as a tool for resolving problems of a certain form. A deeper explanation is given in Woodin's celebrated Σ^2_1-absoluteness theorem (see [100]).

By the above, CH implies that an ultrapower $A^{\mathcal{U}}$ of a separable, infinite-dimensional algebra has automorphisms that do not lift to automorphisms of $\ell_\infty(A)$. Much deeper is a complementary series of results of Shelah, to the effect that if ZFC is consistent then so is the assertion that any isomorphism between ultraproducts of models with the strong independence property lifts to an isomorphism of the products of these models [87]. No continuous version of this result is known. One difficulty in taming ultrapowers is that the ultrafilter is not a definable object; in particular Shelah's results apply only to a carefully constructed ultrafilter in a specific model of ZFC.

Motivated by work on extension theory and a very concrete question about the unilateral shift, in [10] it was asked whether the Calkin algebra has outer automorphisms. Since the Calkin algebra is not countably saturated (§7.0.3) it took some time before such an automorphism was constructed using CH [73]. This is one of the most complicated known CH constructions, involving an intricate use of EE-theory to extend isomorphisms of direct limits of separable subalgebras. A simpler proof was given in [28, §1], and the method was further refined in [20]. Instead of following the usual back-and-forth construction in which isomorphisms between separable subalgebras are recursively extended, one uses CH to embed the first derived limit of an inverse system of abelian groups into the outer automorphism group.

Forcing axioms imply that the Calkin algebra has only inner automorphisms [28]. Conjecturally, for every non-unital separable C*-algebra the assertion that its corona has only (appropriately defined) 'trivial' automorphisms is independent of ZFC (see [20]). Even the abelian case of this conjecture is wide open [42].

The 'very concrete question' of Brown–Douglas–Fillmore alluded to two paragraphs ago is still wide open: Is there an automorphism of $\mathcal{Q}(H)$ that sends the image of the unilateral shift $\dot{s}$ to its adjoint? Fredholm index obstruction shows that such an automorphism cannot be inner. Since the nonexistence of outer automorphisms of $\mathcal{Q}(H)$ is relatively consistent with ZFC, so is a negative answer to the BDF question. Every known automorphism α of $\mathcal{Q}(H)$ in every model of ZFC has the property that its restriction to any separable subalgebra is implemented by a unitary. Both $\dot{s}$ and $\dot{s}^*$ are unitaries with full spectrum and no nontrivial roots. It is, however, not even known whether $\dot{s}$ and $\dot{s}^*$ have the same (parameter-free) type in $\mathcal{Q}(H)$; a positive answer would provide a strong motivation for the question of whether $\mathcal{Q}(H)$ is countably homogeneous.

7.2. Gaps. A *gap* in a semilattice $\mathcal{B}$ is a pair $\mathcal{A}$, $\mathcal{B}$ such that $a \wedge b = 0$ for all $a \in \mathcal{A}$ and all $b \in \mathcal{B}$ but there is no c such that $c \wedge a = a$ and $c \wedge b = 0$ for all $a \in \mathcal{A}$ and $b \in \mathcal{B}$. There are no countable gaps in a countably saturated Boolean algebra such as $\mathcal{P}(\mathbb{N})/\operatorname{Fin}$, the quotient of $\mathcal{P}(\mathbb{N})$ over the ideal Fin of finite sets. In 1908 Hausdorff constructed a gap in $\mathcal{P}(\mathbb{N})/\operatorname{Fin}$ with both of its sides of cardinality $\aleph_1$. Later Luzin constructed a family of $\aleph_1$ orthogonal elements in $\mathcal{P}(\mathbb{N})/\operatorname{Fin}$ such that any two of its disjoint uncountable subsets form a gap. It should be emphasized that both results were proved without using CH or any other additional set-theoretic axioms.

Hausdorff's and Luzin's results show that $\mathcal{P}(\mathbb{N})/\operatorname{Fin}$ is not more than countably saturated. In particular, if the Continuum Hypothesis fails then the obvious back-and-forth method for constructing automorphisms of $\mathcal{P}(\mathbb{N})/\operatorname{Fin}$ runs into difficulties after the first $\aleph_1$ stages. In one form or another, gaps were used as an obstruction to the existence of morphisms in several consistency results in analysis, notably as obstructions to extending a partial isomorphism ([84, §V], [21, 28]).

Two subalgebras A and B of an ambient algebra C form a *gap* if $ab = 0$ for all $a \in A$ and $b \in B$, but there is no positive element c such that $ca = a$ and $cb = 0$ for all $a \in A$ and all $b \in B$. The gap structure of $\mathcal{P}(\mathbb{N})/\operatorname{Fin}$ can be imported into the Calkin algebra, but the gap structure of the latter is also much richer [101].

However, the failure of higher saturation in coronas is also manifested in a genuinely noncommutative fashion. A countable family of commuting operators in a corona of a separable algebra can be lifted to a family of commuting operators if and only if this is true for each one of its finite subsets.

Proposition 7.3. *In $M_2(\ell_\infty/c_0)$ there exists a family of $\aleph_1$ orthogonal projections such that none of its uncountable subsets can be lifted to a commuting family of projections in $M_2(\ell_\infty)$.*

This was stated in [45] for the Calkin algebra in place of (barely noncommutative) $M_2(\ell_\infty/c_0)$, but the proof given there clearly gives the stronger result. The combinatorial essence for the proof of Proposition 7.3 echoes Luzin's original idea. One recursively constructs projections p_γ in $M_2(\ell_\infty)$ so that $p_\gamma p_{\gamma'}$ is compact but $\|[p_\gamma, p_{\gamma'}]\| > 1/4$ for all $\gamma \neq \gamma'$. Then the image this family in the corona is as required, as a counting argument shows that no uncountable subfamily can be simultaneously diagonalized.

Recall that every uniformly bounded representation of a countable amenable group in a countably degree-1 saturated algebra is unitarizable (Proposition 7.2). This is false for uncountable groups. This was proved in [17] and improved to the present form in [93] using Luzin's gap.

Proposition 7.4. *There is a uniformly bounded representation π of $\bigoplus_{\aleph_1}\mathbb{Z}/2\mathbb{Z}$ on $M_2(\ell_\infty/c_0)$ such that the restriction of π to a subgroup is unitarizable if and only if the subgroup is countable.*

The construction of Kadison–Kastler-near, but not isomorphic, nonseparable algebras in [16] involves what at the hindsight can be considered as a gap. It is not known whether there is a separable example (see [18] for several partial positive results).

8. Nonseparable algebras

Not surprisingly, the theory of nonseparable algebras hides surprises and problems not present in the separable case; see [95].

8.1. Nonseparable UHF algebras. Uniformly hyperfinite (UHF) algebras are defined as tensor products of full matrix algebras (§2.2). However, there are two other natural ways to define uniformly hyperfinite: as (i) an inductive limit of a net of full matrix algebras, or (ii) as an algebra in which every finite subset can be arbitrarily well approximated by a full matrix subalgebra. These three notions, given in the order of decreasing strength, coincide in the separable unital case. Dixmier asked whether separability is needed for this conclusion. The answer is that in every uncountable density character, UHF and (i) differ, but that one needs an algebra of density character $\aleph_2$ in order to distinguish between (i) and (ii) [38]. An extension of methods of [38] resulted in a nuclear, simple C*-algebra that has irreducible representations on both separable and nonseparable Hilbert space [27]. This is in contrast with the transitivity of the space of irreducible representations of a separable simple C*-algebra [63].

8.2. Representation theory. Representation theory of separable algebras has deeply affected development of the classical descriptive set theory, as evident from the terminology of both subjects (terms 'smooth' and 'analytic' have the same, albeit nonstandard in other areas of mathematics, meaning). Extension of the work of Glimm and Effros on representation theory combined with methods from logic initiated the abstract classification theory (§3). The representation theory of nonseparable algebras was largely abandoned because some of the central problems proved to be intractable (see the introduction to [1]). One of these stumbling blocks, *Naimark's problem*, was partially solved in [1] (see also [96]). By using a strengthening of CH (Jensen's $\diamondsuit_{\aleph_1}$ principle) and a deep result on representation theory of separable C*-algebras (an extension of [63] mentioned above), Akemann and Weaver constructed a C*-algebra that has a unique (up to spatial equivalence) irreducible representation on a Hilbert space, but is not isomorphic to the algebra of compact operators on any Hilbert space. An extension of [1] shows that $\diamondsuit_{\aleph_1}$ implies the existence of a simple C*-algebra with exactly m inequivalent irreducible representations. By a classical result of Glimm (closely related to the Glimm–Effros dichotomy), a simple separable C*-algebra with two inequivalent representations has $2^{\aleph_0}$ inequivalent representations. It is not known

whether a counterexample to Naimark's problem can be found in ZFC alone or by using an axiom other than $\diamondsuit_{\aleph_1}$ (such as $\diamondsuit_\kappa$ for $\kappa > \aleph_1$). The fact that every forcing notion that adds a new real number destroys all ground-model examples is a bit of an annoying teaser.

Cyclic representations of C*-algebras are, via the GNS construction (§2), in a natural bijective correspondence with their states (i.e., positive unital functionals). Pure (i.e., extremal) states are noncommutative versions of ultrafilters. The space of nonprincipal ultrafilters on $\mathbb{N}$, (along with the associated quotient structure $\mathcal{P}(\mathbb{N})/\operatorname{Fin}$) is arguably the most important set-theoretically malleable object known to man. The study of pure states on $\mathcal{B}(H)$ (i.e., 'quantized ultrafilters') has already produced some surprising results ([2, 7]; also see [66]).

8.3. Amenable operator algebras. A prominent open problem in the theory of operator algebras is whether every algebra of operators on a Hilbert space which is amenable is isomorphic to a C*-algebra. By using Proposition 7.4, one obtains the following [17, 93]).

Theorem 8.1. *There exists a nonseparable amenable subalgebra of $M_2(\ell_\infty)$ which is not isomorphic to a C*-algebra. None of its nonseparable amenable subalgebras is isomorphic to a C*-algebras, yet it is an inductive limit of separable subalgebras (even elementary submodels) each of which is isomorphic to a C*-algebra. Moreover, for every $\varepsilon > 0$ such an algebra can be found in an ε-Kadison–Kastler neighbourhood of a C*-algebra.*

The question whether there exists a separable counterexample remains open; see [65].

9. Concluding remarks

The most recent wave of applications of logic to operator algebras started by work of Nik Weaver and his coauthors, in which several long-standing problems were solved by using additional set-theoretic axioms (see [96]). Although we now know that the answers to some of those problems (such as the existence of outer automorphisms of the Calkin algebra) are independent from ZFC, statements of many prominent open problems in operator algebras are absolute between models of ZFC and therefore unlikely to be independent (see the appendix to [29] for a discussion).

Nevertheless, operator algebras do mix very well with logic. Jon Barwise said "As logicians, we do our subject a disservice by convincing others that the logic is first-order and then convincing them that almost none of the concepts of modern mathematics can really be captured in first-order logic." Remarkably, some of the deepest results on the structure of C*-algebras have equivalent formulation in the language of (metric) first-order logic (this applies e.g., to [97] and [98]).

In many of the developments presented here methods from logic were blended with highly nontrivial operator-algebraic methods. Good examples are the proof that the theory of R does not allow elimination of quantifiers [51] the key component of which comes from [13], the already mentioned use of [56], and blending of $\diamondsuit_{\aleph_1}$ with the transitivity of pure state space of separable simple algebras [63] in [1].

Finally, some results in pure logic were motivated by work on operator algebras. Examples are Theorem 6.5, which is new even for discrete structures, and negative and positive results on omitting types (§4.4).

Acknowledements. I am indebted to Bradd Hart, Isaac Goldbring, Aaron Tikuisis and Yemon Choi for a number of remarks on the first draft of the present paper that considerably improved it in many ways. This work was partially supported by NSERC.

Amalgamation functors and homology groups in model theory

John Goodrick, Byunghan Kim, and Alexei Kolesnikov

Abstract. We introduce the concept of an *amenable class of functors* and define homology groups for such classes. Amenable classes of functors arise naturally in model theory from considering types of independent systems of elements. Basic lemmas for computing these homology groups are established, and we discuss connections with type amalgamation properties.

Mathematics Subject Classification (2010). Primary 03C45; Secondary 55N35.

Keywords. Amalgamation functors, homology groups, model theory, Hurewicz correspondence, groupoids.

This paper abstracts the model theoretic results from [6] to a more general category-theoretic context. Namely, we introduce the concept of an *amenable class of functors*. It is a class of functors from a family of finite sets which is closed under subsets into a fixed image category satisfying a short list of axioms. We show that most of the general results proved in [6] hold in the broader *amenable* context. In addition we give some fundamental lemmas and examples which supplement the results of [6].

In Section 1, we introduce the notion of an amenable class of functors into a fixed category and we define the homology groups $H_n(\mathcal{A}, B)$ for an amenable class $\mathcal{A}$ and an object B in the image category. Model theory provides the best examples of amenable classes of functors, as described in [6].

In Section 2, given a rosy structure, we introduce the notion of the *type* homology groups, in contrast to the *set* homology groups defined in [6]. We show that the two homology groups are isomorphic.

Section 3 supplies some basic sufficient conditions for triviality of the homology groups and gives some additional examples of homology groups from model theory.

In Section 4 we outline some ongoing investigations related to our homology theory.

1. Simplicial homology in a category

In this section, we generalize the homology groups for rosy theories defined in [6] to a more general category-theoretic setting. Then we aim to provide a general framework for homology group computations. This section uses model theory only as a source of examples.

Proceedings of the International Congress of Mathematicians, Seoul, 2014

1.1. Basic definitions and facts. Throughout this section, $\mathcal{C}$ denotes a category. If s is a set, then we consider the power set $\mathcal{P}(s)$ of s to be a category with a single inclusion map $\iota_{u,v} : u \to v$ between any pair of subsets u and v with $u \subseteq v$. A subset $X \subseteq \mathcal{P}(s)$ is called *downward-closed* if whenever $u \subseteq v \in X$, then $u \in X$. In this case we consider X to be a full subcategory of $\mathcal{P}(s)$. An example of a downward-closed collection that we will use often below is $\mathcal{P}^-(s) := \mathcal{P}(s) \setminus \{s\}$. We use ω for the set of natural numbers.

We are interested in a family of functors $f : X \to \mathcal{C}$ for downward-closed subsets $X \subseteq \mathcal{P}(s)$ for various finite subset sets s of the set of natural numbers. For $u \subseteq v \in X$, we shall write $f^u_v := f(\iota_{u,v}) \in \mathrm{Mor}_{\mathcal{C}}(f(u), f(v))$. Before specifying the desirable closure properties of the collection $\mathcal{A}$ of such functors, we need some auxiliary definitions.

Definition 1.1.

(1) Let X be a downward closed subset of $\mathcal{P}(s)$ and let $t \in X$. The symbol $X|_t$ denotes the set $\{u \in \mathcal{P}(s \setminus t) \mid t \cup u \in X\} \subseteq X$.

(2) For s, t, and X as above, let $f : X \to \mathcal{C}$ be a functor. Then *the localization of f at t* is the functor $f|_t : X|_t \to \mathcal{C}$ such that

$$f|_t(u) = f(t \cup u)$$

and whenever $u \subseteq v \in X|_t$,

$$(f|_t)^u_v = f^{u \cup t}_{v \cup t}.$$

(3) Let $X \subset \mathcal{P}(s)$ and $Y \subset \mathcal{P}(t)$ be downward closed subsets, where s and t are finite sets of natural numbers. Let $f : X \to \mathcal{C}$ and $g : Y \to \mathcal{C}$ be functors.

We say that f and g are *isomorphic* if there is an order-preserving bijection $\sigma : s \to t$ with $Y = \{\sigma(u) : u \in X\}$ and a family of isomorphisms $\langle h_u : f(u) \to g(\sigma(u)) : u \in X\rangle$ in $\mathcal{C}$ such that for any $u \subseteq v \in X$, the following diagram commutes:

$$\begin{array}{ccc} f(u) & \xrightarrow{h_u} & g(\sigma(u)) \\ \downarrow{\scriptstyle f^u_v} & & \downarrow{\scriptstyle g^{\sigma(u)}_{\sigma(v)}} \\ f(v) & \xrightarrow{h_v} & g(\sigma(v)) \end{array}$$

In the definition if σ is an arbitrary bijection, then f and g are said to be *weakly isomorphic*.

Remark 1.2. If X is a downward closed subset of $\mathcal{P}(s)$ and $t \in X$, then $X|_t$ is a downward closed subset of $\mathcal{P}(s \setminus t)$. Moreover $X|_t$ does not depend on the choice of s.

Definition 1.3. Let $\mathcal{A}$ be a non-empty set of functors $f : X \to \mathcal{C}$ such that $X \subseteq \mathcal{P}(\omega)$ is finite and downward closed and $\mathcal{C}$ is a fixed category (called the *image category of* $\mathcal{A}$). We say that $\mathcal{A}$ is *amenable* if it satisfies all of the following properties:

(1) (Invariance under weak isomorphisms) If $f : X \to \mathcal{C}$ is in $\mathcal{A}$ and $g : Y \to \mathcal{C}$ is weakly isomorphic to f, then $g \in \mathcal{A}$.

(2) (Closure under restrictions and unions) If $X \subseteq \mathcal{P}(s)$ is downward-closed and $f : X \to \mathcal{C}$ is a functor, then $f \in \mathcal{A}$ if and only if for every $u \in X$, we have that $f \restriction \mathcal{P}(u) \in \mathcal{A}$.

(3) (Closure under localizations) Suppose that $f : X \to \mathcal{C}$ is in $\mathcal{A}$ for some $X \subseteq \mathcal{P}(s)$ and $t \in X$. Then $f|_t : X|_t \to \mathcal{C}$ is also in $\mathcal{A}$.

(4) (Extensions of localizations are localizations of extensions) Suppose that $f : X \to \mathcal{C}$ is in $\mathcal{A}$ and $t \in X \subseteq \mathcal{P}(s)$ is such that $X|_t = X \cap \mathcal{P}(s \setminus t)$. Suppose that the localization $f|_t : X \cap \mathcal{P}(s \setminus t) \to \mathcal{C}$ has an extension $g : Z \to \mathcal{C}$ in $\mathcal{A}$ for some $Z \subseteq \mathcal{P}(s \setminus t)$. Then there is a map $g_0 : Z_0 \to \mathcal{C}$ in $\mathcal{A}$ such that $Z_0 = \{u \cup v : u \in Z, v \subseteq t\}$, $f \subseteq g_0$, and $g_0|_t = g$.

Remark 1.4. Model theory supplies the best examples of the amenable collection of functors. For example, as in [6] we could take $\mathcal{C}$ to be all boundedly (or algebraically) closed subsets of the monster model of a first-order theory, and let $\mathcal{A}$ be all functors which are "independence-preserving" (in Hrushovski's terminology [11]) and such that every face $f(u)$ is the bounded (or algebraic) closure of its vertices; then $\mathcal{A}$ is amenable. We may further restrict $\mathcal{A}$ by requiring, for instance, that all the "vertices" $f(\{i\})$ of functors $f \in \mathcal{A}$ realize the same type, or by placing further restrictions on "edges" $f(\{i, j\})$ and other higher-dimensional faces. We can also take $\mathcal{C}$ to be a category of *types* of the closed subsets of the model. These examples will be explained more precisely in Section 2.

Definition 1.5. Suppose that $f : X \to \mathcal{C}$ is a functor from a downward-closed collection X of sets and $B \in \mathrm{Ob}(\mathcal{C})$. If $f(\emptyset) = B$ then we say that f *is over* B. Let $\mathcal{A}_B$ denote the set of all functors $f \in \mathcal{A}$ that are over B.

Remark 1.6. It is easy to see that condition (2) in Definition 1.3 is equivalent to the conjunction of the following two conditions:

(1) (Closure under restrictions) If $f : X \to \mathcal{C}$ is in $\mathcal{A}$ and $Y \subseteq X$ with Y downward-closed, then $f \restriction Y$ is also in $\mathcal{A}$.

(2) (Closure under unions) Suppose that $f : X \to \mathcal{C}$ and $g : Y \to \mathcal{C}$ are both in $\mathcal{A}$ and that $f \restriction X \cap Y = g \restriction X \cap Y$. Then the union $f \cup g : X \cup Y \to \mathcal{C}$ is also in $\mathcal{A}$.

For instance, if these two conditions are true and $f : X \to \mathcal{C}$ is a functor from a downward-closed set X such that $f \restriction \mathcal{P}(u) \in \mathcal{A}$ for every $u \in X$, then if $u_1, \ldots, u_n$ are maximal sets in X, we can use closure under unions $(n-1)$ times to see that $f \in \mathcal{A}$ (since it is the union of the functors $f \restriction \mathcal{P}(u_i)$).

For the remainder of this section, we fix a category $\mathcal{C}$ and a non-empty amenable collection $\mathcal{A}$ of functors mapping into $\mathcal{C}$. As we mentioned in the above remark, every functor in $\mathcal{A}$ can be described as the union of functors whose domains are $\mathcal{P}(s)$ for various finite sets s. Such functors will play a central role in this paper.

Definition 1.7. Let $n \geq 0$ be a natural number. A (*regular*) n*-simplex in* $\mathcal{C}$ is a functor $f : \mathcal{P}(s) \to \mathcal{C}$ for some set $s \subseteq \omega$ with $|s| = n + 1$. The set s is called the *support of* f, or $\mathrm{supp}(f)$.

Let $S_n(\mathcal{A}; B)$ denote the collection of all regular n-simplices in $\mathcal{A}_B$. Then let $S(\mathcal{A}; B) := \bigcup_n S_n(\mathcal{A}; B)$ and $S(\mathcal{A}) := \bigcup_{B \in \mathrm{Ob}(\mathcal{C})} S(\mathcal{A}; B)$.

Let $C_n(\mathcal{A}; B)$ denote the free abelian group generated by $S_n(\mathcal{A}; B)$; its elements are called n*-chains in* $\mathcal{A}_B$, or n*-chains over* B. Similarly, we define $C(\mathcal{A}; B) := \bigcup_n C_n(\mathcal{A}; B)$ and $C(\mathcal{A}) := \bigcup_{B \in \mathrm{Ob}(\mathcal{C})} C(\mathcal{A}; B)$. The *support of a chain* c is the union of the supports of all the simplices that appear in c with a non-zero coefficient.

The adjective "regular" in the definition above is to emphasize that none of our simplices are "degenerate:" their domains must be *strictly* linearly ordered. It is more usual to allow for degenerate simplices, but for our purposes, this extra generality does not seem to be useful. Since all of our simplices will be regular, we will omit the word "regular" in what follows.

Now the rest of the development of the homology theory in this section will be exactly the same as the particular case of model theory described in the first section of [6]. The proofs are exactly the same and the reader will notice that the list of axioms for amenable family of functors singles out basic technical properties which enable the arguments in section 1 of [6] work. For the sake of completeness, we list here the all the definitions, lemmas, and theorems we will need for later sections but without giving proofs.

We begin with the notion of boundary operators used to define homology groups in our context.

Definition 1.8. If $n \geq 1$ and $0 \leq i \leq n$, then the *ith boundary operator* $\partial_n^i : C_n(\mathcal{A}; B) \to C_{n-1}(\mathcal{A}; B)$ is defined so that if f is an n-simplex with support $s = \{s_0 < \cdots < s_n\}$, then

$$\partial_n^i(f) = f \restriction \mathcal{P}(s \setminus \{s_i\})$$

and extended linearly to a group map on all of $C_n(\mathcal{A}; B)$.

If $n \geq 1$ and $0 \leq i \leq n$, then the *boundary map* $\partial_n : C_n(\mathcal{A}; B) \to C_{n-1}(\mathcal{A}; B)$ is defined by the rule

$$\partial_n(c) = \sum_{0 \leq i \leq n} (-1)^i \partial_n^i(c).$$

We write ∂^i and ∂ for ∂_n^i and ∂_n, respectively, if n is clear from context.

Definition 1.9. The kernel of ∂_n is denoted $Z_n(\mathcal{A}; B)$, and its elements are called $(n$-*)cycles*. The image of ∂_{n+1} in $C_n(\mathcal{A}; B)$ is denoted $B_n(\mathcal{A}; B)$. The elements of $B_n(\mathcal{A}; B)$ are called $(n$-*)boundaries*.

It can be shown (by the usual combinatorial argument) that $B_n(\mathcal{A}; B) \subseteq Z_n(\mathcal{A}; B)$, or more briefly, "$\partial_n \circ \partial_{n+1} = 0$." Therefore we can define simplicial homology groups relative to $\mathcal{A}$:

Definition 1.10. The *nth* (*simplicial*) *homology group of* $\mathcal{A}$ *over* B is

$$H_n(\mathcal{A}; B) = Z_n(\mathcal{A}; B)/B_n(\mathcal{A}; B).$$

There are two natural candidates for the definition of the boundary of a 0-simplex. One possibility is to define $\partial_0(f) = 0$ for all $f \in S_0(\mathcal{A}; B)$. Another possibility is to extend the definition of an n-simplex to $n = -1$; namely a (-1)-simplex f is an object $f(\emptyset)$ in $\mathcal{C}$. Then the definition of a boundary operator extends naturally to the operator $\partial_0 : f \in S_0(\mathcal{A}; B) \mapsto B$.

As we show in Lemma 3.1, computing the group H_0 in a specific context using the first definition gives $H_0 \cong \mathbb{Z}$ while using the second definition we get $H_0 = 0$. Thus, the difference between the approaches is parallel to that between the homology and reduced homology groups in algebraic topology [1].

Next we define the amalgamation properties. We use the convention that n denotes the set $\{0, 1, \ldots, n-1\}$.

Definition 1.11. Let $\mathcal{A}$ be an amenable family of functors into a category $\mathcal{C}$ and let $n \geq 1$.

(1) $\mathcal{A}$ has *n-amalgamation* if for any functor $f : \mathcal{P}^-(n) \to \mathcal{C}$, $f \in \mathcal{A}$, there is an $(n-1)$-simplex $g \supseteq f$ such that $g \in \mathcal{A}$.

(2) $\mathcal{A}$ has *n-complete amalgamation* or *n-CA* if $\mathcal{A}$ has k-amalgamation for every k with $1 \leq k \leq n$.

(3) $\mathcal{A}$ has *strong 2-amalgamation* if whenever $f : \mathcal{P}(s) \to \mathcal{C}$, $g : \mathcal{P}(t) \to \mathcal{C}$ are simplices in $\mathcal{A}$ and $f \restriction \mathcal{P}(s \cap t) = g \restriction \mathcal{P}(s \cap t)$, then $f \cup g$ can be extended to a simplex $h : \mathcal{P}(s \cup t) \to \mathcal{C}$ in $\mathcal{A}$.

(4) $\mathcal{A}$ has *n-uniqueness* if for any functor $f : \mathcal{P}^-(n) \to \mathcal{C}$ in $\mathcal{A}$ and any two $(n-1)$-simplices g_1 and g_2 in $\mathcal{A}$ extending f, there is a natural isomorphism $F : g_1 \to g_2$ such that $F \restriction \mathrm{dom}(f)$ is the identity.

Remark 1.12.

(1) There is a mismatch that n-amalgamation refers to the existence of $(n-1)$-simplex extending its boundary. But this numbering is coherent with historical developments of amalgamation theory in model theory and homology theory in algebraic topology.

(2) The definition of n-amalgamation can be naturally extended to $n = 0$: $\mathcal{A}$ has 0-amalgamation if it contains a functor $f : \{\emptyset\} \to \mathcal{C}$. This holds in any amenable family of functors.

Definition 1.13. We say that an amenable family of functors $\mathcal{A}$ is *non-trivial* if $\mathcal{A}$ has 1-amalgamation, and satisfies the strong 2-amalgamation property.

The following remark is immediate from the definitions.

Remark 1.14. Any non-trivial amenable collection of functors $\mathcal{A}$ contains an n-simplex for each $n \geq 1$.

Everywhere below, we only deal with non-trivial amenable families of functors.

1.2. Computing homology groups. As in [6] we introduce special kinds of n-chains which are useful for computing homology groups.

Definition 1.15. If $n \geq 1$, an *n-shell* is an n-chain c of the form

$$\pm \sum_{0 \leq i \leq n+1} (-1)^i f_i,$$

where $f_0, \ldots, f_{n+1}$ are n-simplices such that whenever $0 \leq i < j \leq n+1$, we have $\partial^i f_j = \partial^{j-1} f_i$.

Definition 1.16. If $n \geq 1$, and *n-fan* is an n-chain of the form

$$\pm \sum_{i \in \{0,..,\widehat{k},\ldots,n+1\}} (-1)^i f_i$$

for some $k \leq n+1$, where the f_i are n-simplices such that whenever $0 \leq i < j \leq n$, we have $\partial^i f_j = \partial^{j-1} f_i$. In other words, an n-fan is an n-shell missing one term.

If c is an n-fan, then ∂c is an $(n-1)$-shell; and $\mathcal{A}$ has n-amalgamation if and only if every $(n-2)$-shell in $\mathcal{A}$ is the boundary of an $(n-1)$-simplex in $\mathcal{A}$. And $\mathcal{A}$ has n-uniqueness if and only if every $(n-2)$-shell in $\mathcal{A}$ is the boundary of at most one $(n-1)$-simplex in $\mathcal{A}$ up to isomorphism.

As mentioned earlier, we now state without proofs a series of lemmas and theorems analogous to those in [6], Section 1. In particular, we state two "prism lemmas" (1.25 and 1.27) and a result that every element of a homology group is the equivalence class of a shell (Theorem 1.28).

Lemma 1.17. *If $n \geq 2$ and $\mathcal{A}$ has n-CA, then every $(n-1)$-cycle is a sum of $(n-1)$-shells. Namely, for each $c \in Z_{n-1}(\mathcal{A}; B)$, $c = \sum_i \alpha_i f_i$, there is a finite collection of $(n-1)$-shells $c_i \in Z_{n-1}(\mathcal{A}; B)$ such that $c = \sum_i (-1)^n \alpha_i c_i$.*

Moreover, if S is the support of the chain c and m is any element not in S, then we can choose $\sum_i \alpha_i c_i$ so that its support is $S \cup \{m\}$.

Corollary 1.18. *Assume $\mathcal{A}$ has n-CA for some $n \geq 2$. Then $H_{n-1}(\mathcal{A}; B)$ is generated by*

$$\{[c] \,:\, c \text{ is an } (n-1)\text{-shell over } B\}.$$

In particular, if any $(n-1)$-shell over B is a boundary, then so is any $(n-1)$-cycle.

Corollary 1.19. *If $\mathcal{A}$ has n-CA for some $n \geq 3$, then $H_{n-2}(\mathcal{A}; B) = 0$.*

Corollary 1.18 will be strengthened to Theorem 1.28.

Definition 1.20. If $n \geq 1$, an *n-pocket* is an n-cycle of the form $f - g$, where f and g are n-simplices with support S (where S is an $(n+1)$-element set).

Lemma 1.21. *Suppose that $f, g \in S_n(\mathcal{A})$ are* isomorphic *functors such that $\partial_n f = \partial_n g$. Then the n-pocket $f - g$ is a boundary.*

Lemma 1.22. *Suppose that $n \geq 1$ and $\mathcal{A}$ has $(n+1)$-amalgamation. Then for any n-fan*

$$g = \pm \sum_{i \in \{0,\ldots,\widehat{k},\ldots,n+1\}} (-1)^i f_i$$

there is some n-simplex f_k and some $(n+1)$-simplex f such that $g + (-1)^k f_k = \partial f$.

The next lemma says that n-pockets are equal to n-shells, "up to a boundary."

Lemma 1.23. *Assume that $\mathcal{A}$ has the $(n+1)$-amalgamation property for some $n \geq 1$. For any $B \in \mathcal{C}$, any n-shell in $\mathcal{A}_B$ with support $n+2$ is equivalent, up to a boundary in $B_n(\mathcal{A}; B)$, to an n-pocket in $\mathcal{A}_B$ with support $n+1$. Conversely, any n-pocket with support $n+1$ is equivalent, up to a boundary, to an n-shell with support $n+2$.*

From Corollary 1.18 and Lemma 1.23 we derive the following:

Corollary 1.24. *If $\mathcal{A}$ has 3-amalgamation, then $H_2(\mathcal{A}; B)$ is generated by equivalence classes of 2-pockets.*

Lemma 1.25 (Prism lemma). *Let $n \geq 1$. Suppose that $\mathcal{A}$ has $(n+1)$-amalgamation. Let $f - f'$ be an n-pocket in $\mathcal{A}_B$ with support s, where $|s| = n+1$. Let t be an $(n+1)$-element set disjoint from s. Then given n-simplex g in $\mathcal{A}_B$ with the domain $\mathcal{P}(t)$, there is an n-simplex g' such that $g - g'$ forms an n-pocket in $\mathcal{A}_B$ and is equivalent, modulo $B_n(\mathcal{A}; B)$, to the pocket $f - f'$. We may choose g' first and then find g to have the same conclusion.*

Corollary 1.26. *Let $n \geq 1$. Suppose $\mathcal{A}$ has $(n+1)$-CA. The group $H_n(\mathcal{A}; B)$ is generated by equivalence classes n-shells with support $n+2$.*

We have a shell version of the prism lemma as well:

Lemma 1.27 (Prism lemma, shell version). *Let $\mathcal{A}$ satisfy $(n+1)$-amalgamation for some $n \geq 1$. Suppose that an n-shell $f := \sum_{0 \leq i \leq n+1} (-1)^i f_i$ and an n-fan*

$$g^- := \sum_{i \in \{0,\ldots,\hat{k},\ldots,n+1\}} (-1)^i g_i$$

are given, where f_i, g_i are n-simplices over B, $\text{supp}(f) = s$ with $|s| = n+2$, and $\text{supp}(g^-) = t = \{t_0, ..., t_{n+1}\}$, where $t_0 < ... < t_{n+1}$ and $s \cap t = \emptyset$. Then there is an n-simplex g_k over B with support $\partial_k t := t \setminus \{t_k\}$ such that $g := g^- + (-1)^k g_k$ is an n-shell over B and $f - g \in B_n(\mathcal{A}; B)$.

The next theorem gives an even simpler standard form for elements of $H_n(\mathcal{A}; B)$.

Theorem 1.28. *If $\mathcal{A}$ has $(n+1)$-CA for some $n \geq 1$, then*

$$H_n(\mathcal{A}; B) = \{[c] : c \text{ is an } n\text{-shell over } B \text{ with support } n+2\}.$$

Now using Theorem 1.28 and Lemma 1.23, we obtain the following:

Corollary 1.29. *If $(n+1)$-CA (for some $n \geq 1$) holds in $\mathcal{A}$, then*

$$H_n(\mathcal{A}; B) = \{[c] : c \text{ is an } n\text{-pocket in } \mathcal{A} \text{ over } B \text{ with support } n+1\}.$$

2. Type versus set homology groups in model theory

In this section, we define some amenable classes of functors that arise in model theory. Namely given either a complete rosy theory T or a complete type $p \in S(A)$ in a rosy theory, we will define both the "type homology groups" $H_n^t(T)$ (or $H_n^t(p)$) and the "set homology groups" $H_n^{set}(T)$ (or $H_n^{set}(p)$). As noted, $H_n^{set}(p)$ and the classes of p-set-functors were already introduced in [6] and the properties of those were the motivation for Definition 1.3. As we show below, these definitions will lead to isomorphic homology groups (Proposition 2.12).

We make the same assumptions on our underlying theory T as in [6]: **in what follows, we assume that $T = T^{\text{eq}}$ is a complete rosy theory** (e.g. stable, simple, or o-minimal) and we work in its fixed large saturated model $\mathfrak{C} = \mathfrak{C}^{\text{eq}}$. The reason for this is so that we have a nice independence notion [3]. Throughout, "$\downarrow$", "independence" or "non-forking" will mean thorn-independence. So if T is simple then we assume it has elimination of hyperimaginaries in order for non-forking independence to be equal to thorn-independence [3]. But the assumptions are for convenience not for full generality. For example if T is simple, then one may assume the independence is usual non-forking in $\mathfrak{C}^{\text{heq}}$ while replacing acl by bdd and so on. Moreover there are non-rosy examples having suitable independence notions that fit in our amenable category context (see [10] and [13]).

We refer the reader to [12, 20] and to [3, 18] for general background on simple and rosy theories, respectively.

2.1. Type homology. We will work with $*$-types – that is, types with possibly infinite sets of variables – and to avoid some technical issues, we will place an absolute bound on the cardinality of the variable sets of the types we consider. Fix some infinite cardinal $\kappa_0 \geq |T|$. We will assume that every $*$-type has no more than κ_0 free variables. We also fix a set $\mathcal{V}$ of variables such that $|\mathcal{V}| > \kappa_0$ and assume that all variables in $*$-types come from the set $\mathcal{V}$ (which is a "master set of variables.") We work in a monster model $\mathfrak{C} = \mathfrak{C}^{\text{eq}}$ which is saturated in some cardinality greater than $2^{|\mathcal{V}|}$. We let $\bar{\kappa} = |\mathfrak{C}|$. As we will see in the next section, the precise values of κ_0 and $|\mathcal{V}|$ will not affect the homology groups.

Given a set A, strictly speaking we should write "**a** complete $*$-type of A" instead of "**the** complete $*$-type of A" – there are different such types corresponding to different choices for associating each element of A with a variable from $\mathcal{V}$, and this distinction is crucial for our purposes.

If X is any subset of the variable set $\mathcal{V}$, $\sigma : X \to \mathcal{V}$ is any injective function, and $p(\overline{x})$ is any $*$-type such that $\overline{x}$ is contained in X, then we let

$$\sigma_* p = \{\varphi(\sigma(\overline{x})) : \varphi(\overline{x}) \in p\}.$$

Definition 2.1. If A is a small subset of the monster model, then $\mathcal{T}_A$ is the category such that

(1) The objects of $\mathcal{T}_A$ are are all the complete $*$-types in T over A, including (for convenience) a single distinguished type $p_\emptyset$ with no free variables;

(2) $\text{Mor}_{\mathcal{T}_A}(p(\overline{x}), q(\overline{y}))$ is the set of all injective maps $\sigma : \overline{x} \to \overline{y}$ such that $\sigma_*(p) \subseteq q$.

Note that this definition gives a notion of two types $p(\overline{x})$ and $q(\overline{y})$ being "isomorphic:" namely, that q can be obtained from p by relabeling variables.

Definition 2.2. If $A = \text{acl}(A)$ is a small subset of the monster model, a *closed independent type-functor based on* A is a functor $f : X \to \mathcal{T}_A$ such that:

(1) X is a downward-closed subset of $\mathcal{P}(s)$ for some finite $s \subseteq \omega$.

(2) Suppose $w \in X$ and $u, v \subseteq w$. Recall our notational convention $f^u_w := f(\iota_{u,w})$. Let us write $\overline{x}_w$ to be the variable set of $f(w)$. Then whenever $\overline{a}$ realizes the type $f(w)$ and $\overline{a}_u$, $\overline{a}_v$, and $\overline{a}_{u\cap v}$ denote subtuples corresponding to the variable sets $f^u_w(\overline{x}_u)$, $f^v_w(\overline{x}_v)$, and $f^{u\cap v}_w(\overline{x}_{u\cap v})$, then

$$\overline{a}_u \underset{A \cup \overline{a}_{u\cap v}}{\downarrow} \overline{a}_v.$$

(3) For all non-empty $u \in X$ and any $\overline{a}$ realizing $f(u)$, we have (using the notation above) $\overline{a} = \text{acl}\left(A \cup \bigcup_{i\in u} \overline{a}_{\{i\}}\right)$.

(The adjective "closed" in the definition refers to the fact that, by (3), all the types $f(u)$ are $*$-types of algebraically closed tuples.)

Let $\mathcal{A}^t(T; A)$ denote all closed independent type-functors based on A.

Remark 2.3. It follows from the definition above and the basic properties of nonforking that if f is a closed independent type-functor based on A and $u \in \text{dom}(f)$ is a non-empty set of size k, then any realization $\overline{a}$ of $f(u)$ is the algebraic closure of an AB-independent set $\{\overline{a}_1, \ldots, \overline{a}_k\}$, where B is the subtuple of $\overline{a}$ corresponding to the variables $f^\emptyset_u(\overline{x}_\emptyset)$ and each $\overline{a}_i$ is the subtuple corresponding to the variables in $f^{\{i\}}_u(\overline{x}_{\{i\}})$.

Definition 2.4. If $A = \mathrm{acl}(A)$ is a small subset of the monster model and $p \in S(A)$, then a *closed independent type-functor in* p is a closed independent type-functor $f : X \to \mathcal{T}_A$ based on A such that if $X \subseteq \mathcal{P}(s)$ and $i \in s$, then $f(\{i\})$ is the complete $*$-type of $\mathrm{acl}(AC \cup \{b\})$ over A, where C is some realization of $f(\emptyset)$ and b is some realization of a nonforking extension of p to AC.

Let $\mathcal{A}^t(p)$ denote all closed independent type-functors in p.

Now using the basic independence properties of rosy theories, it is not hard to verify amenability of the above families of functors. In particular one may consult the proof of [6, 1.19]

Proposition 2.5. *The sets $\mathcal{A}^t(T; A)$ and $\mathcal{A}^t(p)$ are non-trivial amenable families of functors.*

Definition 2.6. If A is a small algebraically closed subset of $\mathfrak{C}$, then we write $S_n\mathcal{T}_A$ as an abbreviation for $S_n(\mathcal{A}^t(T; A); p_\emptyset)$ (the collection of closed n-simplices in $\mathcal{A}^t(T; A)$ over the distinguished type $p_\emptyset$), $B_n\mathcal{T}_A$ and $Z_n\mathcal{T}_A$ for the boundary and cycle groups, and $H^t_n(T; A)$ for the homology group $H_n(\mathcal{A}^t(T; A); p_\emptyset)$.

Similarly if $p \in S(A)$, then we use the abbreviations $S_n\mathcal{T}(p)$ for $S_n(\mathcal{A}^t(p); p_\emptyset)$; and $B_n\mathcal{T}(p)$, $Z_n\mathcal{T}(p)$, and $H^t_n(p)$.

2.2. Set homology.

Definition 2.7. Let A be a small subset of $\mathfrak{C}$. By $\mathcal{C}_A$ we denote the category of all subsets *containing* A of $\mathfrak{C}$ of size no more that κ_0, where morphisms are partial elementary maps over A (that is, fixing A pointwise).

For a functor $f : X \to \mathcal{C}_A$ and $u \subseteq v \in X$, we write $f^u_v(u) := f^u_v(f(u)) \subseteq f(v)$.

Definition 2.8. A *closed independent set-functor based on* $A = \mathrm{acl}(A)$ is a functor $f : X \to \mathcal{C}_A$ such that:

(1) X is a downward-closed subset of $\mathcal{P}(s)$ for some finite $s \subseteq \omega$.

(2) For all non-empty $u \in X$, we have that $f(u) = \mathrm{acl}(A \cup \bigcup_{i\in u} f^{\{i\}}_u(\{i\}))$ and the set $\{f^{\{i\}}_u(\{i\}) : i \in u\}$ is independent over $f^\emptyset_u(\emptyset)$.

Let $\mathcal{A}^{set}(T; A)$ denote all closed independent set-functors based on A.

Now we recall the following in [6].

Definition 2.9. If $A = \mathrm{acl}(A)$ is a small subset of the monster model and $p \in S(A)$, then a *closed independent set-functor in* p is a closed independent set-functor $f : X \to \mathcal{C}_A$ based on A such that if $X \subseteq \mathcal{P}(s)$ and $i \in s$, then $f(\{i\})$ is a set of the form $\mathrm{acl}(C \cup \{b\})$ where $C = f^\emptyset_{\{i\}}(\emptyset) \supseteq A$ and b realizes some non-forking extension of p to C.

Let $\mathcal{A}^{set}(p)$ denote all closed independent set-functors in p.

Just as in the previous subsection, we have:

Proposition 2.10. *The sets $\mathcal{A}^{set}(T; A)$ and $\mathcal{A}^{set}(p)$ are non-trivial amenable families of functors.*

Definition 2.11. If A is a small subset of $\mathfrak{C}$, then we write $S_n\mathcal{C}_A$ to denote $S_n(\mathcal{A}^{set}(T;A);A)$ (the collection of closed n-simplices in $\mathcal{A}^{set}(T;A)$ *over* A), and similarly we write $B_n\mathcal{C}_A$ and $Z_n\mathcal{C}_A$ for the boundary and cycle groups over A, and use the notation $H_n^{set}(T;A)$ for the homology group $H_n(\mathcal{A}^{set}(T;A);A)$.

If $A = \mathrm{acl}(A)$ and $p \in S(A)$, then we use similar abbreviations

$$S_n\mathcal{C}(p) := S_n(\mathcal{A}^{set}(p);A), B_n\mathcal{C}(p), Z_n\mathcal{C}(p), \text{ and } H_n^{set}(p).$$

Proposition 2.12.

(1) *For any n and any set A, $H_n^t(T;A) \cong H_n^{set}(T;A)$.*

(2) *For any n and any complete type $p \in S(A)$, $H_n^t(p) \cong H_n^{set}(p)$.*

Proof. The idea is that we can build a correspondence $F : S\mathcal{C}_A \to S\mathcal{T}_A$ which maps each set-simplex f to its "complete $*$-type" $F(f)$. Note that this will involve some non-canonical choices: namely, which variables to use for $F(f)$, and in what order to enumerate the various sets in f (since our variable set $\mathcal{V}$ is indexed and thus implicitly ordered). We will write out a proof of part (1) of the proposition, and part (2) can be proved similarly by relativizing to p.

Let $S_{\leq n}\mathcal{C}_A$ and $S_{\leq n}\mathcal{T}_A$ denote, respectively, $\bigcup_{i\leq n} S_i\mathcal{C}_A$ and $\bigcup_{i\leq n} S_i\mathcal{T}_A$. We will build a sequence of maps $F_n : S_{\leq n}\mathcal{C}_A \to S_{\leq n}\mathcal{T}_A$ whose union will be F. Given such an F_n, let $\overline{F}_n : C_{\leq n}\mathcal{C}_A \to C_{\leq n}\mathcal{T}_A$ be its natural extension to the class of all set-k-chains over A for $k \leq n$.

Claim 2.13. *There are maps $F_n : S_{\leq n}\mathcal{C}_A \to S_{\leq n}\mathcal{T}_A$ such that:*

(1) *F_{n+1} is an extension of F_n;*

(2) *If $f \in S_{\leq n}\mathcal{C}_A$ and $\mathrm{dom}(f) = \mathcal{P}(s)$, then $\mathrm{dom}(F_n(f)) = \mathcal{P}(s)$ and $[F_n(f)](s)$ is a complete $*$-type of $f(s)$ over A;*

(3) *For any $k \leq n$, any $f \in S_k\mathcal{C}_A$, and any $i \leq k$, $F_n(\partial^i f) = \partial^i [F_n(f)]$; and*

(4) *F_n is surjective, and in fact for every $g \in S_k\mathcal{T}_A$ (where $0 \leq k \leq n$), there are **more** than $2^{|\mathcal{V}|}$ simplices $f \in S_k\mathcal{C}_A$ such that $F_n(f) = g$.*

Proof. We prove the claim by induction on n. The case where $n = 0$ is simple: only conditions (2) and (4) are relevant, and note that we can insure (4) because the monster model $\mathfrak{C}$ is $(2^{|\mathcal{V}|})^+$-saturated and there are at most $2^{|\mathcal{V}|}$ elements of $S_0\mathcal{T}_A$. So suppose that $n > 0$ and we have $F_0, \ldots, F_n$ satisfying all these properties, and we want to build F_{n+1}. We build F_{n+1} as a union of a chain of partial maps from $S_{\leq n+1}\mathcal{C}_A$ to $S_{\leq n+1}\mathcal{T}_A$ extending F_n (that is, functions whose domains are subsets of $S_{\leq n+1}\mathcal{C}_A$).

Subclaim 2.14. *Suppose that $F : X \to S_{\leq n+1}\mathcal{T}_A$ is a function on a set $X \subseteq S_{\leq n+1}\mathcal{C}_A$ of size at most $(2^{|\mathcal{V}|})^+$ and that F satisfies (1) through (3). Then for any simplex $g \in S_{n+1}\mathcal{T}_A$, there is an extension F_0 of F satisfying (1) through (3) such that $|\mathrm{dom}(F_0)| \leq (2^{|\mathcal{V}|})^+$ and:*

$$(*) \text{ There are } (2^{|\mathcal{V}|})^+ \text{ distinct } f \in S_{n+1}\mathcal{C}_A \text{ such that } F'(f) = g.$$

Proof. Let $\partial g = g_0 - g_1 + \ldots + (-1)^n g_n$ (where $g_i = \partial^i g$), and let $\mathcal{P}(s)$ be the domain of g. By induction, each g_i is the image under F_n of $(2^{|\mathcal{V}|})^+$ different n-simplices in $\mathcal{C}_A$; let $\langle f_i^j : j < (2^{|\mathcal{V}|})^+ \rangle$ be a sequence of distinct simplices such that for every $j < (2^{|\mathcal{V}|})^+$, $F_n(f_i^j) =$

g_i. By saturation of the monster model, for each $j < (2^{|\mathcal{V}|})^+$ we can pick an $(n+1)$-simplex $f_j \in \mathcal{C}_A$ with domain $\mathcal{P}(s)$ such that $\partial f_j = f_0^j - f_1^j + \ldots + (-1)^n f_n^j$ and $\mathrm{tp}(f_j(s)) = g(s)$. Then the f_j are all distinct, so we can let $F_0 = F \cup \{(f_j, g) : j < (2^{|\mathcal{V}|})^+\}$. □

Now by the subclaim, we can use transfinite induction to build a **partial** map $F' : S_{\leq n+1}\mathcal{C}_A \to S_{\leq n+1}\mathcal{T}_A$ satisfying (1) through (4) (also using the fact that there only (at most) $2^{|\mathcal{V}|}$ different simplices in $S_{n+1}\mathcal{T}_A$ and the fact that the union of a chain of partial maps from $S_{\leq n+1}\mathcal{C}_A$ to $S_{\leq n+1}\mathcal{T}_A$ satisfying conditions (2) and (3) will still satisfy these conditions).

Finally, we can extend F' to a function on all of $S_{\leq n+1}\mathcal{C}_A$ by a second transfinite induction, extending F' to each $f : \mathcal{P}(s) \to \mathcal{C}_A$ in $\mathcal{C}_A$ one at a time; to ensure that properties (2) and (3) hold, we just have to pick $F_{n+1}(f)$ to be some $(n+1)$-simplex with the same domain $\mathcal{P}(s)$ whose n-faces are as specified by F_n and such that $[F_{n+1}(f)](s)$ is a complete $*$-type of $f(s)$ over A. □

Now let $F = \bigcup_{n<\omega} F_n$. By property (3) above, it follows that for any chain $c \in C\mathcal{C}_A$, we have $\overline{F}(\partial c) = \partial\left[\overline{F}(c)\right]$. Hence $\overline{F}$ maps $Z_n\mathcal{C}_A$ into $Z_n\mathcal{T}_A$ and $B_n\mathcal{C}_A$ into $B_n\mathcal{T}_A$, and so $\overline{F}$ induces group homomorphisms $\varphi_n : H_n^{set}(T; A) \to H_n^t(T; A)$. Verifying that φ_n is injective amounts to checking that whenever $\overline{F}(c) \in B_n\mathcal{T}_A$, the set-chain c is in $B_n\mathcal{C}_A$, but this is staightforward: if, say, $\overline{F}(c) = \partial c'$, then we can pick a set-simplex $\hat{c}$ "realizing" c' such that $\partial\hat{c} = c$. Finally, condition (4) implies that φ_n is surjective, so $H_n^{set}(T; A) \cong H_n^t(T; A)$. □

Remark 2.15. Since Proposition 2.12 is true for any choices of κ_0, $\mathcal{V}$, and the monster model $\mathfrak{C}$ as long as $|T| \leq \kappa_0 < |\mathcal{V}|$ and $2^{|\mathcal{V}|} \leq |\mathfrak{C}|$, it follows that our homology groups (with the restriction of the set A) do not depend on the choices of κ_0, $|\mathcal{V}|$, or the monster model.

Without specifying a base set A, one could also define $C_n(T)$ to be the direct sum $\bigoplus_{i<\bar{\kappa}} C_n\mathcal{C}_{A_i}$ where $\{A_i | i < \bar{\kappa}\}$ is the collection of all small subsets of $\mathfrak{C}$, and similarly $Z_n(T)$, $B_n(T)$, and $H_n(T) := Z_n(T)/B_n(T)$. Then the boundary operator ∂ sends n-chains to $(n-1)$-chains componentwise. Hence it follows $H_n(T) = \bigoplus_{i<\bar{\kappa}} H_n(T; A_i)$. This means the homology groups defined without specifying a base set depends on the choice of monster model, and so this approach would not give invariants for the theory T.

2.3. An alternate definition of the set homology groups. In our definition of the set homology groups $H_n^{set}(T; A)$ and $H_n^{set}(p)$ (where $p \in S(A)$), we have been assuming that the base set A is fixed pointwise by all of the elementary maps in a set-simplex – this is built into our definition of $\mathcal{C}_A$. It will turn out that we get an equivalent definition of the homology groups if we allow the base set to be "moved" by the images of the inclusion maps in a set-simplex, as we will show in this subsection.

Definition 2.16.

(1) A *set-n-simplex weakly over A* is a set-n-simplex $f : \mathcal{P}(s) \to \mathcal{C}(= \mathcal{C}_\emptyset)$ such that $f(\emptyset) = A$.

(2) If $p \in S(A)$, then a set-n-simplex $f : \mathcal{P}(s) \to \mathcal{C}$ is *weakly of type p* if $f(\emptyset) = A$, and for every $i \in s$,

$$f(\{i\}) = \mathrm{acl}\left(f^\emptyset_{\{i\}}(A) \cup \{a_i\}\right)$$

for some a_i such that $\mathrm{tp}(a_i/f^{\emptyset}_{\{i\}}(A))$ is a conjugate of p.

Let $S'_n\mathcal{C}_A$ be the collection of all set-n-simplices weakly over A. Note that the boundary operator ∂ takes an n-simplex weakly over A to a chain of $(n-1)$-simplices weakly over A, and so we can define "weak set homology groups over A," which we denote $H'_n(T;A)$. Similarly, we can define $H'_n(p)$, the "weak set homology groups of p," from chains of set-simplices that are weakly of type p.

Proposition 2.17.

(1) *For any n and any $A \in \mathcal{C}$, $H'_n(T;A) \cong H^{set}_n(T;A)$.*

(2) *For any n and any complete type $p \in S(A)$, $H'_n(p) \cong H^{set}_n(p)$.*

Proof. As usual, the two parts have identical proofs, and we only prove the second part.

We will identify $S'_0\mathcal{C}_A$ as a big single *complex* as follows. Due to our cardinality assumption, for each $n < \omega$, there are $\bar{\kappa}$-many 0-simplices in $S'_0\mathcal{C}_A$ having the common domain $\mathcal{P}(\{n\})$. Then we consider the following domain set $\mathcal{D}_0 = \{\emptyset\} \cup \{\{(n,i)\} |\ n < \omega, i < \bar{\kappa}\}$. Now as said we identify $S'_0\mathcal{C}_A$ as a *single* functor F'_0 from $\mathcal{D}_0$ to $\mathcal{C}$ such that $F'_0(\emptyset) = A$, and $F'_0(\{(n,i)\}) = (f')^n_i(\{n\})$ where $(f')^n_i \in S'_0\mathcal{C}_A$ is the corresponding 0-simplex with $((f')^n_i)^{\emptyset}_{\{n\}} = (F'_0)^{\emptyset}_{\{(n,i)\}}$. Similarly we consider $S_0\mathcal{C}_A$ as a functor F_0 from $\mathcal{D}_0$ to $\mathcal{C}_A$ such that $F_0(\emptyset) = A$, and $F_0(\{(n,i)\}) = f^n_i(\{n\}) \equiv (f')^n_i(\{n\})$ where $f^n_i \in S_0\mathcal{C}_A$ is the corresponding 0-simplex over A with $(f^n_i)^{\emptyset}_{\{n\}} = (F_0)^{\emptyset}_{\{(n,i)\}}$. Now F'_0 and F_0 are naturally isomorphic by η^0 with $\eta^0_{\emptyset}$ =the identity map of A, and suitable $\eta^0_{\{(n,i)\}}$ sending $(f')^n_i(\{n\})$ to $f^n_i(\{n\})$.

Now for $S'_1\mathcal{C}_A$, note that for each pair $(f')^{n_0}_{i_0}, (f')^{n_1}_{i_1}$ with $n_0 < n_1$, there are $\bar{\kappa}$-many 1-simplices f'_j in $S'_1\mathcal{C}_A$ having the common domain $\mathcal{P}(\{n_0, n_1\})$ with $\partial^0 f'_j = (f')^{n_1}_{i_1}$ and $\partial^1 f'_j = (f')^{n_0}_{i_0}$. Hence we now put the domain set

$$\mathcal{D}_1 = \mathcal{D}_0 \cup \{\{(n_0,i_0),(n_1,i_1),j\} |\ n_0 < n_1 < \omega; i_0, i_1, j < \bar{\kappa}\}.$$

Then we identify $S'_1\mathcal{C}_A$ as a functor F'_1 from $\mathcal{D}_1$ to $\mathcal{C}$ such that $F'_1 \restriction \mathcal{D}_0 = F'_{01}$, and $F'_1(\{(n_0,i_0),(n_1,i_1),j\})$ corresponds jth 1-simplex having $(f')^{n_0}_{i_0}, (f')^{n_1}_{i_1}$ as 0-faces. Similarly we try to identify $S'_1\mathcal{C}_A$ as a functor F_1 from $\mathcal{D}_1$ to $\mathcal{C}_A$, extending F_0. But to make F'_1 and F_1 isomorphic, we need extra care when defining F_1. For each $j < \bar{\kappa}$ and a set $a'_j = f'_j(\{n_0, n_1\})$ of corresponding 1-simplex f'_j, assign an embedding $\eta^1_j = \eta^1_{\{(n_0,i_0),(n_1,i_1),j\}}$ sending a'_j to a_j, extending the inverse of $(f'_j)^{\emptyset}_{\{n_0,n_1\}}$. Then we define

$$F_1(\{(n_0,i_0),(n_1,i_1),j\}) = a'_j \text{ and } (F_1)^{\{(n_k,i_k)\}}_{\{(n_0,i_0),(n_1,i_1),j\}} = \eta^1_j \circ (f'_j)^{\{n_k\}}_{\{n_0,n_1\}} \circ (\eta^0_{\{(n_k,i_k)\}})^{-1}.$$

Now then clearly η^1 with $\eta^1 \restriction \mathcal{D}_0 = \eta^0$ is an isomorphism between F'_1 and F_1.

By iterating this argument we can respectively identify $S'_n\mathcal{C}_A$ and $S_n\mathcal{C}_A$, as functors F'_n and F_n having the same domain $\mathcal{D}_n$ extending $\mathcal{D}_1$. Moreover we can also construct an isomorphism η^n, extending η^1, between F'_n and F_n. Note that each $x \in \mathcal{D}_n - \mathcal{D}_{n-1}$ corresponds an n-simplex $f' \in S'_n\mathcal{C}$, and η^n_x corresponds an n-simplex over A $f \in S_n\mathcal{C}$. This correspondence $f' \mapsto f$ induces a bijection from $C'_n\mathcal{C}_A$ to $C_n\mathcal{C}_A$, mapping $c' \mapsto c$, which indeed is an isomorphism of the two groups. Notice that by the construction, if an n-shell c' is the boundary of some $(n+1)$-simplex f', then c is the boundary of f. In general, it follows $(\partial d)' = \partial d'$ (*). Thus this correspondence also induces an isomorphism between $Z'_n(T;A)$

and $Z_n(T;A)$. Moreover it follows from (*) that the correspondence sends $B'_n(T;A)$ to $B_n(T;A)$: Let $c' = \partial d' \in B'_n(T;A)$. Then by (*), we have $c = \partial d \in B_n(T;A)$. Conversely for $c' \in Z'_n(T;A)$, assume $c = \partial e \in B_n(T;A)$. Now for e', again by (*), $\partial e' = c'$. Hence we have $c' \in B'_n(T;A)$. □

3. Basic facts and examples

From now on, we will usually drop the superscripts t and set from $H^t_n(p)$ and $H^{set}_n(p)$ defined in Section 2, since these groups are isomorphic, and use "$H_n(p)$" to refer to the isomorphism class of these two groups. In computing the groups below, we generally use $H^{set}_n(p)$ rather than $H^t_n(p)$.

3.1. Computing H_0. In this subsection, we observe that H_0 does not give any information, since it is always isomorphic to $\mathbb{Z}$, if $\partial_0(f) = 0$ for any 0-simplex f; or is trivial if $\partial_0(f)$ is defined to be $f(\emptyset)$:

Lemma 3.1.

(1) *If $\partial_0(f) = 0$, then for any complete type p over an algebraically closed set A, $H_0(p) \cong \mathbb{Z}$ and for any small subset A of $\mathfrak{C}$, $H_0(T;A) \cong \mathbb{Z}$.*

(2) *If $\partial_0(f) = f(\emptyset)$, then both groups in (1) are trivial.*

Proof. Both parts of the lemma can be proved by essentially the same argument, so we only write out the proof for the group $H_0(p)$ in (1).

For the proof we will define an augmentation map ϵ as in topology. Since we can add parameters to the language for A, we can assume that $A = \emptyset$.

Define $\epsilon : C_0\mathcal{C}(p) \to \mathbb{Z}$ by $\epsilon(c) = \sum_i n_i$ for a 0-chain $c = \sum_i n_i f_i$ of type p. Then ϵ is a homomorphism such that $\epsilon(b) = 0$ for any 0-boundary b (since $\epsilon(\partial f) = 0$ for any 1-simplex f). Thus ϵ induces a homomorphism $\epsilon_* : H_0(p) \to \mathbb{Z}$. Note that *any* 0-chain c is in $Z_0(p)$, so clearly ϵ_* is onto. We claim that ϵ_* is one-to-one, i.e. $\ker \epsilon_* = B_0(p)$. Given a 0-chain $c = \sum_{i\in I} n_i f_i$ such that $\epsilon_*(c) = \sum_{i\in I} n_i = 0$, we shall show c is a boundary. Pick some natural number m greater than every k_i where $\operatorname{dom} f_i = \mathcal{P}(\{k_i\})$. Let $a_i = \operatorname{acl}(a_i) = f_i(\{k_i\})$. Then choose a realizing p such that $a \downarrow \{a_i : i \in I\}$. Now let g_i be a closed 1-simplex of p such that $\operatorname{dom} g_i = \mathcal{P}(\{k_i, m\})$, $g_i(\{k_i\}) = a_i$, and $g_i(\{m\}) = a$. Then $\partial g_i = c_m - f_i$, where c_m is the 0-simplex such that $c_m(\emptyset) = \emptyset$ and $c_m(\{m\}) = a$. Then $c + \partial(\sum_i n_i g_i) = \sum_i n_i f_i + \sum_i n_i(c_m - f_i) = (\sum_i n_i)c_m = 0$. Hence c is a 0-boundary, and $H_0(p) \cong \mathbb{Z}$. □

3.2. Amalgamation properties. The amalgamation properties in Definition 1.11 can be specialized to the context of model theory, yielding the usual notion of n-amalgamation (as in [11]).

Definition 3.2.

(1) If A is a small subset of $\mathfrak{C}$, then T has the *n-amalgamation property over* (*based on*, resp.) A if for every $(n-2)$-shell c *over* (*based on*, resp.) A, there is an $(n-1)$-simplex f such that $c = \partial f$.

(2) A complete type p has the *n-amalgamation* if any closed functor $f : \mathcal{P}^-(n) \to \mathcal{C}_A$ in p can be extended to an $(n-1)$-simplex.

(3) Similarly, "n-uniqueness" *over* A, *based on* A, or *of the type* p can be defined and so can be the notion of "n-CA".

Remark 3.3.

(1) Amalgamation properties *based on* A is equivalent to amalgamation properties *over* all $B \supseteq A$, which implies n-amalgamation for any type p. A stable theory has 4-amalgamation over any model M, as noted in [2]. However, it need not have 4-amalgamation based on M. For suppose that T is a stable theory in which there is a definable groupoid $\mathcal{G}$ which has unboundedly many connected components, each of which is not almost retractable (see [4]). Then if $M \models T$, a is the name of a connected component of $\mathcal{G}$ which does not intersect M (noting that these are equivalence classes which live in T^{eq}), and $B = \mathrm{acl}(Ma)$, then T does not have 4-amalgamation over the set B.

(2) Similarly, if p has n-amalgamation, then so does any non-forking extension, but the converse need not hold even in a stable theory; see Remark 1.8 of [6].

(3) As is well known, if T is simple then T has 3-CA; and if T is stable, then T has 2-uniqueness by stationarity. A non-simple rosy theory cannot have 3-amalgamation [16] but it may have n-amalgamation for all $n \geq 4$ (e.g. the theory of dense linear ordering).

Now we can restate Corollary 1.28 as:

Fact 3.4. *Assume T has n-CA based on $A = \mathrm{acl}(A)$ for $n \geq 2$. Then*

$$H_{n-1}(T; A) = \{[c] |\ c \text{ is an } (n-1)\text{-shell over } A \text{ with support } n+1\}.$$

and

$$H_{n-1}(p) = \{[c] |\ c \text{ is an } (n-1)\text{-shell of } p \text{ with support } n+1\}.$$

So it follows:

Fact 3.5. *Suppose $n \geq 3$.*

(1) *If T has n-CA based on $A = \mathrm{acl}(A)$, then $H_{n-2}(T; A) = 0$.*

(2) *If $p \in S(A)$ (where $A = \mathrm{acl}(A)$) has n-CA, then $H_{n-2}(p) = 0$.*

However, the converse of the above fact is false in general: the theory of the random tetrahedron-free hypergraph does not have 4-amalgamation, but all of its homology groups are trivial ([6, 1.32]).

Fact 3.6. *If T is simple, then $H_1(T; A) = 0$ and $H_1(p) = 0$ for any strong type p in T.*

The fact above is extended to any rosy theory in [14].

3.3. More examples. Homology groups of some examples are already given in [6, Section 1.2]. There $H_2(p)$ of a strong type p in a stable theory is computed too. In this subsection,

we compute some homology groups for o-minimal examples.

Example 3.7. Let p be the unique 1-type over $\emptyset$ in the theory T_{dlo} of dense linear ordering (without end points). Due to weak elimination of imaginaries it is a strong type. We show that $H_n(p) = 0$ for every $n \geq 1$, even though it does not have 3-amalgamation. It is not hard to see that p has n-amalgamation for all $n \neq 3$. Now we claim that, just like in Claim 1.33 in [5], any n-cycle is a sum of n-shells. The proof will be similar, and we use the same notation. We want to construct the edges h_{ij}. The trick this time is to take a^* greater than all the points of the form $a' = g_{ij}(\{k\})$. Then given any edge $\{b, c\} = g_{ij}(\{k, \ell\})$, where either $b < c$ or $c < b$, pick $a > b, c$. Then since $\mathrm{tp}(a'a^*) = \mathrm{tp}(ba) = \mathrm{tp}(ca)$, the construction of h_{ij} on this level is compatible. For the rest of the construction, use n-amalgamation.

Due to the claim and $(n + 2)$-amalgamation, all of the groups $H_n(p)$ are 0 for $n \neq 1$. Furthermore, $H_1(p) = 0$ because any 1-shell is the boundary of a 2-fan (choose a point greater than all the vertices of all the terms in the 1-shell).

Example 3.8. In [14], it is shown that for any strong type p in $\mathfrak{C}^{\mathrm{eq}}$ of a rosy theory, if it is a Lascar type too then $H_1(p) = 0$. But the reason for the triviality of $H_1(p)$ can be arbitrarily complicated. Here we argue that if p is a complete 1-type over $A = \mathrm{acl}(A)$ in the home sort of an o-minimal theory then $H_1(p) = 0$ due to a rather simple reason. Now fix such a p in an o-minimal theory.

Lemma 3.9. *Assume p is non-algebraic. Then there is a type $q(x, y) \in S(A)$ such that:*

(1) *whenever $(a, b) \models q(x, y)$, then a and b are A-independent, and each realizes p; and*

(2) *for any pair (a, b) of A-independent realizations of p, there is a third realization c of p such that c is A-independent from ab and both (a, c) and (b, c) realize q.*

Proof. Recall that since T is o-minimal, any A-definable unary function $f(x)$ is either eventually increasing (that is, there is some point c such that if $c < x < y$ then $f(x) < f(y)$, eventually decreasing, or eventually constant. If f is eventually constant with eventual value d, then $d \in \mathrm{dcl}(A)$.

We say an A-definable function $f(x_1, \ldots, x_n)$ *bounded within* p if for any realizations $c_1, \ldots, c_n \models p$, there is d realizing p such that $d > f(c_1, \ldots, c_n)$. We call a pair of realizations (a, b) of p an *extreme pair* if whenever $f(x)$ is bounded within p, then $b > f(a)$.

First note that by the compactness theorem, for any a realizing p, there is a b realizing p such that (a, b) is an extreme pair. Also, if $b \in \mathrm{dcl}(aA) = \mathrm{acl}(aA)$, then there is an A-definable function $f : p(\mathfrak{C}) \to p(\mathfrak{C})$ such that $b = f(a)$, so since there is no maximal realization c of p (because such a realization c would be in $\mathrm{dcl}(A)$ and we are assuming that p is non-algebraic), it follows that (a, b) is **not** an extreme pair. So any extreme pair is algebraically independent over A and hence thorn-independent (see [18]).

Claim 3.10. *Any two extreme pairs have the same type over A.*

Proof. It is enough to check that if (a, b) and (a, c) are two extreme pairs, then $\mathrm{tp}(b/Aa) = \mathrm{tp}(c/Aa)$. By o-minimality, any Aa-definable set X is a finite union of intervals, and the endpoints $\{d_1, \ldots, d_n\}$ of these intervals lie in $\mathrm{dcl}(Aa)$. So $d_i = f(a)$ for some A-definable function f, and as we already observed $b, c \neq d_i$. Hence it suffices to see $b > d_i$ iff $c > d_i$. Now by the definition of an extreme pair,

$$\forall x \models p \ \exists y \models p \, [y > f(x)] \Rightarrow b > f(a) = d_i.$$

Also,

$$\exists x \models p \ \forall y \models p\,[y \leq f(x)] \Rightarrow \forall x \models p \ \forall y \models p\,[y \leq f(x)]$$

because any two realizations of p are conjugate under an automorphism in $\mathrm{Aut}(\mathfrak{C}/A)$ which permutes $p(\mathfrak{C})$, and so

$$\exists x \models p \ \forall y \models p\,[y \leq f(x)] \Rightarrow b \leq f(a) = d_i.$$

The same reasoning applies with c in place of b, so

$$\begin{aligned} b > d_i = f(a) &\Leftrightarrow \forall x \models p \ \exists y \models p\,[y > f(x)] \\ &\Leftrightarrow c > f(a) = d_i. \end{aligned}$$

□

Let $q(x, y) = \mathrm{tp}(a', b'/A)$ for some extreme pair. Condition (2) of the definition of weak 3-amalgamation can be ensured by picking $c \models p$ so that $c > g(a, b)$ for any A-definable function $g(y, z)$ bounded within p, which is possible by the compactness theorem. □

The two conditions in Lemma 3.9 clearly mean that p has weak 3-amalgamation defined in [14]. Because of this or direct observation it follows $H_1(p) = 0$.

4. Work in progress

Here we summarize some work in progress concerning our homology groups.

In [6] the following was conjectured: Let T be stable having $(n+1)$-CA (over any algebraically closed set), and $p \in S(A)$ with $A = \mathrm{acl}(A)$. Then for every $n \geq 1$,

$$H_n(p) \cong \Gamma_n(p) := \mathrm{Aut}(\widetilde{a_0 \ldots a_{n-1}}/\bigcup_{i=0}^{n-1} \overline{\{a_0 \ldots a_{n-1}\} \setminus \{a_i\}}),$$

where $\overline{a}$ denotes $\mathrm{acl}(aA)$; $\mathrm{Aut}(C/B)$ denotes the group of elementary permutations of the set C fixing B pointwise; $\{a_0, \ldots, a_n\}$ is A-independent, $a_i \models p$; and

$$\widetilde{a_0 \ldots a_{n-1}} := \overline{a_0 \ldots a_{n-1}} \cap \mathrm{dcl}(\bigcup_{i=0}^{n-1} \overline{\{a_0 \ldots a_n\} \setminus \{a_i\}}).$$

In [6], the conjecture is proved when $n = 1, 2$. We plan to publish a proof for all n in the forthcoming preprint [8]. We may call this the Hurewicz correspondence since the result connects the homology groups to something analogous to a homotopy group, as in algebraic topology. To accomplish this, we needed to generalize the notion of groupoids to higher dimensions, and the vertex groups of the higher groupoids should be isomorphic to the groups $\Gamma_n(p)$ defined above. We could not find suitable generalization in the literature fit in our needs, so in [7] we define *n-ary polygroupoids*. A 2-ary polygroupoid is just an ordinary groupoid. In an n-ary polgroupoid, the "morphisms" live in fibers above ordered n-tuples of objects, and there is a sort of n-ary composition rule on these morphisms. Composition is only possible under certain compatibility conditions, and there are axioms generalizing invertibility and associativity for ordinary groupoids. In [7], we show that in any stable

first-order theory that has k-uniqueness for all $k \leq n$ but fails $(n+1)$-uniqueness, there is an n-ary polygroupoid (definable in a mild extension of the language) which witnesses the failure of $(n+1)$-uniqueness.

In [14], as mentioned above it is proved that $H_1(p) = 0$ for any strong type p in a rosy theory as long as p is a Lascar type too; so any 1-shell in p is the boundary of a 2-chain. However, in contrast to the case of simple theories, we construct a series of types in rosy examples showing that there is no uniform bound for the minimal lengths of the 2-chains in the types having 1-shell boundaries. For this and its own research interests, in [14] and [17], all the possible 2-chains having the same 1-shell boundary are classified in a non-trivial amenable collection of functors. In this classification, the following results are obtained, among others: Any 2-chain with a 1-shell boundary is equivalent (preserving the boundary) to either an NR-type or an RN-type 2-chain with a support of size 3. Combinatorial and algebraic criteria determining the two types are given. A planar 2-chain is equivalent to a Lascar 2-chain.

In [4] and [5], from the failure of 3-uniqueness of a strong type p in a stable theory, a way of constructing canonical relatively definable groupiods is introduced. The profinite limit of vertex groups of the groupoids will be the automorphism group $\Gamma_2(p)$, and this seems to play a role in our setting analogous to that of a fundamental group; however, unlike $\pi_1(X)$ in topology, $\Gamma_2(p)$ is always abelian, since $\Gamma_2(p) \cong H_2(p)$. But in [15], a different canonical "fundamental" group for the type p is constructed which seems to give more information: this new group need not be abelian, and the group $\Gamma_2(p)$ is in the center of the new group.

In [6, 2.29], given an arbitrary profinite group G, only a brief sketch is given how to build a type p_G in a stable theory T_G such that $H_2(p_G) \cong G$. In [9], a more detailed proof is supplied.

Sustretov has recently found connections between 4-amalgamation and Galois cohomology in the preprint [19]. It would be very interesting to know if his work could be related to the computation of the homology groups discussed in this article.

Definability in non-archimedean geometry

François Loeser

Abstract. We discuss several situations involving valued fields for which the model-theoretic notion of definability plays a central role. In particular, we consider applications to p-adic integration, diophantine geometry and topology of non-archimedean spaces.

Mathematics Subject Classification (2010). Primary 03C10, 03C65, 03C98,12J10, 14G22, 22E35; Secondary 03C64, 03C68, 11S80, 11F85, 14G20, 14T05, 20G25, 22E50.

Keywords. Valued fields, p-adic integration, non-archimedean geometry, motivic integration, Berkovich spaces.

1. Introduction

After the groundbreaking work of Ax-Kochen [2] and Eršov [25] in the sixties and of Denef [16] in the eighties, a wide array of applications of model theory of valued fields is now flourishing, ranging over topics as diverse as counting subgroups, the Langlands program and singularity theory. In all these applications the concept of definability in first order logic is central. In this survey, we shall focus on three such applications, each using the notion of definability in the context of valued fields in an essential way.

We start by presenting several transfer theorems for p-adic integrals. Such results allow to transfer statements over $\mathbb{Q}_p$ to statements over $\mathbb{F}_p(\!(t)\!)$ and vice versa. A first result, obtained in collaboration with R. Cluckers deals with identities between integrals with parameters. In work with R. Cluckers and T. Hales it was shown how it can used for the integrals occuring in the fundamental lemma. We shall also present more recent results obtained by R. Cluckers, J. Gordon and I. Halupczok on transfering local integrability or uniform boundedeness statements and some of their applications to p-adic harmonic analysis. In the next section, we shall explain how by working in a definable setting one can deduce global bounds from local bounds on differentials, despite the totally disconnected nature of non-archimedean valued fields and present some diophantine applications. This is recent joint work with R. Cluckers and G. Comte. The last section is about the topology of non-archimedean spaces. We shall present our work with E. Hrushovski on stable completion of algebraic varieties over a valued field, a model-theoretic analogue of the Berkovich analytification. A fundamental statement is that the stable completion of an algebraic variety is pro-definable. We shall explain how using this approach one can prove new tameness results for the topology of Berkovich spaces.

The present overview is far from being exhaustive, for instance it completely leaves out important work of Hrushovski and Kazhdan on motivic integration [29, 30], and some of its

Proceedings of the International Congress of Mathematicians, Seoul, 2014

recent applications [32, 35].

2. Definability and integration

2.1. Definable sets. A language $\mathcal{L}$ is a set consisting of symbols for constants (= 0-ary functions), n-ary functions and n-ary relations. Basic examples are the ring language $\{0, 1, +, -, \times, =\}$, the order language $\{<, =\}$, or the ordered abelian group language $\{<, 0, +, -, =\}$.

An $\mathcal{L}$-structure consists of a set M together with interpretations for symbols in $\mathcal{L}$. One requires that $=$ is interpreted by equality in M. A subset of M^n is said to be definable if it is of the form

$$\{(a_1, \cdots, a_n) \in M^n : \varphi(a_1, \cdots, a_n) \text{ holds }\}$$

with φ a first-order formula in $\mathcal{L}$ with n-free variables. When the formula φ involves parameters running over some $A \subset M$, one says the subset is A-definable. A map between A-definable sets is said to be A-definable if its graph is. In this way one defines the category Def_A of A-definable sets. All these notions extend naturally to many-sorted languages.

2.2. *p*-adic integrals. In his breakthrough paper [16] on the rationality of the Poincaré series associated to the p-adic points on a variety, Denef proved the following general rationality result for p-adic integrals:

Theorem 2.3. *Let X be a definable subset of $\mathbb{Q}_p^n$ and $g : X \to \mathbb{Q}_p$ be a bounded definable function. Then the integral*

$$\int_X |g|^s |dx|$$

is a rational function of p^{-s}.

Here definability refers to the ring language with parameters in $\mathbb{Q}_p$ (or, which amounts to the same here, any standard valued ring language, for instance $\mathcal{L}_{k,\Gamma}$ considered in 4.8). The proof relies on Macintyre's quantifier elimination theorem [36] for $\mathbb{Q}_p$.

For X a definable subset of $\mathbb{Q}_p^n$, denote by $\mathcal{C}_p(X)$ the $\mathbb{Q}$-algebra generated by functions of the form $|g|$ and $\mathrm{val}(g)$ with $g : X \to \mathbb{Q}_p$ definable. In the paper [17] in which he extended his rationality result to the setting of integrals with parameters, Denef proved the following result about stability under integration for functions in $\mathcal{C}_p$.

Theorem 2.4. *Let X be a definable subset of $\mathbb{Q}_p^n$. Let $\varphi \in C_p(X \times \mathbb{Q}_p^m)$. Assume for any $x \in X$, the function $\varphi_x : \lambda \mapsto \varphi(x, \lambda)$ is integrable. Then the function $x \mapsto \int_{\mathbb{Q}_p^m} \varphi_x |d\lambda|$ belongs to $\mathcal{C}_p(X)$.*

In [18], Denef proved a general cell decomposition theorem for $\mathbb{Q}_p$-definable sets, providing direct proofs of Theorems 2.3 and 2.4 and also of Macintyre's quantifier elimination theorem. The natural question of uniformity in p in Denef's Theorem 2.3 has been addressed by Pas in [39] and by Macintyre in [37]. In the paper [39] a three sorted language has been introduced, nowadays called the Denef-Pas language $\mathcal{L}_{\mathrm{DP}}$. In this language, there are three sorts of variables:

- variables running over the valued field for which the language is the ring language

- variables running over the residue field sort for which the language is the ring language
- variables running over the value group sort for which the language is the language of ordered groups.

and two additional symbols ac and val from the valued field sort to the residue field and value group sort, respectively. For $\mathbb{Q}_p$ or $k(\!(t)\!)$ the angular component map ac is interpreted as the first non zero coefficient in the p-adic, resp. t-adic, expansion and val as the valuation. In this setting, Pas proved a cell decomposition theorem which is uniform in p in [39]. In particular, this provides a new elementary proof of the following version of the classical result of Ax-Kochen-Eršov.

Theorem 2.5. *Let φ be a sentence (that is, a formula with no free variable) in the language $\mathcal{L}_{DP}$. For all but finitely prime numbers p, φ is satisfied in $\mathbb{F}_p(\!(t)\!)$ if and only if it is satisfied in $\mathbb{Q}_p$.*

2.6. Motivic integrals. In the series of papers [10] and [11] in collaboration with Raf Cluckers we have developed a general framework for motivic integration on definable sets in the Denef-Pas language. More precisely let k be a field of characteristic zero and set $K = k(\!(t)\!)$. We consider K as a structure for the Denef-Pas language. For any definable subset S of K^m (or more generally of $K^m \times k^n \times \mathbb{Z}^r$), we define in [10] an algebra $\mathcal{C}(S)$ of "constructible motivic functions" on S. For such functions one defines inductively the notion of being integrable and the value of the integral, using the cell decomposition theorem of Pas [39], and one proves an analogue of Theorem 2.4 in this context. Working in a relative setting is essential here. One of the main advantage of working in the definable setting over previous constructions as those in [19] or [20], is that there is no need anymore to consider completions of Grothendieck rings. Also, we are able to state and prove Fubini and change of variables theorems in full generality, and to deal with integrals with parameters. For more detailed, though accessible, presentations of this theory, we refer to the introduction of [10] and to the paper [12].

2.7. Transfer theorems for constructible motivic functions. Let $\mathbf{F}$ be a number field with ring of integers $\mathcal{O}$. Let $\mathcal{C}_{\mathcal{O}}$ denote the collection of triples (F, ι, ϖ), where F is non-archimedean local field, $\iota : \mathcal{O} \to F$ a ring homomorphism and ϖ a uniformizer in F. We denote by k_F the residue field of F and by q_F the cardinality of k_F. For $M > 0$, we denote by $\mathcal{C}_{\mathcal{O},M}$ the subcollection of triples (F, ι, ϖ) with F of residue characteristic $> M$.

Assume now $k = \mathbf{F}$, and fix a definable subset S of K^n. For some M large enough, for any (F, ι, ϖ) in $\mathcal{C}_{\mathcal{O},M}$ one may consider the specialization S_F of S in F^n obtained by specializing the formulas defining S using ι and sending t to ϖ. Similarly, for M large enough, a function φ in $\mathcal{C}(S)$ may be specialized to a function on S_F which we shall denote by φ_F.

In [11], we prove the following:

Theorem 2.8. *Let $\psi \in \mathcal{C}(S \times K^m)$ and $\psi' \in \mathcal{C}(S \times K^{m'})$. Then, there exists $M > 0$ such that, for every F_1 and F_2 in $\mathcal{C}_{\mathcal{O},M}$ such that $k_{F_1} \simeq k_{F_2}$,*

$$\int_{F_1^m} (\psi_{F_1})_x |d\lambda| = \int_{F_1^{m'}} (\psi'_{F_1})_x |d\lambda'|$$

for every $x \in S_{F_1}$ if and only if

$$\int_{F_2^m} (\psi_{F_2})_x |d\lambda| = \int_{F_2^{m'}} (\psi'_{F_2})_x |d\lambda'|$$

for every $x \in S_{F_2}$.

In particular, when $\mathbf{F} = \mathbb{Q}$, we get that, for almost all p, the identity

$$\int_{\mathbb{Q}_p^m} (\psi_{\mathbb{Q}_p})_x |d\lambda| = \int_{\mathbb{Q}_p^{m'}} (\psi'_{\mathbb{Q}_p})_x |d\lambda'|$$

holds for every $x \in S_{\mathbb{Q}_p}$ if and only if

$$\int_{\mathbb{F}_p((t))^m} (\psi_{\mathbb{F}_p((t))})_x |d\lambda| = \int_{\mathbb{F}_p((t))^{m'}} (\psi'_{\mathbb{F}_p((t))})_x |d\lambda'|$$

holds for every $x \in S_{\mathbb{F}_p((t))}$. Note that Theorem 2.5 can be viewed as a special case of Theorem 2.8 when $m = m' = 0$ and S is the definable subset of K^0 defined by the sentence φ.

In work with Cluckers and Hales [12] we have shown that Theorem 2.8 applies in particular to the integrals occurring in the fundamental lemma, both in the unweighted and weighted case. This is performed by representing all the data entering into the fundamental lemma within the general framework of identities of motivic integrals of constructible functions. This provides alternative proofs of results of Waldspurger in [46] and [47] and is of special interest in view of Ngô's proof of the fundamental lemma over local fields of positive characteristic [38]. One advantage of our approach is that it may be applied quite directly to other versions of the fundamental lemma, as in [50].

Another important property of motivic constructible functions is that they satisfy strong uniform boundedness statements, as proved by Cluckers, Gordon, Halupczok in the appendix B of [44]:

Theorem 2.9. *Let S be a definable set and let $\varphi \in \mathcal{C}(S \times \mathbb{Z}^n)$.*

(1) *There exist integers a and b, M, such that for every F in $\mathcal{C}_{\mathcal{O},M}$, if there exists a set-theoretical function $\alpha : \mathbb{Z}^n \to \mathbb{R}$ such that $|\varphi_F(s,\lambda)|_{\mathbb{R}} \leq \alpha(\lambda)$ on $S_F \times \mathbb{Z}^n$, then $|\varphi_F(s,\lambda)|_{\mathbb{R}} \leq q_F^{a+b||\lambda||}$ on $S_F \times \mathbb{Z}^n$, with $||\lambda|| = \sum_i |\lambda_i|$.*

(2) *Given integers a and b, there exists M, such that whether the bound*

$$|\varphi_F(s,\lambda)|_{\mathbb{R}} \leq q_F^{a+b||\lambda||}$$

holds or not on the whole of $S_F \times \mathbb{Z}^n$ depends only on k_F, for F in $\mathcal{C}_{\mathcal{O},M}$.

In the same paper they show this result may be applied to provide uniform bounds for orbitals integrals that are used in an essential way in the paper [44].

2.10. Transfer theorems for exponential constructible motivic functions. In [11], we extend the construction of algebras constructible motivic functions $\mathcal{C}(S)$, to take in account motivic versions of exponential functions, by constructing the algebra $\mathcal{C}^{exp}(S)$ of exponential constructible motivic functions on S for any definable set S. The formalism developed in [10] for $\mathcal{C}(S)$ carries over to $\mathcal{C}^{exp}(S)$.

Given an non-archimedean field F, one denotes by $\mathcal{D}_F$ the set of additive characters on F that are trivial on the maximal ideal and nontrivial on the valuation ring. Now, given φ in $\mathcal{C}^{exp}(S)$, for any F in $\mathcal{C}_{\mathcal{O},M}$ and any character θ in $\mathcal{D}_F$, one may specialize φ to a function $\varphi_{F,\theta}$ on S_F.

In this setting, Theorem 2.8 may be generalized as follows:

Theorem 2.11. *Let $\psi \in \mathcal{C}^{exp}(S \times K^m)$ and $\psi' \in \mathcal{C}^{exp}(S \times K^{m'})$. Then, there exists $M > 0$ such that, for every F_1 and F_2 in $\mathcal{C}_{\mathcal{O},M}$ such that $k_{F_1} \simeq k_{F_2}$,*

$$\int_{F_1^m} (\psi_{F_1,\theta})_x |d\lambda| = \int_{F_1^{m'}} (\psi'_{F_1,\theta})_x |d\lambda'|$$

for every $x \in S_{F_1}$ and any $\theta \in \mathcal{D}_{F_1}$ if and only if

$$\int_{F_1^m} (\psi_{F_1,\theta})_x |d\lambda| = \int_{F_1^{m'}} (\psi'_{F_1,\theta})_x |d\lambda'|$$

for every $x \in S_{F_1}$ and any $\theta \in \mathcal{D}_{F_1}$.

In the paper [13], Cluckers, Gordon, Halupczok prove the following remarkable transfer theorem for (local) integrability and boundedness:

Theorem 2.12. *Let S be a definable subset of K^m and let $\varphi \in \mathcal{C}^{exp}(S)$. There exists $M > 0$ such that, for fields F in $\mathcal{C}_{\mathcal{O},M}$, the validity of the statement that $\varphi_{F,\theta}$ is (locally) integrable, resp. (locally) bounded, for all $\theta \in \mathcal{D}_F$ depends only on the isomorphism class of k_F.*

Using Theorem 2.12, Cluckers, Gordon, Halupczok have been able in [14] to transfer Harish-Chandra's theorems on local integrability of characters of irreducible admissible representations of connected reductive p-adic groups from characteristic zero to (large) positive characteristic. An important ingredient in their approach is the definability of the Moy-Prasad filration subgroups, which they have proved in a number of important special cases.

3. Definability and non-archimedean diophantine geometry

3.1. Lipschitz functions. A C^1-function on an interval in $\mathbb{R}$ which has bounded derivative is automatically Lipschitz continuous. It is well known that such a result cannot hold for general C^1-functions over the p-adics since $\mathbb{Q}_p$ is total disconnectedness. However, under some definability conditions it is still possible to get results of this kind, as we shall explain now.

Let K be a field endowed with a discrete valuation for which it is complete. In this section, by definable we shall mean definable in the ring language L_K with parameters in K (in this case definable sets are also called semi-algebraic sets), or in the analytic language L_K^{an} which is obtained by adding to L_K a symbol for each restricted power series f in $K\{x_1, \ldots, x_m\}$, for $m \geq 1$. Such a symbol is interpreted as the function $K^m \to K$ which is zero outside $\mathcal{O}_K^m$ and given by $x \mapsto f(x)$ for $x \in \mathcal{O}_K^m$. In this case definable sets are also called subanalytic sets.

Let X be a subset of K^m. We say a function $f : X \to K$ is C-Lipschitz if for every x and y in X, $|f(x) - f(y)| \leq C|x - y|$. We say it is locally C-Lipschitz if for each point x_0 in X, the restriction of f to some neighborhood of x_0 is C-Lipschitz.

In the paper [7] with Cluckers and Comte we prove the following:

Theorem 3.2. *Let X be a definable subset of $\mathbb{Q}_p^m$ and let $f : X \to \mathbb{Q}_p$ be a definable map. Assume f is locally C-Lipschitz. Then there exists a finite partition of X into definable sets X_i and C' such that the restriction of f to each X_i is C'-Lipschitz.*

This statement is a p-adic analogue of a theorem of Kurdyka for real subanalytic sets [34]. In [9] Cluckers and Halupczok proved that it is in fact always possible to take $C' = C$.

3.3. A p-adic analogue of the Yomdin-Gromov lemma. A very efficient tool in diophantine geometry is the so-called determinant method which was developed by Bombieri and Pila in the influential paper [6] about the number of integral points of bounded height on affine algebraic and transcendental plane curves. Basically, the method consists in using a determinant of a suitable set of monomials evaluated at the integral points, in order to construct a family of auxiliary polynomials vanishing at all integral points on the curve within a small enough box. Building on the estimates in [6] for algebraic curves, Pila proved in [40] bounds on the number of integral (resp. rational) points of bounded height on affine (resp. projective) algebraic varieties of any dimension, improving on previous results by S. D. Cohen using the large sieve method [15].

In [41], Pila and Wilkie proved a general estimate for the number of rational points on the transcendental part of sets definable in an o-minimal structure; this has been used in a spectacular way by Pila to provide an unconditional proof of some cases of the André-Oort Conjecture [42]. Lying at the heart of Pila and Wilkie's approach is the possibility of having uniform - in terms of number of parametrizations and in terms of bounds on the partial derivatives - C^k-parametrizations. These parametrizations are provided by an o-minimal version of Gromov's algebraic parametrization Lemma [26], itself a refinement of a previous result of Yomdin [48],[49]. Such C^k-parametrizations enter the determinant method via Taylor approximation.

In the work [8] with Cluckers and Comte we provide a version of the Yomdin-Gromov lemma and the Pila-Wilkie theorem valid over $\mathbb{Q}_p$. At first sight one may have doubts such a statement could exist, since there seem there is no way for a global Taylor formula to make sense in this framework. However Theorem 3.2 which provides a version of first-order Taylor approximation, piecewise globally, in the definable p-adic setting is an encouraging sign. In [8], instead of generalizing this result to higher order, we show directly the existence of uniform C^k-parametrizations that do satisfy Taylor approximation, which is enough for our purpose.

Our p-adic analogue of the Yomdin-Gromov lemma is the following statement:

Theorem 3.4. *Let $n \geq 0$, $m \geq 0$ and $r \geq 0$ be integers and let $X \subset \mathbb{Z}_p^n$ be a subanalytic set of dimension m. Then there exists a finite collection of subanalytic functions $g_i : P_i \subset \mathbb{Z}_p^m \to X$ such that the union of the $g_i(P_i)$ equals X, the g_i have C^r norm bounded by 1, and the g_i may be approximated by Taylor polynomials of degree $r-1$ with remainder of order r, globally on P_i.*

For the precise definition of the C^r norm and of approximation by Taylor polynomials of certain degree and with certain error we refer to [8].

3.5. A p-adic analogue of the Pila-Wilkie theorem. For X a subset of $\mathbb{Q}_p^n$ and $T > 1$ a real number, write $X(\mathbb{Q}, T)$ for the set consisting of points $(x_1, \cdots, x_n)$ in $X \cap \mathbb{Q}^n$ such that one can write x_i as a_i/b_i where a_i and $b_i \neq 0$ are integers with $|a_i|_{\mathbb{R}} \leq T$ and $|b_i|_{\mathbb{R}} \leq T$.

For X a subset of $\mathbb{Q}_p^n$, write X^{alg} for the subset of X consisting of points x such that

there exists an algebraic curve $C \subset \mathbb{A}^n_{\mathbb{Q}_p}$ such that $C(\mathbb{Q}_p) \cap X$ is locally at x of dimension 1.

We prove in [8] the following p-adic analogue of the Pila-Wilkie theorem:

Theorem 3.6. *Let $X \subset \mathbb{Q}_p^n$ be a subanalytic set of dimension m with $m < n$. Let $\varepsilon > 0$ be given. Then there exist an integer $C = C(\varepsilon, X) > 0$ and a semialgebraic set $W = W(\varepsilon, X) \subset \mathbb{Q}_p^n$ such that $W \cap X$ lies inside X^{alg}, and such that for each T, one has*

$$\#(X \setminus W)(\mathbb{Q}, T) \leq CT^{\varepsilon}.$$

3.7. Results over $\mathbb{C}[\![t]\!]$. In the paper [8] we also obtain results when $K = \mathbb{C}(\!(t)\!)$. For instance a version of Theorem 3.2 still holds over $\mathbb{C}(\!(t)\!)$ (with $C' = C$), if one replaces "a finite partition of X" by "a partition parametrized by $\mathbb{C}^r$, for some r". For this to make sense one has to enlarge the language to have (higher) angular components maps à la Denef-Pas, see [8] for more details. Similarly, a version of Theorem 3.4 over $\mathbb{C}(\!(t)\!)$ is also proved in [8]. We end this section by stating a diophantine application of this result.

For each positive integer r one denotes by $\mathbb{C}[t]_{<r}$ the set of complex polynomials of degree $< r$. When A is a subset of $\mathbb{C}(\!(t)\!)^n$, one denotes by A_r the set $A \cap (\mathbb{C}[t]_{<r})^n$ and by $n_r(A)$ the dimension of the Zariski closure of A_r in $(\mathbb{C}[t]_{<r})^n \simeq \mathbb{C}^{nr}$.

Let X be an algebraic subvariety of $\mathbb{A}^n_{\mathbb{C}(\!(t)\!)}$ of dimension m. One can prove that for any $r > 0$, $n_r(X) \leq rm$. When X is linear this "trivial" estimate is the best possible. However, we prove in [8] that as soon as X has degree $d \geq 2$, the following non-trivial bound holds:

Theorem 3.8. *Let X be an irreducible subvariety of $\mathbb{A}^n_{\mathbb{C}(\!(t)\!)}$ of dimension m and degree $d \geq 2$. Then, for every positive integer r, one has*

$$n_r(X) \leq r(m-1) + \left\lceil \frac{r}{d} \right\rceil.$$

This result is a geometric analogue of a result of Pila in [40] on the number of integral (resp. rational) points of bounded height on affine (resp. projective) algebraic varieties of any dimension. Pila's proof proceeds by reducing to the case of curves which was considered by Bombieri and Pila in [6].

4. Definability and topology

In this section we present a model-theoretic approach to proving topological tameness properties in non-archimedean geometry which we developed in collaboration with Ehud Hrushovski [31].

4.1. o-minimality. It is by now quite well known that o-minimal geometry provides an efficient framework for the study of topology arising from an ordered structure, in particular in the context of ordered fields. Let us recall that an infinite structure M which is totally ordered by a binary relation $<$ is said to be o-minimal if every definable subset $X \subset M$, with parameters in M, is a finite union of intervals and points. Sets definable in a o-minimal structure have nice topological properties. For instance, for o-minimal expansions of the field $\mathbb{R}$ of real numbers, and $n \in \mathbb{N}$, definable subsets of $\mathbb{R}^n$ have a finite number of connected components which furthermore are definable, they are locally contractible and triangulable;

in particular they have the homotopy type of a finite simplicial complex. Classical examples of subsets of $\mathbb{R}^n$ definable in a o-minimal structure include semi-algebraic sets, subanalytic sets, or sets definable in the language of ordered rings with an exponential function. Another class of examples of o-minimal structures, playing an important role in our work, is provided by divisible ordered abelian groups Γ. In this last setting definable subsets of Γ^n essentially correspond to piecewise linear sets. An important feature of this model-theoretic framework for tameness is that it is particularly well adapted to proving uniformity statements for the topology of definable sets varying in definable families, for instance finiteness of homotopy types occuring in a given such family.

4.2. Valued fields. By a valued field we mean a field K, together with a surjective multiplicative map $\mathrm{val} : K^\times \to \Gamma$, with $\Gamma = (\Gamma, 0, +, <)$ an ordered abelian group such that $\mathrm{val}(x+y) \geq \min(\mathrm{val}(x), \mathrm{val}(y))$. We extend val to a map $\mathrm{val} : K \to \Gamma_\infty$, with Γ_∞ the disjoint union of Γ with a distinguished element ∞ which is larger than any element of Γ and absorbing for the addition. We shall denote by $\mathcal{O}_K$ the valuation ring of K and by $\mathcal{M}_K$ the maximal ideal of K.

4.3. Berkovich spaces. Let K be a valued field such that Γ is a subgroup of $(\mathbb{R}, +)$. Then $x \mapsto |x| = e^{-\mathrm{val}(x)}$ defines an absolute value $|\cdot| : K \to \mathbb{R}_{\geq 0}$. One says K is ultrametric if it is complete for this norm.

In [3], Berkovich introduced a general notion of analytic spaces over an ultrametric field K. In particular, for any algebraic variety V over K one may consider its Berkovich analytification V^{an}. In case V is affine with ring of regular functions $K[V]$, let us define V^{an} as a topological space. As a set V^{an} is the set of multiplicative seminorms on $K[V]$ extending the absolute value on K. There is a natural embedding $V^{an} \subset \mathbb{R}^{K[V]}$ and one endows V^{an} with the topology induced by the product topology on $\mathbb{R}^{K[V]}$. For an arbitrary algebraic variety V over K, one defines V^{an} by glueing. This construction is functorial: any morphism of algebraic variety $f : V \to W$ gives rise to a morphism $f^{an} : V^{an} \to W^{an}$. Note that $V(K)$ may be naturally identified with a subset of V^{an}. When V is affine, this is done by assigning to a point a in $V(K)$ the seminorm $f \mapsto |f(a)|$.

4.4. Some previously known topological properties of Berkovich spaces. Already in [3] Berkovich proved that general analytic spaces (including analytifications of algebraic varieties) have excellent general topological properties, in particular they are locally compact and locally path-connected.

More recently, in his paper [4], Berkovich proved that the general fibre of any polystable formal scheme admits a strong deformation retraction to a finite polyhedron, and using de Jong's results on alterations he deduced that any smooth analytic space is locally contractible.

On the other hand, Ducros proved in [21] that semi-algebraic subsets of V^{an}, i.e. subsets which are Zariski locally boolean combinations of subsets defined by inequalities $|f| \bowtie \lambda|g|$ with f, g in $K[V]$ and $\lambda \in \mathbb{R}_{\geq 0}$, where $\bowtie \in \{<, >, \leq, \geq\}$, have only a finite number of connected components, each of them semi-algebraic.

Another statement with an o-minimal flavour us the following. Let X be a compact analytic space and let f be an analytic function on X. For every $\varepsilon \geq 0$, let X_ε denote the set of points x in X such that $|f(x)| \geq \varepsilon$. According to Abbes and Saito under the assumption that f is invertible [1] and to Poineau in general [43], there is a finite partition of $\mathbb{R}_{\geq 0}$ into intervals such that on each of these intervals the natural map $\pi_0(X_{\varepsilon'}) \to \pi_0(X_\varepsilon)$

is a bijection whenever $\varepsilon \leq \varepsilon'$.

4.5. Statement of results. The results recalled in 4.4 provide rather strong evidence that there should exist general tameness results for the topology of non-archimedean spaces, quite analogous to the ones available in the o-minimal world. In the paper [31], we prove the following general statements on the topology of analytifications of algebraic varieties:

Theorem 4.6. *Let K be an ultrametric[1] field. Let V be a quasi-projective variety over K and let X be a semi-algebraic subset of V^{an}.*

(1) *There exists a strong homotopy retraction $h : [0,1] \times X \to X$ onto a closed subset of X which is homeomorphic to a compact finite polyhedral complex.*

(2) *The space X is locally contractible (one may drop the assumption V quasi-projective here).*

(3) *Let $f : V \to W$ be a morphism of algebraic varieties over K. Then the set of homotopy types of fibers of the map $f^{an}|_X : X \to W^{an}$ is finite.*

(4) *Let $f : V \to \mathbb{A}^1_K$ a morphism. For every $\varepsilon \geq 0$, let X_ε denote the set of points x in X such that $|f(x)| \geq 0$. Then there exists a finite partition of $\mathbb{R}_{\geq 0}$ into intervals such that the natural map $X_{\varepsilon'} \hookrightarrow X_\varepsilon$ is a homotopy equivalence whenever $\varepsilon \leq \varepsilon'$ belong to the same interval.*

4.7. Model-theoretic preliminaries. We shall deal with a complete theory T having quantifier elimination and work in a fixed universe $\mathbb{U}$, by which we mean a large very saturated and homogeneous model. All models M (and parameter sets A) we shall consider will be small substructures (resp. subsets) of $\mathbb{U}$.

If A is a small subset of $\mathbb{U}$, the definable closure $\mathrm{dcl}(A)$ is the set of all elements c in $\mathbb{U}$ such that there exists a formula $\varphi(x)$ with one free variable and parameters in A such that c is the only element of $\mathbb{U}$ such that $\varphi(c)$ holds. If X is a C-definable set and $C \subset A$, we write $X(A)$ for $X(\mathbb{U}) \cap \mathrm{dcl}(A)$.

A basic notion we shall use is that of a definable type. Let assume for simplicity of notation that there is only one sort. Let B be a set of parameters. Let $c = (c_1, \cdots, c_n)$ be a finite tuple of elements of $\mathbb{U}$. The set of all B-formulas satisfied by c in some model of T containing the c_i's is denoted by $\mathrm{tp}(c/B)$ and called the type of c over B. Such a set of formulas is called an n-type over B. In the special case where all c_i's already belong to B one says the type is realized (over B). Let $A \subset M$. We say an n-type p over M is A-definable if for every formula $\varphi(x_1, \cdots, x_n, y_1, \cdots, y_m)$ without parameters, there exists a formula $\varphi_p(y_1, \cdots, y_m)$ with parameters in A, such that for any $(b_1, \cdots, b_m)$ in M^m, $\varphi(x_1, \cdots, x_n, b_1, \cdots, b_m)$ belongs to p if and only if $\varphi_p(b_1, \cdots, b_m)$ holds in M. The mapping $\varphi \mapsto \varphi_p$ is called a defining scheme for p. If p is such an A-definable type over M, for any model M' containing M one can extend p to an A-definable type over M', by using the same defining scheme. Thus, we will not care about a specific M anymore when dealing A-definable types. Note that a realized type over A is always A-definable. These definitions extend naturally to many-sorted languages.

Let X be a C-definable set with $C \subset A$. We say that an A-definable type p is on X if the formula expressing that $x \in X$ belongs to the type p. We denote by $S_{X,def}(A)$ the set of A-definable types on X and set $S_{X,def} = \cup_A S_{X,def}(A)$. Any C-definable map

[1] In fact the completeness hypothesis on K plays no role here.

$f : X \to Y$ between C-definable sets induces a natural push-forward maps

$$f_* : S_{X,def}(A) \to S_{Y,def}(A) \text{ and } f_* : S_{X,def} \to S_{Y,def}.$$

4.8. The language. Classically, to study valued fields one considers a 3-sorted language $\mathcal{L}_{k,\Gamma}$ (or one of its variants) with sorts VF, Γ and $\mathbf{k}$ for the valued field, value group and residue field sorts, with respectively the ring, ordered abelian group and ring language, and additional symbols for the valuation val and the map $\mathrm{Res} : \mathrm{VF}^2 \to k$ sending (x, y) to the residue of xy^{-1} if $\mathrm{val}(x) \geq \mathrm{val}(y)$ and $y \neq 0$ and to 0 otherwise. We consider ACVF, the theory of algebraically closed fields with non trivial valuation such that val is surjective in this language. This theory become complete once the characteristic of the valued field and of its residue field are both fixed. It is a classical result of A. Robinson that ACVF admits quantifier elimination. Note that this result has already nice consequences in non-archimedean geometry. For instance in the paper of Ducros [23] it is used to give an alternate proof of the Bieri-Groves theorem [5].

We shall use an expansion $\mathcal{L}_{\mathcal{G}}$ of this language introduced by Haskell, Hrushovski and Macpherson in [27]. It has additional sorts S_n and T_n for $n \geq 1$, coding respectively n-dimensional lattices over the valuation ring, and elements in the reduction modulo the maximal ideal of such lattices. The main result of [27] is that ACVF has elimination of imaginaries in the language $\mathcal{L}_{\mathcal{G}}$ (which was not the case in the original language $\mathcal{L}_{k,\Gamma}$). A theory T is said to have elimination of imaginaries in a given language if all quotients of definable sets by definable equivalence relations are representable by definable sets. It is also proved in [27] that ACVF still has elimination of quantifiers in $\mathcal{L}_{\mathcal{G}}$.

One should note that expanding the language from $\mathcal{L}_{k,\Gamma}$ to $\mathcal{L}_{\mathcal{G}}$ does not create new definable sets in the sorts VF, Γ and $\mathbf{k}$. If V is an algebraic variety over a valued field, we may define definable subsets of V by requiring that their intersection with any affine open is a definable set.

Given a valued field F, a in F and α in $\mathrm{val}(F)$, resp. α in $\mathrm{val}(F^\times)$, one denotes by $B(a, \alpha)$ and $B^o(a, \alpha)$ respectively the closed and open ball of center a and valuative radius α. They are definable sets defined respectively by the formulas $\mathrm{val}(x - a) \geq \alpha$ and $\mathrm{val}(x - a) > \alpha$. If B is a ball defined over a model K of ACVF, the type expressing that $x \in B$ and $x \notin B'$ for every K-definable ball B' strictly contained in B is a K-definable type, called the generic type of B, and denoted by p_B.

Remark 4.9. Note that the set of all closed balls for K running over all models of ACVF (contained in $\mathbb{U}$) is definable in $\mathcal{L}_{\mathcal{G}}$ (without parameters). Indeed, it suffices to prove that the set of all closed balls of finite valuative radius is definable in $\mathcal{L}_{\mathcal{G}}$, and this follows from the following observation: given a, a' in K and b, b' in $K^\times$, the balls $B(a, \mathrm{val}(b))$ and $B(a', \mathrm{val}(b'))$ are equal if and only if the two-dimensional $\mathcal{O}_K$-lattices generated by $((b, 0), (a, b))$ and by $((b', 0), (a', b'))$ are equal. More precisely, there exists a definable set D in $\mathcal{L}_{\mathcal{G}}$ such that for any $A \subset \mathbb{U}$, $D(A)$ is in natural bijection with the set of A-definable closed balls.

4.10. Stably dominated types. In [28], Haskell, Hrushovski and Macpherson introduced within a general model-theoretic framework the notion of stably dominated types. Roughly speaking, a stably dominated type is a definable type which is "controlled by its stable part". In ACVF, stable domination is equivalent to being orthogonal to Γ in the following sense. Let X be a C-definable set and let $p \in S_{X,def}(A)$, for $C \subset A$. We shall say that p is orthog-

onal to Γ if for every model M of ACVF containing A, every tuple c such that $p = \mathrm{tp}(c/M)$, and every M-definable map $f : X \to \Gamma_\infty$, $f(c) \in \mathrm{val}(M)$. We denote by $\widehat{X}(A)$ the set of A-definable types on X that are orthogonal to Γ and by $\widehat{X}$ the union of all the sets $\widehat{X}(A)$, for $A \subset \mathbb{U}$. We call $\widehat{X}$ the stable completion of X.

Examples 4.11.

1. Realized types are stably dominated, i.e. for any definable set X there is a natural inclusion $\iota : X \to \widehat{X}$.
2. A type over Γ_∞^n is stably dominated if and only it is realized, i.e. $\iota : \Gamma_\infty^n \to \widehat{\Gamma_\infty^n}$ is a bijection.
3. The generic type of a ball is stably dominated if and only if the ball is closed.

It follows from Remark 4.9 and Example 4.11 (3) that, given a valued field F, there is a natural bijection ϑ between $\widehat{\mathbb{A}^1_F}$ and a definable set D, inducing, for any $A \subset \mathbb{U}$, a bijection between $\widehat{\mathbb{A}^1_F}(A)$ and $D(A)$. This is a special case of Theorem 4.14, but before going any further, we should introduce the notion of a pro-definable set. One defines the category ProDef_C of pro-definable sets over C as the category of pro-objects in the category of C-definable sets indexed by a small directed partially ordered set. Thus, if $X = (X_i)_{i\in I}$ and $Y = (Y_j)_{i\in J}$ are two such pro-objects

$$\mathrm{Hom}_{\mathrm{ProDef}_C}(X, Y) = \varprojlim_j \varinjlim_i \mathrm{Hom}_{\mathrm{Def}_C}(X_i, Y_j).$$

Elements of $\mathrm{Hom}_{\mathrm{ProDef}_C}(X, Y)$ will be called C-pro-definable morphisms between X and Y. By a result of Kamensky [33], the functor of "taking $\mathbb{U}$-points" induces an equivalence of categories between the category ProDef_C and the sub-category of the category of sets whose objects and morphisms are inverse limits of $\mathbb{U}$-points of definable sets indexed by a small directed partially ordered set. By pro-definable, we mean pro-definable over some C. We shall thus freely identify a pro-definable set $X = (X_i)_{i\in I}$ with the set $X(\mathbb{U}) = \varprojlim_i X_i(\mathbb{U})$. For any set B with $C \subset B \subset \mathbb{U}$, we set $X(B) = X(\mathbb{U}) \cap \mathrm{dcl}(B) = \varprojlim_i X_i(B)$.

Definition 4.12. Let X be a pro-definable set.

(1) X is called strict pro-definable if it can be written as a pro-definable set with surjective transition morphisms.

(2) X is called iso-definable if it is in pro-definable bijection with a definable set.

(3) $Y \subset X$ is called relatively definable if there exists $i \in I$ and a definable subset W of X_i such that $Y = \pi_i^{-1}(W)$, with π_i the canonical projection $X \to X_i$.

Theorem 4.13. *Let X be a B-definable set. Then $\widehat{X}$ may be canonically endowed with the structure of a strict B-pro-definable set. In particular, there exists a strict B-pro-definable set E such that for any $B \subset A$, there is a canonical identification $\widehat{X}(A) = D(A)$.*

For curves we have the following stronger statement:

Theorem 4.14. *Let C be an algebraic curve over a valued field K and let X be a definable subset of C. Then $\widehat{X}$ is iso-definable.*

For $C = \widehat{\mathbb{P}^1}$ the result follows from the description of $\widehat{\mathbb{A}^1}$ in terms of closed balls given above. The proof in the general case uses Riemann-Roch and Theorem 4.13.

Remark 4.15. The previous statement is optimal since one can show that, for X a definable subset of K^n, $\widehat{X}$ is iso-definable if and only the dimension of the Zariski closure of X is ≤ 1.

Lemma-Definition 4.16. Let $f : X \to Y$ be a map between B-definable sets. Then the map $f_* : S_{X,def} \to S_{Y,def}$ restricts to a B-pro-definable map $\widehat{f} : \widehat{X} \to \widehat{Y}$. In this way we have a functor from the category of B-definable sets to the category of B-pro-definable sets.

Let X be a definable subset. If Y is a definable subset of X, then $\widehat{Y}$ is a relatively definable subset of $\widehat{X}$. The set of realized types in $\widehat{X}$, which can be identified with $X(\mathbb{U})$ is iso-definable and relatively definable in $\widehat{X}$. Its points are called simple points of $\widehat{X}$.

4.17. $\widehat{V}$ as a topological space. We endow $\widehat{\mathbb{A}^n}$ with the coarsest topology such that for every polynomial $F \in \mathbb{U}[x_1, \cdots, x_n]$, the map $\widehat{\mathrm{val} \circ F} : \widehat{\mathbb{A}^n} \to \Gamma_\infty$ is continuous, where the topology on Γ_∞ is the order topology. For any definable subset X of $\mathbb{A}^n$, we endow $\widehat{X}$ with the induced topology. If V is an algebraic variety over a valued field K, we define the topology on $\widehat{V}$ by gluing: it is the unique topology inducing the previous topology on $\widehat{U}$ for U an affine open in V. If X is a definable subset of V, we endow the relatively definable subset $\widehat{X}$ with the induced topology.

We have the following basic properties:

Proposition 4.18. *Let V be an algebraic variety defined over a valued field K. Then:*

(1) *The topology on $\widehat{V}$ is pro-definable in the following sense: there exists a small set I, and for each $i \in I$, a K-definable family $U_i = (U_{i,b})_{b \in \mathbb{U}}$ of relatively definable subsets of $\widehat{V}$, such that the sets $U_{i,b}$, for $b \in \mathbb{U}$ and $i \in I$ generate the topology on $\widehat{V}$.*

(2) *The topology on $\widehat{V}$ is Hausdorff.*

(3) *The subset of simple points is dense in $\widehat{V}$.*

(4) *The induced topology on the set of simple points is the valuation topology.*

In general, we shall call pro-definable sets with a pro-definable topology, pro-definable spaces.

More generally, consider the map $\pi : V \times \mathbb{A}^m \to V \times \Gamma_\infty^m$ which is the identity on the V factor and val on the remaining ones. It induces a map $\widehat{\pi} : \widehat{V \times \mathbb{A}^m} \to \widehat{V \times \Gamma_\infty^m}$ and we endow $\widehat{V \times \Gamma_\infty^m}$ with the direct image topology, making it a pro-definable space. One shows that the canonical map $\widehat{V \times \Gamma_\infty^m} \to \widehat{V} \times \widehat{\Gamma_\infty^m} = \widehat{V} \times \Gamma_\infty^m$ is an homeomorphism.

4.19. Definable compactness. The usual notion of compactness is not well suited to the present setting as shown by the following example. Let K be a valued field with $\mathrm{val}(K^\times) = \mathbb{Q}$. Fix $\varepsilon \in \mathrm{val}(\mathbb{U}^\times)$ such that $0 < \varepsilon < \alpha$ for every positive α in $\mathbb{Q}$. Let C be set defined by the formula $0 \leq \mathrm{val}(x) \leq 1$. For $\alpha \in \mathbb{Q} \cap [0, 1]$ let U_α be defined by $\alpha - \varepsilon < \mathrm{val}(x) < \alpha + \varepsilon$. The family of open sets $\widehat{U_\alpha}$ is a cover of $\widehat{C}$ with no finite subcover.

To remidy this we shall introduce the notion of definable compactness for pro-definable spaces. Let us note that the definition we gave of a definable type still makes sense on pro-definable set.

Definition 4.20. Let X be a pro-definable space.

(1) Let p be a definable type on X. We say $a \in X$ is a limit of p if for every relatively definable neighborhood W of a, the formula expressing $x \in W$ belongs to p.

(2) We say X is definably compact if every definable type on X has a limit.

Note that if X is Hausdorff, limits are unique when they exist.

Let V be a closed subvariety of $\mathbb{A}^m$. A subset $X \subset V$ is said to be bounded in V if it is contained in a product of closed balls. For an arbitrary variety V, a definable subset $X \subset V$ is said to be bounded, if one may write $V = \cup_{i=1}^n V_i$ with V_i open and affine and $X = \cup_{i=1}^n X_i$, with X_i bounded in V_i. A subset of $V \times \Gamma_\infty^m$ will be said to be bounded if its preimage in $V \times \mathbb{A}^m$ is. Finally, a pro-definable subset $X \subset \widehat{V} \times \Gamma_\infty^m$ will be said to be bounded if there exists a bounded definable subset W of $V \times \Gamma_\infty^m$ such that $X \subset \widehat{W}$.

Theorem 4.21. *Let X be a pro-definable subset of $\widehat{V} \times \Gamma_\infty^m$. Then X is definably compact if and only if it is closed and bounded.*

Corollary 4.22. *A variety V over a valued field is complete if and only if $\widehat{V}$ is definably compact.*

4.23. Γ-internality. We shall now define an important class of subsets of $\widehat{V} \times \Gamma_\infty^m$ which "look like o-minimal sets".

Definition 4.24. A subset Z of $\widehat{V} \times \Gamma_\infty^m$ is said to be Γ-internal if it is iso-definable and there is a definable subset D of some Γ_∞^n and a surjective pro-definable map $D \to Z$.

The iso-definability condition is crucial here, and cannot be replaced by just requiring pro-definability. This definition is purely definable and does not say anything a priori about the topology of Z. The following embedding result shows that being Γ-internal imposes strong restrictions on the topology:

Theorem 4.25. *Let Z be a Γ-internal subset of $\widehat{V} \times \Gamma_\infty^m$. Then there exists an injective continuous definable map $f : Z \hookrightarrow \Gamma_\infty^n$ for some n. If Z is definably compact, such an f is an homeomorphism.*

If V and Z are defined over some set of parameters A, one cannot in general expect such an f to be defined, because it should be respect the Galois action. However the following holds:

Proposition 4.26. *Assume V and Z are defined over some set of parameters A in the* VF *and Γ sorts. Then there exists a finite A-definable set w and an injective continuous A-definable map $f : Z \hookrightarrow \Gamma_\infty^w$.*

4.27. Paths and definable connectedness. The mapping $[0, \infty] \to \widehat{\mathbb{P}^1}$ sending t to the generic type of the ball $B(0, t)$ may be seen as a path connecting 0 and the generic type $p_\mathcal{O}$ of the closed unit ball. Similarly the mapping $[0, \infty] \to \widehat{\mathbb{P}^1}$ sending t to the generic type of the ball $B(1, t)$ connects 1 and $p_\mathcal{O}$. By composing these paths one connects the point 0 and 1. However a technical issue occurs here. Since multiplication is not part of the structure Γ_∞, there is no way to identify the space obtained by gluing two copies of $[0, \infty]$ at 0 with an interval. We are thus led to consider generalized intervals, that is spaces obtained by

concatening a finite number of closed intevals in Γ_∞ either with the order from Γ_∞ or with the reverse order.

We denote by $I = [i_I, e_I]$ such a generalized interval. A path $\gamma : I \to \widehat{V} \times \Gamma_\infty^m$ is a continuous (pro)-definable map.

Let V be an algebraic variety over some valued field. We say a strict pro-definable subset Z of $\widehat{V}$ is definably connected if it contains no clopen strict pro-definable subsets other than $\emptyset$ and Z. We say that Z is definably path connected if for any two points a and b of Z there exists a definable path in Z connecting a and b. Clearly definable path connectedness implies definable connectedness. When V is quasi-projective and $Z = \widehat{X}$ with X a definable subset of V, the reverse implication will eventually follow from Theorem 4.32.

We have the following GAGA type theorem:

Theorem 4.28. *Let V be an algebraic variety over some valued field. Then $\widehat{V}$ is definably connected if and only if V is geometrically connected.*

4.29. Strong retractions for curves. Let $I = [i_I, e_I]$ be a generalized interval. A continuous pro-definable map $H : I \times \widehat{X} \to \widehat{Y}$ is called a definable homotopy between the maps $H_i = H_{|\{i_I\}\times\widehat{X}}$ and $H_e = H_{|\{e_I\}\times\widehat{X}}$, viewed as maps $\widehat{X} \to \widehat{Y}$. A definable homotopy $H : I \times \widehat{X} \to \widehat{X}$ is called a strong deformation retraction onto the set $\Sigma \subset \widehat{X}$ if $H_i = \mathrm{Id}_{\widehat{X}}$, $H(t, x) = x$ for every $t \in I$ and every $x \in \Sigma$ and $H_e(\widehat{X}) = \Sigma$.

There is a canonical strong deformation retraction of $\widehat{\mathbb{P}^1}$ onto the point $p_{\mathcal{O}}$ which is described as follows. Using the two standards affine charts, one may write each point of $\widehat{\mathbb{P}^1}$ as $p_{B(a,\alpha)}$ with $a \in \mathbb{P}^1(\mathbb{U})$ and $\alpha \geq 0$. The homotopy is given by taking $I = [\infty, 0]$ (thus $i_I = \infty$ and $e_I = 0$) and setting $\psi(t, p_{B(a,\alpha)}) = p_{B(a,\min(t,\alpha))}$.

More generally, given any finite subset D in $\mathbb{P}^1(\mathbb{U})$, let C_D be the image of $I \times (D \cup p_{\mathcal{O}})$ under ψ. The set C_D is a closed Γ-internal subset of $\widehat{\mathbb{P}^1}$. Set $\gamma(a) = \max\{t \in I; \psi(t, a) \in C_D\}$. Then $\psi_D : I \times \widehat{\mathbb{P}^1} \to \widehat{\mathbb{P}^1}$ sending (t, a) to $\psi(\max(\gamma(a), t), a)$ is a strong deformation retraction of $\widehat{\mathbb{P}^1}$ onto C_D.

Theorem 4.30. *Let C be an algebraic curve over a valued field K. There exists a strong deformation retraction, defined over K, $H : [0, \infty] \times \widehat{C} \to \widehat{C}$ onto a Γ-internal subset of $\widehat{C}$.*

Let us sketch the proof. A standard outward path on $\widehat{\mathbb{A}^1}$ at $x = p_{B(a,\alpha)}$ is given by $t \mapsto p_{B(a,t)}$ for $t \in (\beta, \alpha]$ for some $\beta < \alpha$. Now if $g : C \to \mathbb{A}^1$ is finite, with C a curve, by an outward path starting at $x \in \widehat{C}$, we mean a continuous definable lifting of a standard outward path starting at $g(x)$. One proves that for any $x \in \widehat{C}$ there exists at least one outward path starting at x and one says that x is branching if there is more than one outward path starting at x. A key lemma states that the number of such branching points is finite. For the proof of the theorem we may assume C is projective and consider $f : C \to \mathbb{P}^1$ finite and generically étale. One considers a finite set $D \subset \mathbb{P}^1$, defined over K, such that f is étale above the complement of D and C_D contains all the branching points, with respect to the restriction of g over both standards affine charts. One concludes the proof by showing that ψ_D lifts to the strong deformation retraction we are looking for.

4.31. The main theorem. We may now state the main result from [31]:

Theorem 4.32. *Let K be a valued field and $A = (K, G)$ with G a subset of Γ containing $\mathrm{val}(K)$. Let V a quasi-projective variety defined over K, X an A-definable subset of V. Assume given finitely many A-definable functions $\xi_i : X \to \Gamma_\infty$ and an action of a finite algebraic group over K on V leaving X globally invariant. Then there exists an A-definable strong deformation $H : I \times \widehat{X} \to \widehat{X}$ onto a Γ-internal subset Υ of $\widehat{X}$ such that:*

(1) *The set Υ embeds homeomorphically into Γ_∞^w for some finite A-definable set.*

(2) *H respects the functions ξ_i and is equivariant with respect to the group action.*

The structure of the proof goes as follows. One uses induction on the dimension of V. One start by reducing to the case where $X = V$ is projective equidimensional. One fixes an hypersurface $D_0 \subset V$ containing the singular locus of V and such that there exists an equivariant étale morphism $V \setminus D_0 \to \mathbb{A}^n$. Some further geometric considerations allow to reduce to the case when there is a morphism $u : V \to U = \mathbb{P}^{n-1}$, whose restriction to D_0 is finite, and a Zariski dense open subset U_0 of U such that, setting $V_0 = u^{-1}(U_0)$, $u|V_0$ factorizes as $q \circ f$ with $f : V_0 \to E_0 = U_0 \times \mathbb{P}^1$ a finite morphism and $q : E_0 \to U_0$ the projection.

Over U_0 the situation is that of a relative curve. Performing the curve construction in this relative setting provides a strong deformation retraction

$$H_{curves} : [0, \infty] \times \widehat{V_0 \cup D_0} \longrightarrow \widehat{V_0 \cup D_0}$$

fixing pointwise $\widehat{D_0}$ and with image a relatively Γ-internal set Υ_{curves}. By using the induction hypothesis (note that even if one starts with V without group action and no ξ_i's, they are needed at this stage of this induction), one constructs a definable homotopy $I \times \widehat{U} \to \widehat{U}$ whose restriction lifts to a strong deformation retraction

$$H_{base} : I \times \Upsilon_{curves} \longrightarrow \Upsilon_{curves}.$$

A third homotopy, which we call "inflation" is used to get out of of the complement of $\widehat{V_0 \cup D_0}$. On $\widehat{\mathbb{A}^n}$ one may consider the standard homotopy given by "increasing the polyradius". Using an appopriate stopping time function one gets another homotopy which we may lift, via the étale map $V \setminus D_0 \to \mathbb{A}^n$, to an homotopy

$$H_{inf} : [0, \infty] \times \widehat{V} \longrightarrow \widehat{V_0 \cup D_0}$$

fixing pointwise $\widehat{D_0}$.

After composing these three homotopies, one gets an homotopy $H' : I' \times \widehat{V} \to \widehat{V}$ that almost does the job, except that because of the use of inflation, we cannot insure that the points of the image of H' are all kept pointwise fixed by H' for all time values. To remedy this issue, we have to construct a fourth homotopy, H_Γ whose construction lies purely in the tropical Γ-internal world, so that the composition $H = H_\Gamma \circ H'$ finally satisfies the conclusion of the theorem.

4.33. Back to Berkovich spaces. A type $p = \mathrm{tp}(c/A)$ is said to be almost orthogonal to Γ is $\Gamma(Ac) = \Gamma(A)$.

Let F be a valued field with $\mathrm{val}(F^\times) \subset \mathbb{R}$. We consider the structure $\mathbb{F} = (F, \mathbb{R})$, where $\mathbb{R}$ belongs to the Γ-sort. Let V be a variety defined over F and X an $\mathbb{F}$-definable subset of V.

One defines $B_X(\mathbb{F})$ as the set of types over $\mathbb{F}$ lying on X and almost orthogonal to Γ. Similarly as for the Berkovich analytification and the stable completion, one endows $B_X(\mathbb{F})$ with a topology coming from the topology on $\mathbb{R}$. When F is complete, $B_V(\mathbb{F})$ and V^{an} are canonically homeomorphic.

By a result of Kaplansky, there exists a unique field F^{max}, up to $\mathbb{F}$-automorphism, which is a maximally complete algebraically closed non trivially valued field containing F, and has value group $\mathbb{R}$ and residue field the algebraic closure of the residue field of F.

The following proposition provides the link allowing to deduce the results about Berkovich spaces stated in Theorem 4.6 from Theorem 4.32 and its relative variants.

Proposition 4.34. *Let X be an $\mathbb{F}$-definable subset of some F-variety. Restriction of types induces a continuous, surjective and closed map $\pi : \widehat{X}(F^{max}) \to B_X(\mathbb{F})$.*

(1) *Let $f : \widehat{X} \to \widehat{Y}$ be a continuous $\mathbb{F}$-pro-definable map, with Y an $\mathbb{F}$-definable subset of some F-variety. Then there exists a unique continuous map $\tilde{f} : B_X(\mathbb{F}) \to B_Y(\mathbb{F})$ such that $\pi \circ f = \tilde{f} \circ \pi$.*

(2) *Let $H : I \times \widehat{X} \to \widehat{X}$ be a definable strong deformation retraction. Then $\tilde{H} : I(\mathbb{R}_\infty) \times B_X(\mathbb{F}) \to B_X(\mathbb{F})$ is a strong deformation retraction.*

(3) *$B_X(\mathbb{F})$ is compact if and only if $\widehat{X}$ is definably compact.*

Acknowledgements. The research of the author has been partially supported by the European Research Council under the European Union's Seventh Framework Programme (FP7/2007-2013) ERC Grant agreement no. 246903/NMNAG. The results presented in this survey are the outcome of long term collaborations with Raf Cluckers, Georges Comte and Ehud Hrushovski. The author would like to express them his heartfelt gratitude.

Computability theoretic classifications for classes of structures

Antonio Montalbán

Abstract. In this paper, we survey recent work in the study of classes of structures from the viewpoint of computability theory. We consider different ways of classifying classes of structures in terms of their global properties, and see how those affect the structures inside the class. On one extreme, we have the classes that are Σ-small. These are the classes which realize only countably many $\exists$-types, and are characterized by having tame computability theoretic behavior. On the opposite end, we look at various notions of completeness for classes which imply that all possible behaviors occur among their structures. We introduce a new notion of completeness, that of being on top for effective-bi-interpretability, which is stronger and more structurally oriented than the previously proposed notions.

Mathematics Subject Classification (2010). Primary 03D45; Secondary 03C57.

Keywords. Sigma small classes, back-and-forth relations, rice relations, low property, bf-ordinal, effective-bi-interpretability.

1. Introduction

In this paper, we survey recent work on the study of classes of structures from the viewpoint of computability theory. By classes of structures we mean classes like the one of fields or of p-groups or of linear orderings. Our general objective is to consider global properties of the classes and derive properties about their individual structures.

Computable structure theory is an area inside computability theory and logic that is concerned with the computable aspects of mathematical objects and constructions. In particular, we are interested in the interplay between structure and complexity, or in other words, in understanding how the algebraic properties of a structure interact with its computational properties. For instance, we ask questions like the following: What kind of information can be encoded into an isomorphism type of a structure? How difficult is it to represent a certain structure? How difficult is it to recognize it?

When we consider classes of structures, there are two ends of the spectrum. On the one end are the classes which have some global property restricting the behavior of their structures. On the other end are the classes which are complete in the sense that they allow all possible behaviors to happen. Let us say a bit more about these two extremes.

Tame classes. In Section 2, we will review some concepts we will need later. One notion of simplicity is that of a class having a bound on the Scott rank of its structures. These classes are not necessarily that simple from a computational viewpoint, and much less from

Proceedings of the International Congress of Mathematicians, Seoul, 2014

the viewpoint of Borel equivalence relations. However, for natural classes this bound tends to be quite low, which makes them easier to analyze. The Scott rank of a structure is related to the number of Turing jumps necessary to fully understand it, and hence, the lower the Scott rank, the more manageable the structure.

A second notion of simplicity, one we believe is the most relevant to computability theory, is that of Σ-smallness, or actually effective Σ-smallness. This notion is studied in Section 3. The author started studying such classes in [46],[1] although the term "Σ-small" is new.

Definition 1.1. A class of structures $\mathbb{K}$ is Σ-*small* if it realizes countably many $\exists$-types, that is, if the set

$$\{\exists\text{-}tp_{\mathcal{A}}(\bar{a}) : \mathcal{A} \in \mathbb{K}, \bar{a} \in \mathcal{A}^{<\omega}\}$$

is countable, where

$$\exists\text{-}tp_{\mathcal{A}}(\bar{a}) = \{\varphi : \varphi(\bar{x}) \text{ is a first order existential formula with } \mathcal{A} \models \varphi(\bar{a})\}.$$

We remark that knowing the $\exists$-type of $\bar{a}$ is equivalent to knowing what finite substructures we can find in $\mathcal{A}$ extending $\bar{a}$. This is not entirely correct when $\mathcal{L}$ is infinite, where we need to consider sub-structures which only mention only a finite number of the symbols in $\mathcal{L}$. Another remark is that the types above are without parameters.

We start Section 3 by developing the effective version of this notion. The effectiveness assumption is not that strong, as it holds of all the examples we have analyzed. A large list of examples can be found in Subsection 3.1. We then study the role of Σ-small classes in many topics that have been widely studied in computable structure theory: Richter's extendibility condition, jumps of structures, the low property, the categoricity property and the Turing ordinal. As more evidence towards its naturalness, we will see in Theorems 3.14 and 3.15 how Σ-smallness induces a strong dichotomy on classes.

Complete classes. In Section 4, we review various ways of mapping structures from one class into another. For each of these reducibilities we have classes that are *on top* in the sense that all other classes can be reduced to it. We start with the well-known notion of Borel reducibility, and then move on to effective reducibility and Turing-computable reducibility, and to classes that are complete in the sense of Hirschfeldt, Khoussainov, Shore and Slinko.

In Section 5, we develop a new and stronger notion of reducibility based on the idea of *effective-bi-interpretability* between structures. We do not know that much about this new notion, but we do show that it preservers even more computational properties than all the previous reducibilities.

Properties on a cone. There are many properties in computability theory which tend to behave nicely when we have a nice natural class of structures, but that do not in general. One can often build strange and unnatural classes of structures where these nice behaviors do not occur. In this paper, we are interested in properties that hold of natural classes. Since we cannot quantify over "all natural classes," we often use the technical device of considering *properties on a cone*.

When we have a computability theoretic property P, we can often consider its relativization P^X for a given oracle $X \in 2^\omega$. We then consider the properties *relatively-P*, which

[1] In [46] we used the phrase "$\mathbb{K}$ has a computable 1-back-and-forth structure" for what we now say "$\mathbb{K}$ is effectively Σ-small."

means that P^X holds for all X, and P *on a cone*, which means that there is a $Z \in 2^\omega$ such that P^X holds for all $X \geq_T Z$. When we have a proof that a natural property P holds (or does not hold) when applied to a natural object, this proof almost always relativizes. Thus, we have a proof of relatively-P, and in particular, of P on a cone. So, if our objects are natural, we should not care whether we are using P, relatively-P, or P on a cone. However, due to the unnatural examples, many results can only be proved in general if we consider the properties *on a cone*. Such results usually call for a further analysis of its degree of effectiveness – we will not concentrate on this here.

Disclaimer. This paper does not pretend to be exhaustive. What it attempts is to convey the author's viewpoint, unifying many ideas that have been floating around for a while. The choice of topics and how much attention they receive is purely motivated by the author's taste, the author's own work, and the new ideas the author wants to develop.

Background and notation. We only consider countable structures throughout, so "structure" means "countable structure." We only consider relational languages, as we do not lose any generality for our purposes. The languages we consider are all computable: that is, if $\mathcal{L}$ consists of relations R_i for $i \in I$, where $I \subseteq \omega$ and R_i has arity $a(i)$, the function $a\colon I \to \omega$ is computable. (This only matters when $\mathcal{L}$ is infinite.)

A *presentation* of a structure $\mathcal{A}$, or a *copy* of $\mathcal{A}$, is just a structure $\mathcal{B}$ isomorphic to $\mathcal{A}$ whose domain is a subset of ω. This allows us to use everything we know about computable functions on ω to study $\mathcal{B}$. Given a presentation $\mathcal{A} = (A; R_i^{\mathcal{A}}, i \in I)$, with $A \subseteq \omega$, we let

$$D(\mathcal{A}) \;=\; A \oplus \bigoplus_{i\in I} R_i^{\mathcal{A}} \;\subseteq\; \omega \sqcup \bigsqcup_{i\in I} \omega^{a(i)}.$$

Via standard coding, we then think of $D(\mathcal{A})$ as a subset of ω, or equivalently a sequence in 2^ω. Note that $D(\mathcal{A})$ is essentially the atomic diagram of $\mathcal{A}$. When we say that the presentation $\mathcal{A}$ computes X, or is computable in Y, we mean that $D(\mathcal{A})$ computes X or is computable in Y. By a *class of $\mathcal{L}$-structures* we mean a set $\mathbb{K}$ of presentations of $\mathcal{L}$-structures which is closed under isomorphism. We often think of $\mathbb{K}$ and of $\{D(\mathcal{A}) : \mathcal{A} \in \mathbb{K}\} \subseteq 2^\omega$ as the same thing, and hence treat $\mathbb{K}$ as a class of reals.

We will often consider the infinity language $\mathcal{L}_{\omega_1,\omega}$, where countably infinite conjunctions and disjunctions are allowed, and its computable version, where these conjunctions and disjunctions must be computable. See [1, Sections 6 and 7]. We use $\Sigma^{\mathtt{in}}_\alpha$ to denote the infinitary Σ_α formulas and $\Sigma^{\mathtt{c}}_\alpha$ to denote the computably infinitary Σ_α formulas. For the *Scott rank* of a structure $\mathcal{A}$ we use the following definition: $SR(\mathcal{A})$ is the least α such that every automorphism orbit in $\mathcal{A}$ is $\Sigma^{\mathtt{in}}_\alpha$-definable without parameters. There are various definitions of Scott rank in the literature that give slightly different values (see [1, Section 6.7]). The reason we prefer ours is that it matches better with other complexity measures used in computability theory and descriptive set theory (see [43]).

2. Axiomatization and the isomorphism problem

The first measure of the complexity for a class is in terms of its complexity as a set of reals. This is directly connected with the complexity of the class in terms of its axiomatizations:

Theorem 2.1 (Lopez-Escobar [37]). *Let $\mathbb{K} \subseteq 2^\omega$ be a class of presentations of structures closed under isomorphisms. Then $\mathbb{K}$ is $\mathbf{\Sigma}^0_\alpha$ in the Borel hierarchy if and only if $\mathbb{K}$ is axiomatizable by an infinitary $\Sigma^{\mathtt{in}}_\alpha$ sentence.*

The lightface version of this theorem is also true: $\mathbb{K}$ is lightface Σ^0_α if and only if it is axiomatizable by a computably infinitary $\Sigma^{\mathtt{c}}_\alpha$ formula [61].

Not all nice classes of structures are $\mathcal{L}_{\omega_1,\omega}$-axiomatizable, or equivalently Borel, as for instance the class of ordinals, which is Π^1_1-complete. We, however, are mostly interested in $\mathcal{L}_{\omega_1,\omega}$-axiomatizable classes. Most of the natural classes we consider are actually $\Pi^{\mathtt{c}}_2$-axiomatizable, so we will sometimes make this assumption when we prove general results.

The second measure of complexity is the difficulty in telling apart different structures in $\mathbb{K}$. This is captured by the set

$$\{\langle D(\mathcal{A}), D(\mathcal{B})\rangle : \mathcal{A}, \mathcal{B} \in \mathbb{K}, \mathcal{A} \cong \mathcal{B}\} \quad \subseteq \quad (2^\omega)^2,$$

usually called the *isomorphism problem* for $\mathbb{K}$. For a Borel class of structures, this set is $\mathbf{\Sigma}^1_1$. For some classes, like linear orderings, this problem is Σ^1_1-complete. For other classes, this problem is quite simple, like $\mathbb{Q}$-vector spaces for which it is Π^0_3-complete. If we assume $\mathsf{ZFC}+\forall X\ (X^\sharp \text{ exists})$, then non-Borel isomorphism problem must be $\mathbf{\Sigma}^1_1$-complete. This follows from Wadge's theorem (see [52, Lemma 7D.3]), as every set that is not $\mathbf{\Pi}^1_1$, is $\mathbf{\Sigma}^1_1$-hard.

Theorem 2.2 ([6, Corollary 7.14]). *Let $\mathbb{K}$ be an $\mathcal{L}_{\omega_1,\omega}$-axiomatizable class. The following are equivalent:*

(1) *The isomorphism problem for $\mathbb{K}$ is Borel.*

(2) *$\mathbb{K}$ has bounded Scott rank.*

When we say that $\mathbb{K}$ has *bounded Scott rank* we mean $\{SR(\mathcal{A}) : \mathcal{A} \in \mathbb{K}\}$ has a supremum $\beta < \omega_1$. For example, the classes of $\mathbb{Q}$-vector spaces and of algebraically closed fields have bound 2 on their Scott ranks. The classes of equivalence structures and of torsion free abelian groups of finite rank have bound 3.

A simple remark is that if $\mathbb{K}$ has countably many structures (up to isomorphism, of course), it has bounded Scott rank. It follows from the model-theoretic Martin's conjecture that if $\mathbb{K}$ has a first order axiomatization and countably many structures, then $\omega+\omega$ is a bound for the Scott ranks of the structures in $\mathbb{K}$ (see [22] for the statement of Martin's conjecture). For more on how high this bound can be see [40, 57].

3. Σ-Small classes of structures

In this section, we see how the notion of Σ-small class connects with a lot of well-known concepts in computable structure theory.

Before looking at examples among familiar classes, let us introduce the effective version of this definition. If $\mathbb{K}$ is a natural class of structures and it is Σ-small, we have a natural countable collection of $\exists$-types. It is then reasonable to expect that one can list, compare and manipulate these types. An effectively Σ-small class is one where we can do this computably:

Definition 3.1. A Σ-small class $\mathbb{K}$ is *effectively* Σ*-small* if there is a computable list $\{p_i : i \in \omega\}$ of computable $\exists$-types listing all the $\exists$-types realized in $\mathbb{K}$ without repetitions, where the operations of erasing and permuting variables are computable, and deciding inclusion of $\exists$-types is also computable.[2]

3.1. Examples. All the classes of structures below are Σ-small. It is worth remarking that most of the examples mentioned below have been attractive to computability theorists for a long time because they enjoy nice computability properties other classes do not.

Vector spaces (over a fixed computable field F). If $\mathbb{K}$ has only countably many structures, it is clearly Σ-small. Proving that F-vector spaces are effectively Σ-small requires understanding their $\exists$-types, which is not hard to do.

Algebraically closed fields. Same as above.

Differentially closed fields of characteristic 0 (DCF_0). They are Σ-small because they are ω-stable. The class of models of an ω-stable theory is always Σ-small, as even using countably many parameters and full first-order types, there are still countably many types. It has not been verified whether DCF_0 is effectively Σ-small or not.

Abelian p-groups. That Abelian p-groups are effectively Σ-small follows from work of Khisamiev [32].

Equivalence structures. We refer the reader to [46, Section 4.2] for an analysis of the $\exists$-types on equivalence structures.

Trees (as partial orderings). By 'trees' we mean downward closed subsets of $\omega^{<\omega}$. That they are effectively Σ-small in the language of partial orderings follows from Richter's work [56]. Let us remark that a key tool in her proof is Kruskal's theorem [35] on the well-quasi-ordering of finite trees.

Trees of finite height (as graphs). The proof is like the case above using Kruskal's theorem for finite trees of a fixed height.

Linear orderings. All an $\exists$-type can say about a tuple $\bar{a} = \langle a_0, ..., a_{k-1} \rangle$ is the order among the elements of the tuple and, for each $n \in \omega$ and each $i, j < |\bar{a}|$, whether there are at least n elements between a_i and a_j. Thus, existential types are determined by the number of elements between the elements of the tuple, and hence there are countably many of them. One can also use this to prove they are effectively Σ-small.

Linear orderings with an added relation for adjacency. When we add the adjacency relation, the $\exists$-types get a bit more complicated, but they are still effective and countable (see [46, Section 4.1]).

Boolean algebras. All an $\exists$-type can say about a tuple is how many elements are below each Boolean combination of the elements of the tuple. These are, again, not that difficult to analyze.

[2]The exact list of properties that are required for a class to be *effectively* Σ-small is currently work in progress, and so far they are motivated from what we see in applications.

Boolean algebras with an added relation that identifies atoms. What makes Boolean algebras particularly interesting is that they remain Σ-small even if we add to them any $\Sigma^{\mathtt{in}}_{<\omega}$ relation. For instance, we can add all of the relations used by Knight and Sob [36] (atom, atomless, infinite, atomic, 1-atomic, atominf, $\sim$-inf, Int$(\omega+\eta)$, infatomicless, 1-atomless, and nomaxatomless) and they remain effectively Σ-small. An in-depth analysis of the $\Sigma^{\mathtt{in}}_n$-types of Boolean algebras was done by Harris and Montalbán in [29]. The fact that there are countably many of them uses key ideas from work of Flum and Ziegler [21].

Generalized Boolean algebras. These are distributive lattices with 0 and where every interval $[a,b]$ is a Boolean algebra. They are usually known in Russia as Ershov algebras. That they are effectively Σ-small follows from work of Khisamiev [32].

3.2. Richter's computable extendibility condition. In her Ph.D. thesis[3] [55], Linda Richter introduced the computable extendibility condition in order to show that there are structures that do not have Turing degree as defined by Jockusch. (A structure $\mathcal{A}$ has Turing degree $\mathbf{x}$ if $\mathbf{x}$ computes a copy of $\mathcal{A}$, and every copy of $\mathcal{A}$ computes $\mathbf{x}$.)

Definition 3.2 ([56, Section 3]). A structure $\mathcal{A}$ has the *computable extendibility condition* if each $\exists$-type realized in $\mathcal{A}$ is computable. A structure $\mathcal{A}$ has the *c.e. extendibility condition* if each $\exists$-type realized in $\mathcal{A}$ is c.e.

Richter's original definition was not in terms of types but in terms of finite structures extending a fixed tuple. As we mentioned right after Definition 1.1, these formulations are equivalent. The c.e. extendibility condition was not considered by Richter, but we include it here because it makes Theorem 3.3 below more rounded. In Russia, structures with the c.e. extendibility condition are said to be *locally constructivizable*.

Of course, if $\mathbb{K}$ is effectively Σ-small, then every structure $\mathcal{A}$ in $\mathbb{K}$ satisfies the computable extendibility condition. On the other hand, if every structure in $\mathbb{K}$ satisfies the c.e. extendibility condition, then $\mathbb{K}$ is Σ-small, because there are only countably many c.e. sets. Furthermore, the proofs in the literature that linear orderings, Boolean algebras and trees (as posets) in [55, 56] and p-groups and generalized Boolean algebras in [32] satisfy the computable extendibility condition are essentially proofs that these classes are effectively Σ-small.

The reason Richter introduced this notion is to prove the following theorem and its corollary below.

Theorem 3.3 (Essentially Richter). *Let $\mathcal{A}$ be any structure. The following are equivalent:*

(1) *$\mathcal{A}$ has the c.e. extendibility condition.*

(2) *Every set $X \subseteq \omega$ which is c.e. in every presentation of $\mathcal{A}$ is already c.e.*

Proof. That (1) implies (2) is essentially the same proof as [56, Theorem 3.1]. For the other direction, notice that every $\exists$-type realized in $\mathcal{A}$ is c.e. in every presentation of $\mathcal{A}$. □

Corollary 3.4. *If $\mathcal{A}$ has the c.e. extendibility condition and has Turing degree $\mathbf{x}$, then $\mathbf{x} = \mathbf{0}$.*

We can read Theorem 3.3 as saying that structures in an effectively Σ-small class cannot directly encode any non-trivial information. In a sense, Σ-smallness is not only a sufficient,

[3] directed by Carl Jockusch

but also a necessary condition for this to be the case. The following theorem shows that if $\mathbb{K}$ is not Σ-small, quite the opposite happens: every real is coded by some structure in $\mathbb{K}$ in a left-c.e. way. We recall that $X \in 2^\omega$ is *left-c.e. in* $A \in 2^\omega$ if the set $\{\sigma \in 2^{<\omega} : \sigma \leq_{lex} X\}$ is c.e. in A, or equivalently, if there is an A-computable approximation to X from the left.

Theorem 3.5 ([46], Theorem 3.1). *Let $\mathbb{K}$ be an $\mathcal{L}_{\omega_1,\omega}$-axiomatizable class of structures. The following are equivalent:*

(1) *$\mathbb{K}$ is not Σ-small.*

(2) *Relative to every oracle on a cone, the following holds: For every $Y \in 2^\omega$, there is a structure $\mathcal{A} \in \mathbb{K}$ such that Y is left-c.e. in every copy of $\mathcal{A}$.*

Part (2) of the theorem can be strengthened by changing "left-c.e." to just "c.e." in most cases. However, an example where left-c.e.ness is required is constructed in [45, Section 2.2].

3.3. Complete sets of r.i.c.e. relations. Another advantage of Σ-small classes is that they have nice structural jumps. We will see below how, when we have a Σ-small class $\mathbb{K}$, we usually have a nice and simple set of relations that give us all the structural information about the jump of the structures in $\mathbb{K}$. Understanding these complete sets of relations is usually very useful in applications.

Before talking about the jump, we need a notion of c.e.-ness among the relations on a structure. We will then look at complete relations among these and use them to define the jump of a structure. An equivalent notion of jump for a structure was originally defined by I. Soskov [4], although he used a very different format. The definition we use here is in the spirit of that introduced in [44] (see [47, Definition 1.2] for more historical remarks).

Definition 3.6. A relation $R \subseteq \mathcal{A}^{<\omega}$ is *relatively intrinsically computably enumerable (r.i.c.e.)* if, on every copy $(\mathcal{B}, R^{\mathcal{B}})$ of $(\mathcal{A}, R)$, we have that $R^{\mathcal{B}}$ (viewed as a subset of $\omega^{<\omega}$) is c.e. in $D(\mathcal{B})$.

Example 3.7. Over a $\mathbb{Q}$-vector space, the relation of linear dependence is r.i.c.e.; Over a ring, the relation that holds of $(r_0, ..., r_k)$ if the polynomial $r_0 + r_1 x + ... + r_k x^k$ has a root is r.i.c.e.

This definition gives a notion of c.e.-ness that we can use to define other standard concepts from computability theory on the subsets of $\mathcal{A}^{<\omega}$.

Definition 3.8. A relation $R \subseteq \mathcal{A}^{<\omega}$ is *relatively intrinsically (r.i.) computable* if it and its complement are both r.i.c.e. R is *r.i. computable in* $Q \subseteq \mathcal{A}^{<\omega}$ if R is r.i. computable in $(\mathcal{A}, Q)$. A partial function $f : \mathcal{A}^{<\omega} \rightharpoonup \mathcal{A}^{<\omega}$ is *partial r.i. computable* if its graph is a r.i.c.e. subset of $(\mathcal{A}^{<\omega})^2$.

Remark 3.9. The use of subsets of $\mathcal{A}^{<\omega}$ not only allows us to consider sequences of subsets of $\mathcal{A}^n$ for all n uniformly, but essentially all finite objects that can be built over $\mathcal{A}$. For instance, given $Q \subseteq (\mathcal{A}^{<\omega})^2$, let us define $R \subseteq \mathcal{A}^{<\omega}$ by $\bar{b} \in R$ iff $|\bar{b}| = \langle n, m\rangle$ for some $n, m \in \omega$ and $((b_0, ..., b_{n-1}), (b_n, ..., b_{n+m-1})) \in Q$. We then have that Q is r.i.c.e. (as in Definition 3.6 but for subsets of $(\mathcal{A}^{<\omega})^2$) if and only if R is r.i.c.e. In a similar way, we can code subsets of $(\mathcal{A}^{<\omega})^{<\omega}$ by subsets of $\mathcal{A}^{<\omega}$. Given $R, Q \subseteq \mathcal{A}^{<\omega}$, we define $R \oplus Q$ by $\bar{b} \in R \oplus Q$ if either $|\bar{b}| = 2n$ and $\bar{b} \upharpoonright n \in R$ or $|\bar{b}| = 2n + 1$ and $\bar{b} \upharpoonright n \in Q$. We can also

encode a set $X \subseteq \omega$ by a set $\vec{X} \subset \mathcal{A}^{<\omega}$ by letting $\bar{b} \in \vec{X}$ if and only if $|\bar{b}| \in X$. With a bit more work, we can encode any subset of $HF(\mathcal{A})$ (the hereditarily finite extension of $\mathcal{A}$) as a subset of $\mathcal{A}^{<\omega}$ (see [47, Section]).

R.i.c.e. relations can be characterized in a purely syntactic way, without referring to the different copies of the structure, using $\Sigma^{\mathtt{c}}_1$ formulas. Recall that a $\Sigma^{\mathtt{c}}$ formula is just a computable disjunction of $\exists$-formulas over a finite set of free variables.

Theorem 3.10 (Ash, Knight, Manasse, Slaman [2]; Chisholm [10]). *Let $\mathcal{A}$ be a structure, and $R \subseteq A^{<\omega}$ a relation on it. The following are equivalent:*

(1) *R is r.i.c.e.*

(2) *R is uniformly definable by $\Sigma^{\mathtt{c}}_1$ formulas with parameters from $\mathcal{A}$. That is, there is a tuple $\bar{a} \in \mathcal{A}^{<\omega}$ and a computable sequence of $\Sigma^{\mathtt{c}}_1$ formulas $\varphi_i(x_1, ..., x_{|\bar{a}|}, y_1, ..., y_i)$, for $i \in \omega$, such that*

$$(\forall \bar{b} \in \mathcal{A}^{<\omega})\ \ \bar{b} \in R \iff \mathcal{A} \models \varphi_{|\bar{b}|}(\bar{a}, \bar{b}).$$

Definition 3.11. A relation $R \subseteq \mathcal{A}^{<\omega}$ is *r.i.c.e. complete in $\mathcal{A}$* if it is r.i.c.e. and every other r.i.c.e. relation $Q \subseteq \mathcal{A}^{<\omega}$ is r.i. computable from R.

R.i.c.e. complete relations always exist. For instance, we can consider the analog of Kleene's predicate K: If we let $\varphi_{i,j}(y_1, ..., y_j)$ be the ith $\Sigma^{\mathtt{c}}_1$ formula of arity j, then the relation $\vec{K}^{\mathcal{A}} \subseteq \mathcal{A}^{<\omega} \times \omega$ defined by

$$(\bar{b}, i) \in \vec{K}^{\mathcal{A}} \iff \mathcal{A} \models \varphi_{i,|\bar{b}|}(\bar{b})$$

is r.i.c.e. complete.

Definition 3.12 ([47]). We define *the jump of $\mathcal{A}$* to be the structure $\mathcal{A}' = (\mathcal{A}, \vec{K}^{\mathcal{A}})$. Given a class $\mathbb{K}$, we let $\mathbb{K}' = \{\mathcal{A}' : \mathcal{A} \in \mathbb{K}\}$.

If $X \subseteq \omega$ is a c.e. set, then $\vec{X} \subseteq \mathcal{A}^{<\omega}$ (as in Remark 3.9) is clearly r.i.c.e. It follows that $\vec{0}'$ must be r.i. computable in every r.i.c.e. complete relation. On some structures, like $(\omega; 0, 1, +)$, $\vec{0}'$ is r.i.c.e. complete, but this is always not the case. If $\mathcal{A}$ is a linear ordering, then $co\text{-}Adj \oplus \vec{0}'$ is r.i.c.e. complete, where $co\text{-}Adj$ is the complement of the adjacency relation. For most linear orderings $co\text{-}Adj$ is not r.i. computable from $\vec{0}'$.

Definition 3.13. We say that R is *structurally r.i.c.e. complete* if $R \oplus \vec{0}'$ is r.i.c.e. complete. We then say that $(\mathcal{A}, R)$ is *a structural jump* of $\mathcal{A}$.

So, for a linear ordering L, $(\mathcal{L}, co\text{-}Adj)$ is a structural jump.

The author showed in [46] that if $\mathbb{K}$ is Σ-small, there is a countable sequence of $\Sigma^{\mathtt{in}}_1$ formulas which define a structurally complete r.i.c.e. relation in all the structures in $\mathbb{K}$ relative to every oracle on a cone.

Theorem 3.14 ([46]). *Let $\mathbb{K}$ be effectively Σ-small, and let $\{p_i : i \in \omega\}$ be a computable list of all the $\exists$-types realized in $\mathbb{K}$. Then, the $\Sigma^{\mathtt{c}}_1$ formulas*

$$\varphi_i \equiv \bigvee \{\psi : \psi \text{ is an } \exists\text{-formula, and } \psi \notin p_i\},$$

for $i \in \omega$ define a structurally r.i.c.e. complete relation on all structures in $\mathbb{K}$.

In most natural examples, we can find simpler structurally r.i.c.e. complete relations than the one given by Theorem 3.14. For instance, on $\mathbb{Q}$-vector spaces and algebraically closed fields, the relations of linear dependence and algebraic dependence are structurally r.i.c.e. complete, and on Boolean algebras, the not-atom relation is structurally r.i.c.e. complete.

It is also shown in [46] that this is not the case when $\mathbb{K}$ is not Σ-small: there is no sequence of formulas which works for all structures simultaneously.

Theorem 3.15. *If $\mathbb{K}$ is not Σ-small, there is no computable sequence of Σ^c_1-formulas defining a structurally r.i.c.e. complete relation simultaneously on all structures in $\mathbb{K}$.*

3.4. The low property. The low property has been studied for various classes in the last couple of decades. Only recently has it been looked at a general setting.

Definition 3.16. A class $\mathbb{K}$ has the *low property* if every low presentation $\mathcal{A} \in \mathbb{K}$ has a computable copy.

We recall that a set $X \subseteq \omega$ is *low* if X' is computable from $0'$. A presentation $\mathcal{A}$ is *low* if $D(\mathcal{A})$ is.

Jockusch and Soare [30] proved that the class of linear orderings does not have the low property, that is, that there is a low linear ordering without a computable copy. Downey and Jockusch [13] proved that the class of Boolean algebras has the low property. In that paper, they asked the following question, that is still open despite the efforts of various researches:

Question 1. Does every low_n Boolean algebras have a computable copy?

Some partial results are known. Thurber [59] proved that Boolean algebras have the low_2 property and Knight and Stob [36] the low_4 property. The low_5 property is still open. Harris and Montalbán showed that the difficulty at level 5 is not just that it needs one more jump, but a qualitatively new behavior: to show this behavioral difference is essential, they produced a low_5 Boolean algebra not $0^{(7)}$-isomorphic to any computable one – for $n = 1, 2, 3, 4$, it was known that every low_n Boolean algebra is $0^{(n+2)}$-isomorphic to a computable one.

Let us review some of the other examples. The class of equivalence structures does not have the low property. However, the class of equivalence structures with infinitely many infinite equivalence classes has the low property, as it follows from [7, Lemmas 2.2.(c) and 2.3]. Even if linear orderings do not have the low property, some sub-classes do. For instance, the class of all linear orderings where all elements have successor and predecessors does. More examples can be found in [3, 18, 19]. The class of linear orderings with only finitely many descending sequences (up to equivalence) was proved to have the low_n property for all n by Kach and Montalbán [33] (where two sequences are equivalent if they determine the same cut). It is open whether scattered linear orderings have the low property. The class of ordinals not only has the low property, but the low_α-property for all computable ordinals α. Classes that have the low_α-property for all $\alpha < \omega_1^{CK}$ are said to satisfy *hyperarithmetic-is-recursive*, that is, every hyperarithmetic structure in the class has a computable copy. We will get back to these classes in Theorem 3.26.

All the examples of classes with the low property we know are Σ-small. This happens for a reason:

Theorem 3.17. *Let $\mathbb{K}$ be a Π^{in}_2-class. If $\mathbb{K}$ has the low property on a cone, then $\mathbb{K}$ is Σ-small.*

Sketch of the proof. It follows from the author's construction in [46, Lemma 2.9 and Theorem 3.1] that if $\mathbb{K}$ is not Σ-small, there is an oracle relative to which the following happens:

For every $X \in 2^\omega$ and Y c.e. in X, there is a structure $\mathcal{A}$ in $\mathbb{K}$ computable from X and such that Y is left-c.e. in every copy of $\mathcal{A}$. All we need to do now is observe that there is a set that is c.e. over a low set but not left-c.e. For instance, Chaitin's Ω relativized to low 1-random real R is c.e. in R and, since it is 2-random, is not of c.e. degree. Thus $\{\sigma \in 2^{<\omega} : \sigma \leq_{lex} \Omega^R\}$ is c.e. in R but not left-c.e (because left-c.e. sets have c.e. degree). □

3.5. Listable classes. The author started looking at this property with the intention of characterizing the low property.

Definition 3.18. A class $\mathbb{K}$ is *listable* if there exists a Turing functional which, for every oracle X, produces an X-computable sequence of structures listing all the X-computable structures in $\mathbb{K}$ (allowing repetitions).

This definition appeared first in [49], but the underlying idea of considering classes whose computable models can be listed computably is much older. However, the uniformity in Definition 3.18 is needed to get the consequences we want. Nurtazin [54], almost four decades ago, gave a sufficient condition for a class of structures to be listable which includes the classes of linear orderings, Boolean algebras, equivalence structures, Abelian p-groups, and algebraic fields of characteristic p. Nurtazin's result says that, if there exists a computable structure in the class such that any other structure can be embedded into it, and such that any subset of that structure generates a structure in the class, then the class is listable (see [24, Theorem 5.1]). Nurtazin's condition is not a necessary condition for a class to be listable, and for many of the cases we are interested in, it is too strong.

The more general way of proving that a class is listable is by a priority argument, where one monitors all computable functions and tries to list the ones that code structures in the class. In [49], the author developed a game, $\mathsf{G}^\infty(\mathbb{K})$, that captures the combinatorial argument behind these constructions. This game is played by two players, C and D. Along the game, player C builds an infinite list of structures in $\mathbb{K}$ via finite approximations, adding a new element to each structure in each move. Player D, however, builds only one structure and he is allowed to wait and only add elements to his structure when he thinks it is worth it. Player C's goal is to get one of his structures to be isomorphic to D's structure (i.e. "to copy"), while D's goal is to diagonalize. See [49] for a more detailed definition and for other related games. The classes $\mathbb{K}$ for which C has a winning strategy are said to be ∞-*copyable*.

The connection between listability, the low property, and the games was unexpected.

Theorem 3.19 ([49]). *Let $\mathbb{K}$ be a $\Pi^{\mathtt{in}}_2$ class of structures. The following are equivalent:*

(1) *$\mathbb{K}$ has the low property on a cone.*

(2) *$\mathbb{K}$ is Σ-small and $\mathbb{K}'$ is listable on a cone.*

(3) *$\mathbb{K}$ is Σ-small and $\mathbb{K}'$ is ∞-copyable.*

3.6. Computable categoricity. The objective of this subsection is to argue that computable categoricity is easier to analyze on Σ-small classes.

The notion of computable categoricity has been studied intensively for the past few decades. A feature of computable structure theory is that computational properties of presentations need not be invariant under isomorphism, and instead they are invariant under computable isomorphisms. In other words, a structure can have two isomorphic computable

presentations which have different computational properties. For instance, there are computable presentations of the countable, infinite-dimensional $\mathbb{Q}$-vector space, $\mathbb{Q}^\infty$, where all the finite-dimensional subspaces are computable, and computable presentations of $\mathbb{Q}^\infty$ where no finite-dimensional subspace is computable (see [12]). The computably categorical structures are exactly the ones where this does not happen:

Definition 3.20. A computable structure $\mathcal{A}$ is *computably categorical* if between any two computable copies of $\mathcal{A}$ there is a computable isomorphism.

There are many results classifying the computably categorical structures within certain classes. A linear order is computably categorical if and only if it has finitely many adjacencies (Dzgoev and Goncharov [23]); a Boolean algebra is computably categorical if and only if it has finitely many atoms (Goncharov, and independently La Roche [39]); a $\mathbb{Q}$-vector space is computably categorical if and only if it has finite dimension; a p-group is computably categorical if and only if it can be written in one of the following forms: (i) $(\mathbb{Z}(p^\infty))^\ell \oplus G$ for $\ell \in \omega \cup \{\infty\}$ and G finite, or (ii) $(\mathbb{Z}(p^\infty))^n \oplus (\mathbb{Z}_{p^k})^\infty \oplus G$ where G is finite, and $n, k \in \omega$ (Goncharov [26] and Smith [58]); a tree of finite height is computably categorical if and only if it is of finite type (Lempp, McCoy, R. Miller, and Solomon [38]); and so on.

There are also many classes where computably categoricity is quite difficult to describe. Indeed, it was recently proved by Downey, Kach, Lempp, Lewis, Montalbán and Turetsky [14] that the index set of computable categorical structures is Π^1_1-complete. The relativized notion is, however, much better behaved and usually easier to characterize (recall the notions of "relatively P" and "P on a cone" from Section 1). A nice characterization of the relatively computably categorical structures was given by Goncharov [25]: they are exactly the atomic models, over a finite set of parameters, where all the types are generated by $\exists$-formulas, and there is a c.e. listing of those formulas. The author [43] has recently found that there is an even nicer characterization of the structures which are computably categorical on a cone. They are exactly the ones that have a $\Sigma^{\mathtt{in}}_3$ Scott sentence. The classes where we have the best hope of characterizing computable categoricity are the ones where the three notions of computable categoricity – plain, relative, and on a cone – coincide.

Definition 3.21. We say that $\mathbb{K}$ has the *categoricity property* if every computably categorical structure in $\mathbb{K}$ is relatively computably categorical.

$\mathbb{Q}$-vectors spaces, algebraically closed fields, Boolean algebras, linear orderings, equivalence structures, trees (as posets), ordered abelian groups, and p-groups all have the categoricity property.

Conjecture 1. Every Σ-small $\Pi^{\mathtt{in}}_2$-class $\mathbb{K}$ satisfies the categoricity property on a cone.

One thing we know is that Σ-small $\Pi^{\mathtt{in}}_2$-classes always contain structures which are categorical on a cone [43].

3.7. The back-and-forth ordinal. It is not hard to observe that $\Sigma^{\mathtt{c}}_2$ types over a structure $\mathcal{A}$ are equivalent to $\exists$-types over $\mathcal{A}'$, and $\Sigma^{\mathtt{c}}_3$-types to $\exists$-types over $\mathcal{A}''$. One can use this to get, for instance, that a structure is Δ^0_2-categorical on a cone if and only if it is $\mathcal{A}'$ is computably categorical on a cone; or that a a class $\mathbb{K}$ has the low_2 property on a cone if and only if both $\mathbb{K}$ and $\mathbb{K}'$ have the low property on a cone. Thus, understanding $\mathbb{K}'$ can be helpful for the understanding of these higher-level properties. If we have an effectively Σ-small class $\mathbb{K}$, we

have a nice and uniform notion of jump among the structures in $\mathbb{K}$ (Theorem 3.14). We then want to know if $\mathbb{K}'$ is effectively Σ-small. If it is, we can then consider $\mathbb{K}''$ and ask if it is Σ-small.

Definition 3.22. $\mathbb{K}$ is $\Sigma^{\mathtt{in}}_\alpha$-small if it realizes countably many $\Sigma^{\mathtt{in}}_\alpha$ types.

The effective notion of $\Sigma^{\mathtt{in}}_n$-smallness is considered in [46, 48] under the name "effective n-back-and-forth structure." We omit the definition here. In [46], we proved that on $\Sigma^{\mathtt{in}}_n$-small classes have nice $\Sigma^{\mathtt{c}}_n$-complete relations and that no set can be coded in the $(n-1)$st jump of their structures. An opposite behaviour happens, on a cone, for structures that are not $\Sigma^{\mathtt{in}}_n$-small. Thus, for a class $\mathbb{K}$, there is a qualitative jump in behavior from the α's at which $\mathbb{K}$ is $\Sigma^{\mathtt{in}}_\alpha$-small to the ones where it is not.

Definition 3.23. The *bf-ordinal* of a class of structures $\mathbb{K}$ is the least $\alpha \in \omega_1 + 1$ such that $\mathbb{K}$ is not $\Sigma^{\mathtt{in}}_\alpha$-small, and we let it be ∞ if there is no such α.

The notion of bf-ordinal is quite close to the notion of "Turing-ordinal" introduced by Jockusch and Soare [31].

Definition 3.24. A structure $\mathcal{A}$ has *βth jump Turing degree* $\mathbf{x}$ if the βth jump of every copy of $\mathcal{A}$ computes $\mathbf{x}$, and $\mathbf{x}$ computes the βth jump of some copy of $\mathcal{A}$.

A class $\mathbb{K}$ has *Turing-ordinal* τ if for all $\beta < \tau$, whenever a structure in $\mathbb{K}$ has βth-jump Turing degree, it is $0^{(\beta)}$, while for all $\mathbf{x} \geq_T 0^{(\tau)}$, there is a structure in $\mathbb{K}$ with τth-jump Truing degree $\mathbf{x}$.

Theorem 3.25. *Let $\mathbb{K}$ be a $\Pi^{\mathtt{in}}_2$-class with bf-ordinal $\tau < \omega_1$, and suppose that it has Turing ordinal on a cone. Then, on a cone, $\mathbb{K}$ has Turing ordinal either τ or $\tau + 1$.*

Sketch of the proof. This sketches assumes familiarity with either [46, Proof of theorem 3.1] or [48, Section 5]. Since for all $\gamma < \tau$, $\mathbb{K}$ is $\Sigma^{\mathtt{in}}_\gamma$-small, on a cone the greatest lower bound of each degree spectrum of structures in $\mathbb{K}$ is $0^{(\gamma)}$. On the other hand, since $\mathbb{K}$ is not $\Sigma^{\mathtt{in}}_\tau$-small, there is a perfect tree T of $\exists$-types over the language $\mathcal{L}_\tau$ as in [46, Proof of theorem 3.1] and also [48, Section 5]. Let us relativize to that tree, and hence assume T is computable. For every X above $0'$, there is a 1-generic G such that $G \oplus 0' \equiv_T G' \equiv_T X$. Then, there is a structure $\mathcal{A}_\tau \in \mathbb{K}$ computable in G realizing the $\exists$-type $T[G]$ (by [46, Lemma 2.9]). So X computes the jump of some copy of $\mathcal{A}_\tau$. On the other hand, G is left-c.e. in every copy of $\mathcal{A}_\tau$. So, the jump of every copy of $\mathcal{A}'_\tau$ computes G and $0'$, and hence X. It follows that $\mathcal{A}$ has $\tau + 1$-jump degree X.

Thus, the Turing ordinal on a cone of $\mathbb{K}$ is at least τ and at most $\tau + 1$. □

It is not hard to see that the bf-ordinal of $\mathbb{K}$ is ∞ if and only if it has countably many structures. If $\mathbb{K}$ is an $\mathcal{L}_{\omega_1,\omega}$-axiomatizable class, it follows from Morley's proof [51] that, for every $\alpha < \omega_1$, the number of $\Sigma^{\mathtt{in}}_\alpha$ types it realizes is either countable or continuum. Therefore, the bf-ordinal of $\mathbb{K}$ is less than ω_1 if and only if $\mathbb{K}$ has continuum many countable models. In the remaining case, when the bf-ordinal of $\mathbb{K}$ is ω_1, $\mathbb{K}$ must then have $\aleph_1$ many countable models. Vaught's conjecture [60] claims that this last case never occurs. Thus, if $\mathbb{K}$ is $\mathcal{L}_{\omega_1,\omega}$-axiomatizable and its bf-ordinal is ω_1, we say that $\mathbb{K}$ is a *counterexample to Vaught's conjecture*.

We actually do not know any example of a $\Pi^{\mathtt{in}}_\alpha$-class $\mathbb{K}$ whose bf-ordinal is greater than $\alpha + \omega$ unless it is ∞. The closest example we know is the class of Boolean algebras which is $\forall_2$ and has bf-ordinal ω.

Question 2. Is there a Π^{in}_2 class $\mathbb{K}$ with $2^{\aleph_0}$ many models whose bf-ordinal is greater than ω?

Let us remark that question 2 asks about a strengthening of Vaught's conjecture in the opposite direction as Martin's conjecture. Martin's model-theoretic conjecture is about complete first order theories which have less than $2^{\aleph_0}$ many countable models, and implies that they all have bounded Scott rank by at most $\omega + \omega$. Wagner had proposed a strengthening of Martin's conjecture which included theories with $2^{\aleph_0}$ many countable models, which turned out to be false (Gao [22]).

The author found the following connection between these examples and the iterates of the low-property mentioned above. Recall that $\mathbb{K}$ satisfies "hyperarithmetic-is-recursive" if it has the low_α property for all $\alpha < \omega_1^{CK}$, which is equivalent to saying that every hyperarithmetic structure in $\mathbb{K}$ has a computable copy.

Theorem 3.26 (ZFC+$\forall X$ ($X^\sharp$ exists)). *Let $\mathbb{K}$ be an $\mathcal{L}_{\omega_1,\omega}$-axiomatizable class with uncountably many models. The following are equivalent:*

(1) *$\mathbb{K}$ is a counterexample to Vaught's conjecture.*

(2) *$\mathbb{K}$ satisfies hyperarithmetic-is-recursive relative to all oracles on a cone.*

The proof in [48] used projective determinacy, but this was then improved to $\forall X$ ($X^\sharp$ exists) in [41]. Furthermore, in [41] the result above is extended to all analytic equivalence classes E: E has $\aleph_1$ equivalence classes if and only if it satisfies hyperarithmetic-is-recursive on a cone non-trivially.

The main theorem of [48] is actually stronger than Theorem 3.26. Assuming $\mathbf{\Sigma}^1_2$-determinacy and relative to all oracles on a cone, $\mathbb{K}$ has the *low-for-ω_1 property*, that is, if a structure in $\mathbb{K}$ has a presentation that is low-for-ω_1, then it has a computable copy. (We recall that X is low-for-ω_1 if $\omega_1^X = \omega_1^{CK}$.)

4. Comparing the complexity of classes

Reducibilities between classes allow us to classify structures in one class in terms of structures in another class. With this in mind, Friedman and Stanley [20] defined the notion of Borel reducibility. Since then, the study of Borel reducibility on arbitrary Borel and analytic equivalence relations has been extremely active in descriptive set theory. We concentrate here on the isomorphism relation.

Definition 4.1 (H. Friedman and L. Stanley [20]). A class of structures $\mathbb{K}$ is *Borel reducible* to a class $\mathbb{S}$, and we write $\mathbb{K} \leq_B \mathbb{S}$, if there is a Borel function $f\colon 2^\omega \to 2^\omega$ that maps presentations of structures in $\mathbb{K}$ to structures in $\mathbb{S}$ and preserves isomorphism. That is, for all $\mathcal{A} \in \mathbb{K}$, $f(D(\mathcal{A})) = D(\mathcal{B})$ for some $\mathcal{B} \in \mathbb{S}$, and if $\tilde{\mathcal{A}} \in \mathbb{K}$ with $f(D(\tilde{\mathcal{A}})) = D(\tilde{B})$, then

$$\mathcal{A} \cong \tilde{\mathcal{A}} \iff \mathcal{B} \cong \tilde{\mathcal{B}}.$$

(Recall that $D(\mathcal{A})$ is the atomic diagram of $\mathcal{A}$ coded as a subset of ω.)

A class $\mathbb{K}$ is *on top for Borel reducibility* if for every language $\mathcal{L}$, the class of $\mathcal{L}$-structures is Borel-reducible to $\mathbb{K}$.[4]

[4] In the literature these classes are sometimes called *Borel complete*, but we want to avoid that notation here.

They first observed that it is enough to use the language with only one binary relation (i.e. directed graphs) in the definition above. Then, they built Borel reductions to show that the classes of trees, linear orderings, 2-step nilpotent groups and fields are all on top for Borel reducibility. Camerlo and Gao [9] added Boolean algebras to that list. Friedman and Stanley observed that if a class is on top, then its isomorphism problem must be $\mathbf{\Sigma}^1_1$-complete, giving them a whole range of examples which are not on top for Borel reducibility. Torsion abelian groups are an interesting class: their isomorphism problem is Σ^1_1-complete, but they are not on top for Borel reducibility [20, Theorem 5]. (The reason is that their isomorphism problem can be reduced to countable subsets of ordinals via de Ulm invariants in a constructible way, and hence E_0 does not reduce to it.) Whether torsion-free abelian groups are on top was stated as an open question then and remains so. Since then, Downey and Montalbán showed that their isomorphism problem is Σ^1_1-complete, using ideas of Hjorth [27]. It is also open if abelian groups are on top.

In this paper, we are interested in effective versions of this reducibility.

4.1. Effective reducibility. One way of effectivizing the notion of Borel reducibility is by considering computable reductions that act on indices of computable structures. There has been some recent interest on this reducibility which has turned out to be much more interesting than expected [11, 16, 17, 42].

Definition 4.2. We say that a class of structures $\mathbb{K}$ is *effectively reducible* to a class $\mathbb{S}$ if there is a computable function $f\colon \omega \to \omega$ which maps indices of computable structures in $\mathbb{K}$ to indices of computable structures in $\mathbb{S}$ preserving isomorphism. A class of structures $\mathbb{K}$ is said to be *on top for effective reducibility* if for any computable language $\mathcal{L}$, the class of $\mathcal{L}$-structures effectively reduces to it.

(One could also consider hyperarithmetic reductions, but the author has recently shown that, on a cone, being on top for effective reducibility is equivalent to being on top for hyperarithmetic reducibility [42, Theorem 1.6], and hence does not make a difference for natural classes.)

E. Fokina, S. Friedman, V. Harizanov, J. Knight, C. MaCoy and A. Montalbán [17] gave proofs that linear orderings, trees, fields, p-groups and torsion-free abelian groups are all on top. Note that this is different from the Borel-reducibility case where p-groups are not on top, and where it is open if abelian groups are.

It is not hard to see that if a class is on top, its isomorphism-index-set,

$$E(\mathbb{K}) = \{\langle n, m\rangle \in \omega^2 : \ n \text{ and } m \text{ are indices for isomorphic computable structures in } \mathbb{K}\},$$

must be Σ^1_1-complete. Thus, $\mathbb{Q}$-vector spaces, equivalence structures, torsion-free abelian groups of finite rank, etc. cannot be on top because they have arithmetic isomorphism problems. So far, this is the only way we know to produce examples of classes which are not on top.

Definition 4.3. A class $\mathbb{K}$ is *intermediate for effective reducibility* if it is not on top for effective reducibility, and its isomorphism-index-set is not hyperarithmetic.

The reason is that when we say that $\mathbb{K}$ is $\mathbf{\Sigma}^1_1$-complete we mean that there is a continuous reduction from any $\mathbf{\Sigma}^1_1$ subset of 2^ω to the isomorphism problem of $\mathbb{K}$ as a set, and not as an equivalence relation. Reductions that preserve equivalence relations are quite different.

No specific example of an intermediate class is known. Becker [5], and independently Knight and Montalbán [unpublished], showed that such a class of structures exists under the assumption that Vaught's conjecture fails (relative to some oracle). The question now is whether such examples can be built without using a counterexample to Vaught's conjecture:

Question 3. Are the following statements equivalent?

- Vaught's conjecture.
- No $L_{\omega_1,\omega}$-axiomatizable class of structures is intermediate for effective reducibility, relative to every oracle on a cone.

Recent work by the author [42] gives a partial reversal, showing that the second statement follows from a strengthening of Vaught's conjecture (which might turn out to be equivalent to Vaught's conjecture too).

4.2. Turing-computable reducibility. The notion of Turing computable reducibility between classes of structures was introduced by Calvert, Cummins, Knight and S. Miller [8]. It is defined exactly as Borel reducibility (Definition 4.1) except that the function f is required to be a computable operator.

Definition 4.4. A class $\mathbb{K}$ is *Turing computable reducible (tc-reducible)* to $\mathbb{S}$, and we write $\mathbb{K} \leq_{tc} \mathbb{S}$, if there is a Turing operator Φ such that for every presentation $\mathcal{A} \in \mathbb{K}$, $\Phi^{D(\mathcal{A})}$ is the characteristic function of $D(\mathcal{B})$ for some $\mathcal{B} \in \mathbb{S}$ in a way that, if also $\Phi^{D(\tilde{\mathcal{A}})} = D(\tilde{\mathcal{B}})$, then

$$\mathcal{A} \cong \tilde{\mathcal{A}} \iff \mathcal{B} \cong \tilde{\mathcal{B}}.$$

So, instead of working on indices, these operators act on the atomic diagrams given as reals. This makes more of a difference than it seems. It is not hard to see that tc-reducibility implies effective reducibility. This implication does not reverse, as tc-reducibility also implies Borel-reducibility, which is not implied by effective-reducibility (e.g. abelian p-groups).

A class $\mathbb{K}$ is then *on top for tc-reducibility* if for every computable language $\mathcal{L}$, the class of $\mathcal{L}$-structures tc-reduces to $\mathbb{K}$. All the reducibilities produced in [20] are not just Borel but also effective, showing that trees, linear orderings, nilpotent groups and fields are actually on top for tc-reducibility. However, the fact that tc-reduction is finer than Borel reduction allows it to get finer comparabilities between certain classes of structures. For instance, any two classes of structures with countably infinitely many models are Borel-equivalent – this is not the case for tc-reductions, and an interesting structure can be found among these (see [34]). There are even classes of finite structures that are not trivial under tc-reducibility. But the most interesting fact about tc-reducibility is that it preserves the back-and-forth structure:

Theorem 4.5 (Pull Back theorem). *(Knight, S. Miller and Vanden Boom [34]) Let Φ be a Turing computable embedding from $\mathbb{K}$ to $\mathbb{S}$. Then, for every Π^c_α-formula φ, there is a Π^c_α formula φ^* such that for all $\mathcal{A} \in \mathbb{K}$,*

$$\mathcal{A} \models \varphi^* \quad \iff \quad \Phi(\mathcal{A}) \models \varphi$$

(where $\Phi(\mathcal{A})$ is the presentation $\mathcal{B}$ such that $\Phi^{D(\mathcal{A})} = D(\mathcal{B})$). It follows that if $\mathcal{A} \leq_\alpha \tilde{\mathcal{A}}$, then $\Phi(\mathcal{A}) \leq_\alpha \Phi(\mathcal{B})$ (where $\leq_\alpha$ is the α-back-and-forth relation as in [1, Chapter 15]).

This theorem allowed Knight, S. Miller and Vanden Boom to characterize the classes $\mathbb{K}$ such that $\mathbb{K} \leq_{tc} \mathbb{S}$ for certain fixed classes $\mathbb{S}$, like $\mathbb{Q}$-vector spaces.

4.3. Completeness for degree spectrum. A stronger notion of completeness was analyzed by Hirschfeldt, Khoussainov, Shore and Slinko [28]. The idea is that these complete classes of structures contains structures exhibiting all the possible computability theoretic behaviors that structures can have. Their objective was to show that certain nice classes of structures are indeed complete in this sense. Their definition is rather cumbersome, but we include it here for completeness.

Definition 4.6 ([28], Definition 1.21). A class of structures $\mathbb{K}$ is *complete with respect to degree spectra of nontrivial structures, effective dimensions, expansion by constants, and degree spectra of relations* (which we will write as HKSS-complete) if for every non-trivial structure $\mathcal{G}$ over a computable language $\mathcal{L}$, there is a structure $\mathcal{A} \in \mathbb{K}$ with the following properties:

(1) $DgSp(\mathcal{A}) = DgSp(\mathcal{G})$.

(2) If $\mathcal{G}$ is computably presentable, then the following holds:

  (i) For any degree $\mathbf{d}$, $\mathcal{A}$ has the same $\mathbf{d}$-computable dimension as $\mathcal{G}$.

  (ii) If $x \in G$, there is an $a \in A$ such that $(\mathcal{A}, a)$ has the same computable dimension as $(\mathcal{G}, x)$.

  (iii) If $S \subseteq G$, there exists $U \subseteq A$ such that $DgSp_{\mathcal{A}}(U) = DgSp_{\mathcal{G}}(S)$ and if S is intrinsically c.e., then so is U.

We recall that the *degree spectrum* of a structure $\mathcal{A}$ is

$$DgSp(\mathcal{A}) = \{X \in 2^\omega : X \text{ computes a copy of } \mathcal{A}\}.$$

They did not talk about a reducibility, but their notion can be easily be made into a reduction.

They showed that undirected graphs, partial orderings, lattices, integral domains of arbitrary characteristic (and in particular rings), commutative semigroups, and 2-step nilpotent groups are all HKSS-complete. Σ-small classes cannot be HKSS-complete. This is because the degree spectrum of a structure in a Σ-small class can never be the upper cone over a base which is higher than the complexity of all the $\exists$-types realized in the structure.

We suspect that if a nice class is not on top for tc-reducibility, it should not be HKSS-complete either.

5. Complete classes for effective-bi-interpretability

In this section, we introduce a notion of completeness much stronger than the ones above. This new notion is more structural, as its definition does not involve presentations of structures. Its main attraction is that it preserves a whole range of computational properties. The notion as defined here is new, although it is composed of a few already-well-known concepts. In [28], one can already see the idea of having interpretations which are somewhat effective. However, the properties they require use presentations and are not as clean cut or as general as the one here.

We start by introducing the notion of *effective-bi-interpretability* which is a variation of the classical model theoretic notion of bi-interpretability.

5.1. Effective-bi-interpretability. Before looking at effective-bi-interpretability, let us consider effective-interpretability in just one direction. Informally, a structure $\mathcal{A}$ is *effectively-interpretable* in a structure $\mathcal{B}$ if there is an interpretation of $\mathcal{A}$ in $\mathcal{B}$ as in model theory, but where the domain of the interpretation is allowed to be a subset of $\mathcal{B}^{<\omega}$, and where all sets in the interpretation are required to be uniformly r.i. computable, except for the domain which is allowed to be uniformly r.i.c.e.[5]

Before giving the formal definition, we need to review one more concept. A relation R on $\mathcal{A}^{<\omega}$ is said to be *uniformly r.i.c.e.* if there is a c.e. operator W such that for every copy $(\mathcal{B}, R^{\mathcal{B}})$ or $(\mathcal{A}, R)$, $R^B = W^{D(\mathcal{B})}$. These are exactly the Σ^{c}_1-definable relations without parameters. We can then extend this definition and define *uniformly r.i. computable* in the obvious way.

Definition 5.1. Let $\mathcal{A}$ be an $\mathcal{L}$-structure, and $\mathcal{B}$ be any structure. Let us assume that $\mathcal{L}$ is a relational language $\mathcal{L} = \{P_0, P_1, P_2, ...\}$ where P_i has arity $a(i)$; so $\mathcal{A} = (A; P_0^{\mathcal{A}}, P_1^{\mathcal{A}}, ...)$ and $P_i^{\mathcal{A}} \subseteq A^{a(i)}$.

We say that $\mathcal{A}$ is *effectively-interpretable* in $\mathcal{B}$ if, in $\mathcal{B}$, there is

- a uniformly r.i.c.e. set $D^{\mathcal{B}}_{\mathcal{A}} \subseteq \mathcal{B}^{<\omega}$ (the domain of the interpretation),
- a uniformly r.i. computable relation $\eta \subseteq \mathcal{B}^{<\omega} \times \mathcal{B}^{<\omega}$ which is an equivalence relation on $D^{\mathcal{B}}_{\mathcal{A}}$ (interpreting equality),
- a uniformly r.i. computable sequence of relations $R_i \subseteq (B^{<\omega})^{a(i)}$, closed under the equivalence η within $D^{\mathcal{B}}_{\mathcal{A}}$ (interpreting the relations P_i),
- and a function $f^{\mathcal{B}}_{\mathcal{A}} \colon D^{\mathcal{B}}_{\mathcal{A}} \to \mathcal{A}$ which induces an isomorphism:

$$(D^{\mathcal{B}}_{\mathcal{A}}/\eta; R_0, R_1, ...) \cong (A; P_0^{\mathcal{A}}, P_1^{\mathcal{A}}, ...).$$

Let us clarify that: The sets R_i do not need to be subsets of $(D^{\mathcal{B}}_{\mathcal{A}})^{a(i)}$, and, when we refer to the structure $(D^{\mathcal{B}}_{\mathcal{A}}/\eta; R_0, R_1, ...)$, we of course mean

$$(D^{\mathcal{B}}_{\mathcal{A}}/\eta; (R_0 \cap (D^{\mathcal{B}}_{\mathcal{A}})^{a(0)})/\eta, (R_1 \cap (D^{\mathcal{B}}_{\mathcal{A}})^{a(1)})/\eta, \ldots).$$

By *uniformly r.i. computable sequence* we mean that $\bigoplus_i R_{i\in I}$ is uniformly r.i. computable.

If we add parameters, this notion is equivalent to that of Σ-definability introduced by Ershov [15] and widely studied in Russia. Ershov's definition is quite different in format: it uses $HF(\mathcal{B})$ instead of $\mathcal{B}^{<\omega}$, and $\exists$-definable sets with parameters instead of uniformly r.i.c.e. ones. (It is known that r.i.c.e. subsets of $\mathcal{B}^{<\omega}$ are equivalent to Σ-definable (with parameters) subsets of $HF(\mathcal{B})$; see [47, Section 4].) Another well-known notion is that of Σ-*equivalence* between two structures, which just means that the structures are Σ-definable in each other. This is, indeed, quite a strong notion of equivalence, but the one we consider below is stronger, as we also require the composition of the isomorphisms to be computable in the respective structures. Here is the formal definition:

Definition 5.2. Two structures $\mathcal{A}$ and $\mathcal{B}$ are *effectively-bi-interpretable* if there are effective-interpretations of each structure in the other as in Definition 5.1 such that the compositions

$$f^{\mathcal{A}}_{\mathcal{B}} \circ \tilde{f}^{\mathcal{B}}_{\mathcal{A}} \colon D^{(D^{\mathcal{B}}_{\mathcal{A}})}_{\mathcal{B}} \to \mathcal{B} \quad \text{and} \quad f^{\mathcal{B}}_{\mathcal{A}} \circ \tilde{f}^{\mathcal{A}}_{\mathcal{B}} \colon D^{(D^{\mathcal{A}}_{\mathcal{B}})}_{\mathcal{A}} \to \mathcal{A}$$

[5] We remark that this definition is slightly different from what the author called effective-interpretability in [50, Definition 1.7], as we now allow the domain to be a subset of $\mathcal{B}^{<\omega}$ rather than $\mathcal{B}^n$ for some n, and we do not allow parameters in the definitions.

are uniformly r.i. computable in $\mathcal{B}$ and $\mathcal{A}$ respectively. (Here $\tilde{f}^{\mathcal{B}}_{\mathcal{A}}\colon (D^{\mathcal{B}}_{\mathcal{A}})^{<\omega} \to \mathcal{A}^{<\omega}$ is the obvious extension of $f^{\mathcal{B}}_{\mathcal{A}}\colon D^{\mathcal{B}}_{\mathcal{A}} \to \mathcal{A}$.)

In the next lemma, we see how effective-bi-interpretability preserves most computability theoretic properties.

Lemma 5.3. *Let $\mathcal{A}$ and $\mathcal{B}$ be effectively-bi-interpretable.*

(1) *$\mathcal{A}$ and $\mathcal{B}$ have the same degree spectrum.*

(2) *$\mathcal{A}$ is computably categorical if and only if $\mathcal{B}$ is.*

(3) *$\mathcal{A}$ and $\mathcal{B}$ have the same computable dimension.*

(4) *$\mathcal{A}$ is rigid if and only if $\mathcal{B}$ is.*

(5) *$\mathcal{A}$ and $\mathcal{B}$ have the same Scott rank.*

(6) *For every $\bar{a} \in \mathcal{A}^{<\omega}$, there is a $\bar{b} \in \mathcal{B}^{<\omega}$ such that $(\mathcal{A}, \bar{a})$ and $(\mathcal{B}, \bar{b})$ have the same computable dimension, and vice-versa.*

(7) *For every $R \subseteq \mathcal{A}^{<\omega}$, there is a $Q \subseteq \mathcal{B}^{<\omega}$ which has the same degree spectrum, and vice-versa.*

(8) *$\mathcal{A}$ has the c.e. extendibility condition if and only if $\mathcal{B}$ does.*

(9) *The index sets of $\mathcal{A}$ and $\mathcal{B}$ are Turing equivalent, assuming $\mathcal{A}$ and $\mathcal{B}$ are infinite structures.*

(10) *The jumps of $\mathcal{A}$ and $\mathcal{B}$ are effectively-bi-interpretable.*

(Of course, items 2-10 assume $\mathcal{A}$ and $\mathcal{B}$ are computable.)

Sketch of the proof. Throughout this proof, assume that $\mathcal{A}$ is the presentation that is coded inside $\mathcal{B}^{<\omega}$, i.e. with domain $D^{\mathcal{B}}_{\mathcal{A}}$, and $\tilde{\mathcal{B}}$ is the copy of $\mathcal{B}$ coded inside $\mathcal{A}^{<\omega}$, i.e. with domain $D^{\mathcal{A}}_{\mathcal{B}} = D^{\mathcal{D}^{\mathcal{B}}_{\mathcal{A}}}_{B}$. We let f be the isomorphism from $\tilde{\mathcal{B}}$ to $\mathcal{B}$.

For part 1, just observe that via the Σ-interpretation, given a copy of $\mathcal{B}$, we can enumerate a copy of $\mathcal{A}$, and hence compute one.

For part 2, we need the following observation: Let $\mathcal{B}_1$ and $\mathcal{B}_2$ be copies of $\mathcal{B}$, and let $\mathcal{A}_1$ and $\mathcal{A}_2$ be the presentations of $\mathcal{A}$ coded inside $\mathcal{B}_1^{<\omega}$ and $\mathcal{B}_2^{<\omega}$ respectively. The point we need to make here is that if $\mathcal{A}_1$ and $\mathcal{A}_2$ are computably isomorphic, then so are $\mathcal{B}_1$ and $\mathcal{B}_2$: A computable isomorphism between $\mathcal{A}_1$ and $\mathcal{A}_2$ induces a computable isomorphism between $\tilde{\mathcal{B}}_1$ and $\tilde{\mathcal{B}}_2$, which each are computably-isomorphic to $\mathcal{B}_1$ and $\mathcal{B}_2$ respectively. Thus, if $\mathcal{A}$ is computably categorical, so is $\mathcal{B}$. For 3, we have that if $\mathcal{B}$ has k non-computably isomorphic copies $\mathcal{B}_1, ..., \mathcal{B}_k$, then the respective structures $\mathcal{A}_1, ..., \mathcal{A}_k$ cannot be computably isomorphic either. So the effective dimension of $\mathcal{A}$ is at least that of $\mathcal{B}$, and hence, by symmetry, they must be equal.

For part 4, suppose $\mathcal{B}$ is not rigid. Let h be a nontrivial automorphism of $\mathcal{B}$. It then induces an automorphism of $\mathcal{B}^{<\omega}$, which then induces an automorphism g of $\mathcal{A}$, which then induces an automorphism h_1 of $\tilde{\mathcal{B}}$. Since f is invariant, we have $h \circ f = f \circ h_1$ and, since h is nontrivial, h_1 is not trivial either. It follows that the automorphism g of $\mathcal{A}$ cannot be trivial either.

For part 5, suppose that $SR(\mathcal{A}) = \alpha$, that is, that every automorphism orbit in $\mathcal{A}$ is $\Sigma^{\mathtt{in}}_\alpha$ definable. Take a tuple $\bar{b} \in \mathcal{B}^{<\omega}$; we will show its orbit is also $\Sigma^{\mathtt{in}}_\alpha$ definable. Let $\bar{c} \in \tilde{\mathcal{B}}^{<\omega} \subseteq \mathcal{B}^{<\omega}$ be such that $f(\bar{c}) = \bar{b}$. The orbit of $\bar{c}$ is $\Sigma^{\mathtt{in}}_\alpha$ definable inside $\mathcal{A}$, and since

$\mathcal{A}$ is $\Sigma^{\mathtt{c}}_1$-definable in $\mathcal{B}$, the orbit of $\bar{c}$ is also $\Sigma^{\mathtt{in}}_\alpha$ definable in $\mathcal{B}$. Since f is $\Sigma^{\mathtt{c}}_1$-definable in $\mathcal{B}$, the orbit of $\bar{b}$ is also $\Sigma^{\mathtt{in}}_\alpha$ definable. It follows that $SR(\mathcal{B}) \leq \alpha$, and, by symmetry, that $SR(\mathcal{B}) = \alpha$.

For part 6, think of $\bar{a}$ as a tuple in $(D^B_{\mathcal{A}})^{<\omega} \subseteq \mathcal{B}^{<\omega}$ and call it $\bar{b}$. It is not hard to show that $(\mathcal{A}, \bar{a})$ and $(\mathcal{B}, \bar{b})$ are effectively-bi-interpretable.

For part 7, think of R as a subset of $(D^B_{\mathcal{A}})^{<\omega} \subseteq \mathcal{B}^{<\omega}$ and call it Q. Clearly, for every copy of $\mathcal{B}$, R and Q have the same degree. Conversely, for each copy of $\mathcal{A}$, if we look at the copy of $\mathcal{B}$ inside and then at the one of $\mathcal{A}$ inside it, we get that R and Q have the same degree too.

For part 8, all we have to notice is that each $\exists$-type in $\mathcal{A}$ is 1-1 reducible to a $\Sigma^{\mathtt{c}}_1$-type in $\mathcal{B}$, and vice-versa.

For part 9, given an index of a structure that we want to know if it is isomorphic to $\mathcal{B}$, we can produce an index for the structure that is then supposed to be isomorphic to $\mathcal{A}$. If it is not, then we know the original structure was not isomorphic to $\mathcal{B}$. If it is, we need to check that the bi-interpretability does produce an isomorphism, which $0''$ can check. One has to notice that all index sets compute $0''$, as their domain must be infinite.

Last, for part 10, it is not hard to interpret the complete r.i.c.e. relations from one structure into the other by interpreting $\Sigma^{\mathtt{c}}_1$-formulas in one by $\Sigma^{\mathtt{c}}_1$ formulas in the other. □

5.2. Reduction via effective-bi-interpretability. As we mentioned before, uniform r.i.c.e. sets are $\Sigma^{\mathtt{c}}_1$ definable. So, an effective-bi-interpretation is given by a list of $\Sigma^{\mathtt{c}}_1$ formulas defining all the relations involved. When we fix these formulas, we obtain a map from one kind of structure into another (which might not always define a bi-interpretation). We can use this to define a reducibility between classes:

Definition 5.4. A class $\mathbb{K}$ is *reducible to* $\mathbb{S}$ *via effective-bi-interpretability* if there are $\Sigma^{\mathtt{c}}_1$ formulas such that for every $\mathcal{A} \in \mathbb{K}$, there is a $\mathcal{B} \in \mathbb{S}$ such that $\mathcal{A}$ and $\mathcal{B}$ are effectively-bi-interpretable using those formulas. A class $\mathbb{K}$ is *on top for effective-bi-interpretability* if for every computable language $\mathcal{L}$, the class of $\mathcal{L}$-structures is reducible to $\mathbb{K}$ via effective-bi-interpretability.

Not much is known about this definition. Classes that are Σ-small are not on top for effective-bi-interpretability for the same reason they are not HKSS-complete. Classes that have bounded Scott rank cannot be on top because effective-bi-interpretability preserves Scott ranks. Using the interpretations defined by Hirschfeldt, Khoussainov, Shore and Slinko [28], we get the following: undirected graphs, partial orderings, and lattices are on top for effective-bi-interpretability; if we add a finite set of constants to the languages of integral domains, commutative semigroups, or 2-step nilpotent groups, they become on top for effective-bi-interpretability too. A recent result by R. Miller, J. Park, B. Poonen, H. Schoutens, and A. Shlapentokh [53] shows that fields are on top for effective-bi-interpretability.

Acknowldgements. The author was partially supported the Packard Fellowship. The author would like to thank Matthew Harrison-Trainor and Noah Schweber for useful comments on an earlier draft of this paper.

Recent developments in finite Ramsey theory: foundational aspects and connections with dynamics

Sławomir Solecki

Abstract. We survey some recent results in Ramsey theory. We indicate their connections with topological dynamics. On the foundational side, we describe an abstract approach to finite Ramsey theory. We give one new application of the abstract approach through which we make a connection with the theme of duality in Ramsey theory. We finish with some open problems.

Mathematics Subject Classification (2010). 03E15, 05D10, 22F50.

Keywords. Ramsey theory, extreme amenability, duality in Ramsey theory.

1. Ramsey theory and topological dynamics

Recent years have seen a renewed interest in Ramsey theory that lead to advances both in proving new concrete Ramsey results and in developing the foundational aspects of the theory. To a large extent this interest in Ramsey theory was sparked by the discovery of its close connections with topological dynamics and especially with the notion of extreme amenability and related to it problem of computing universal minimal flows of topological groups. A topological group is called **extremely amenable** if each continuous action of it on a compact (always assumed Hausdorff) space has a fixed point. First such groups were discovered by Herer and Christensen [13] using functional analytic methods. It was then shown by Veech [40] that extremely amenable groups cannot be locally compact. It turned out, however, that some very interesting groups are extremely amenable; for example, Gromov and Milman [12] showed that the unitary group of a separable infinite dimensional Hilbert space, taken with the strong operator topology and with composition as the group operation, is extremely amenable. The proof in [12] of this theorem used probabilistic methods of concentration of measure through the notion of Lévy group. (Lévy groups are topological groups possessing an increasing sequence of compact subgroups with dense union and with concentration of measure exhibited by the sequence of the normalized Haar measures on the compact subgroups.) Concentration of measure grew to be one of the two main methods used in proving extreme amenability.

It was not until Pestov's paper [27] that the second general method—Ramsey theory—was discovered. Pestov showed that the group of all increasing bijections from $\mathbb{Q}$ to itself, with pointwise convergence topology and composition as the group operation, is extremely amenable. His proof used the classical Ramsey theorem in a way that appeared, as it turned

Proceedings of the International Congress of Mathematicians, Seoul, 2014

out correctly, fundamental. Pestov's article was followed by two papers by Glasner and Weiss [7] and [8], one of which [8] used the dual Ramsey theorem of Graham and Rothschild, see Theorem 3.3 below, to determine the universal minimal flow of the group of all homeomorphisms of the Cantor set. The full and unexpectedly tight connection between extreme amenability and Ramsey theory was then established by Kechris, Pestov, and Todorcevic in [15].

Theorem 1.1 below is the main result of the theory found in [15]. (Paper [25] contains some further developments.) Recall that a topological group is **non-Archimedean** if it has a basis at the identity consisting of open subgroups. A structure, which we understand in the sense of Model Theory, is **ultrahomogeneous** if each isomorphism between two finite substructures extends to an automorphism of the whole structure, and it is **locally finite** if its finitely generated substructures are finite. A class $\mathcal{F}$ of finite structures is said to have the **Ramsey property** if for any positive integer c any two structures A and B in $\mathcal{F}$ there is a structure C in $\mathcal{F}$ such that for each coloring with c colors of all substructures of C isomorphic to A there is a substructure B' of C isomorphic to B such that substructures of B' isomorphic to A get the same color.

Theorem 1.1 (Kechris–Pestov–Todorcevic [15]). *Let G be a non-Archimedean, second countable, completely metrizable group. Then G is extremely amenable if and only if G is isomorphic to the group of all automorphisms (taken with the pointwise convergence topology and composition as the group operation) of a countable, ultra-homogeneous, locally finite structure A such that*

- *A is linearly ordered and*
- *the class of all finite substructures of A has the Ramsey property.*

For example, $\mathbb{Q}$ taken with its linear order is ultrahomogeneous, locally finite, linearly ordered, and the class of its finite substructures consists of finite linear orders, which has the Ramsey property by the classical theorem of Ramsey [30]. This gives back Pestov's theorem [27] mentioned above. More broadly, Theorem 1.1 related topological dynamics to Ramsey theory for finite structures, the latter having been developed by Nešetřil, Rödl [22–24], Abramson and Harrington [1], and others.

As it turned out, the connection from Theorem 1.1 suggested new Ramsey results. One, although not the only one, way this took place was through comparisons with the concentration of measure method. Given a group whose extreme amenability was proved using concentration of measure, one could sometimes formulate a Ramsey statement that would yield the extreme amenability, and then ask if the Ramsey statement itself held. On the other hand, one could also ask for Ramsey statements that gave extreme amenability in situations to which concentration of measure did not apply. We give below two examples, one on either side.

The following theorem for finite linearly ordered metric spaces was proved by Nešetřil [21]. In its statement by an **order isometry** from a linearly ordered metric space A to a linearly ordered metric space B we understand a bijection from A to B that preserves the metric and the linear order.

Theorem 1.2 (Nešetřil [21]). *Given a positive integer c and two finite linearly ordered metric spaces A and B, there exits a finite linearly ordered metric space C such that for each coloring with c colors of all subspaces of C order isometric to A there exists a subspace B'*

of C order isometric to B such that all subspaces of B' order isometric to A have the same color.

The theorem above implies, as shown in [15], that the group of all isometries of the separable Urysohn metric space taken with the pointwise convergence topology is extremely amenable. Extreme amenability of this group was earlier established by Pestov in [28] with concentration of measure methods.

To state the second theorem, also resulting from analyzing connections between Ramsey theory, concentration of measure, and extreme amenability, consider the following notions. Let $[n]$ stand for the set $\{1, 2, \dots, n\}$. Given a prime number p, let $(\mathbb{Z}/p)^{n:l}$ be the set of all partial functions from $[n]$ to $\mathbb{Z}/p$ whose domains have at least $n-l$ elements, and let $(\mathbb{Z}/p)^n$ be the set of all functions from $[n]$ to $\mathbb{Z}/p$. A set $L \subseteq (\mathbb{Z}/p)^{n:l}$ is called **full** if there exists $h \in (\mathbb{Z}/p)^n$ and $a \subseteq [n]$ with $n - l$ elements such that for each $r \in \mathbb{Z}/p$

$$(r + h) \restriction a_r \in L$$

for some $a \subseteq a_r \subseteq [n]$.

We now have the following Ramsey theorem. We will come back to it in the last section of the paper when discussing open problems.

Theorem 1.3 (Farah–Solecki [4]). *Let $p_1, \dots, p_k$ be prime numbers, and let c be a positive integer. Then*

$$\exists l_1 \forall n_1 \geq l_1 \cdots \exists l_k \forall n_k \geq l_k \textit{ for each coloring of } \textstyle\prod_{i=1}^{k} (\mathbb{Z}/p)^{n_i:l_i} \textit{ with } c \textit{ colors}$$

there exist full sets $L_1 \subseteq (\mathbb{Z}/p_1)^{n_1:l_1}, \dots, L_k \subseteq (\mathbb{Z}/p_k)^{n_k:l_k}$ with $L_1 \times \cdots \times L_k$ monochromatic.

The proof of the above result uses Lovasz's method for calculating the chromatic numbers of the Kneser graphs, see [17]. The theorem above implies that, for example, $L_0(\phi, A)$ is extremely amenable. The group $L_0(\phi, A)$ is the completion of the group of all continuous functions (with pointwise addition) from the Cantor set $2^{\mathbb{N}}$ to a finite abelian group A with respect to convergence in ϕ, where ϕ is a diffuse *submeasure* on all closed-and-open subsets of $2^{\mathbb{N}}$. (These groups are related to the ones considered by Herer and Christensen [13].) On the other hand, it is shown in [4] that extreme amenability of $L_0(\phi, A)$ as above cannot be proved using the concentration of measure method—such groups are not Lévy despite possessing sequences of compact subgroups with dense unions.

There are many other examples of recently found Ramsey theorems with application to topological dynamics; for a sample, see [14, 25], or [32].

2. Finite Ramsey theory—abstract approach

The Kechris–Pestov–Todorcevic theory lead indirectly to rethinking of the foundations of finite Ramsey theory. In this section, we present an abstract approach to finite Ramsey theory from [35]. This approach recovers most of the core Ramsey theory and makes it possible to prove new results. At the same time, it reveals the formal algebraic structure underlying finite Ramsey theorems: there exist a single type of structure, called Ramsey domain over a normed composition space, that underlies Ramsey theorems. One formulates within this

algebraic setting an abstract pigeonhole principle and an abstract Ramsey statement, and proves, as the main theorem, that the pigeonhole principle implies the Ramsey statement. This abstract Ramsey theorem, which we state at the end of this section as Theorem 2.1, gives particular Ramsey theorems as instances, or iterative instances, for particular Ramsey domains.

We outline the general approach in this section. For details and proofs the reader should consult [35]. We give one new concrete application in the next section, which will allow us to illustrate the abstract notions in a concrete situation and also to discuss the theme of duality in Ramsey theory. We ask the reader to consult [35, 36], and [42] for more concrete applications. Let us only mention here that the following theorems can be obtained as particular instances of the abstract approach to Ramsey theory, see [35, 36], and [42]:

— the classical Ramsey theorem, see [20];

— the Hales–Jewett theorem, see [20];

— the Graham–Rothschild theorem, [9], see also [20];

— the versions of the two results directly above for partial rigid surjections due to Voigt, [41], see also [20];

— a self-dual Ramsey theorem, [35];

— the Milliken Ramsey theorem for finite trees, [18], see also [31];

— a common generalization of Deuber's and Jasiński's Ramsey theorems for finite trees, [2, 14];

— Spencer's generalization of the Graham–Rothschild theorem and the Ramsey theorem for affine subspaces, [38];

— dual Ramsey theorem for trees, [36].

2.1. Normed composition spaces. The algebraic structure is initially defined at the level of points and it is lifted later to the level of sets. We describe first the point level structure. Let A and X be sets. Assume we are given a *partial* function from $A \times A$ to A,

$$(a, b) \to a \cdot b \in A,$$

and a *partial* function from $A \times X$ to X,

$$(a, x) \to a \,.\, x \in X,$$

such that for $a, b \in A$ and $x \in X$ if $a \,.\, (b \,.\, x)$ and $(a \cdot b) \,.\, x$ are both defined, then

$$a \,.\, (b \,.\, x) = (a \cdot b) \,.\, x.$$

The above equation is just the usual action condition. We assume we also have a function $\partial\colon X \to X$ and a function $|\cdot|\colon X \to L$, where L is equipped with a partial order $\leq$. The operations $\cdot$ and $\,.\,$ are called a **multiplication** and an **action** (of A on X), respectively. We call ∂ a **truncation** and $|\cdot|$ a **norm**.

A structure $(A, X, \,.\,, \cdot, \partial, |\cdot|)$ as above is called a **normed composition space** if the following conditions hold for $a \in A$ and $x, y \in X$:

(i) if $a \,.\, x$ and $a \,.\, \partial x$ are defined, then

$$\partial(a \,.\, x) = a \,.\, \partial x;$$

(ii) $|\partial x| \leq |x|$;

(iii) if $|x| \leq |y|$ and $a \,.\, y$ is defined, then $a \,.\, x$ is defined and $|a \,.\, x| \leq |a \,.\, y|$.

The conditions above record the interactions between pairs of objects among $\,.\,$, ∂, and $|\cdot|$. So the action is done by homomorphisms with respect to the truncation, by (i), the truncation does not increase the norm, by (ii), and the action respects the norm, by (iii).

We isolate one notion that will turn out to be useful later on. Given $a, b \in A$, we say that b **extends** a if for each x for which $a \,.\, x$ is defined, $b \,.\, x$ is defined as well and is equal to $a \,.\, x$.

For $t \in \mathbb{N}$, we write ∂^t for the t-th iteration of ∂. For a subset P of X, we write $\partial P = \{\partial x \colon x \in P\}$.

2.2. Ramsey domains. Here we lift the algebraic structure from points to subsets of A and X. Let $\mathcal{F}$ and $\mathcal{P}$ be families of non-empty subsets of A and X, respectively. Assume we have a *partial* function from $\mathcal{F} \times \mathcal{F}$ to $\mathcal{F}$,

$$(F, G) \to F \bullet G \in \mathcal{F},$$

with the property that if $F \bullet G$ is defined, then it is given point-wise, that is, $f \cdot g$ is defined for all $f \in F$ and $g \in G$ and

$$F \bullet G = \{f \cdot g \colon f \in F,\ g \in G\}.$$

Assume we also have a *partial* function from $\mathcal{F} \times \mathcal{P}$ to $\mathcal{P}$,

$$(F, P) \to F \bullet P \in \mathcal{P},$$

such that if $F \bullet P$ is defined, then $f \,.\, x$ is defined for all $f \in F$ and $x \in P$ and

$$F \bullet P = \{f \,.\, x \colon f \in F,\ x \in P\}.$$

The structure $(\mathcal{F}, \mathcal{P}, \bullet, \bullet)$ as above is called a **Ramsey domain** over the normed composition space $(A, X, \,.\,, \cdot, \partial, |\cdot|)$ if the following conditions hold:

(a) if $F, G \in \mathcal{F}$, $P \in \mathcal{P}$, and $F \bullet (G \bullet P)$ is defined, then so is $(F \bullet G) \bullet P$;

(b) if $P \in \mathcal{P}$, then $\partial P \in \mathcal{P}$;

(c) if $F \in \mathcal{F}$, $P \in \mathcal{P}$, and $F \bullet \partial P$ is defined, then there is $G \in \mathcal{F}$ such that $G \bullet P$ is defined and for each $f \in F$ there is $g \in G$ extending f.

The following two conditions on Ramsey domains are crucial in running inductive arguments. A Ramsey domain is called **vanishing** if for each $P \in \mathcal{P}$ there is $t \in \mathbb{N}$ such that the set $\partial^t P$ has one element. It is called **linear** if for each $P \in \mathcal{P}$, the set $\{|x| \colon x \in P\}$ is a linearly ordered subset of L. The first one of these conditions makes it possible to start inductive arguments, the second one is used to organize induction.

2.3. Ramsey theorem. Using the structure described earlier, we state here the abstract Ramsey theorem—Theorem 2.1. The theorem will say that an appropriate pigeonhole principle implies an appropriate Ramsey condition. The following statement is our Ramsey condition for a Ramsey domain $(\mathcal{F}, \mathcal{P}, \bullet, \bullet)$.

(R) Given a positive integer c, for each $P \in \mathcal{P}$, there is an $F \in \mathcal{F}$ such that $F \bullet P$ is defined, and for every coloring with c colors of $F \bullet P$ there is an $f \in F$ such that $f \,.\, P$ is monochromatic.

For $P \subseteq X$ and $y \in X$, put

$$P_y = \{x \in P \colon \partial x = y\}.$$

For $F \subseteq A$ and $a \in A$, let

$$F_a = \{f \in F \colon f \text{ extends } a\}.$$

The following criterion is our pigeonhole principle, which we called local pigeonhole principle in [35] and denoted it there by (LP). We keep this notation here.

(LP) Given a positive integer c, for all $P \in \mathcal{P}$ and $y \in \partial P$, there are $F \in \mathcal{F}$ and $a \in A$ such that $F \bullet P$ is defined, $a \,.\, y$ is defined, and for every coloring with c colors of $F_a \,.\, P_y$ there is an $f \in F_a$ such that $f \,.\, P_y$ is monochromatic.

The following is the abstract Ramsey theorem.

Theorem 2.1 (Solecki [36]). *Let $(\mathcal{F}, \mathcal{P}, \bullet, \bullet)$ be a linear, vanishing Ramsey domain over a normed composition space. Assume that each set in $\mathcal{P}$ is finite. Then (LP) implies (R).*

3. Duality and the dual Ramsey theorem for trees

In this section, we touch on the theme of duality. In Ramsey theory for finite structures, Abramson–Harrington, Nešetřil–Rödl's theorem [1, 24] has a dual counterpart due to Prömel [29]. This duality was made precise and shown to extend to proofs in [33] and [34]. In the unstructured Ramsey theory, the classical theorem of Ramsey [30] has a dual counterpart due to Graham and Rothschild [9]. We will extend here this last instance of duality to trees and we will relate it to the concept of Galois connection. This new concrete Ramsey result will also allow us to give an illustration of the abstract notions presented in the previous section.

3.1. The context for duality among trees–Galois connections. Let $(S, \sqsubseteq_S)$ and $(T, \sqsubseteq_T)$ be two partial orders. A pair (f, e) is called a **Galois connection** if $f \colon T \to S$, $e \colon S \to T$, and

$$e \circ f \sqsubseteq_T \mathrm{id}_T \text{ and } f \circ e \sqsupseteq_S \mathrm{id}_S, \tag{3.1}$$

that is, $e(f(w)) \sqsubseteq_T w$ and $v \sqsubseteq_S f(e(v))$ for all $w \in T$ and $v \in S$. Usually the functions e and f in a Galois connection are assumed to be monotone. It is crucial for us, however, to use the more relaxed notion given above. Galois connections in their abstract form were first defined by Ore in [26]; for a comprehensive treatment see [5]. As already noticed by Ore, of particular importance are Galois connections fulfilling a strengthening of (3.1) consisting of assuming that equality holds in one of the two inequalities in (3.1). (Ore called such

connections perfect.) Since the situation we consider, when the partial orders are trees, is asymmetric, only one of these strengthenings is interesting—the one with equality holding in the second formula in (3.1), in which case (3.1) becomes

$$e \circ f \sqsubseteq_T \mathrm{id}_T \text{ and } f \circ e = \mathrm{id}_S. \tag{3.2}$$

Galois connections with (3.2) are sometimes called embedding–projection pairs, and are important in denotational semantics of programming languages, see for example [3].

3.2. The notion of rigid surjection and the dual Ramsey theorem for trees. By a **tree** we understand a finite, partially ordered set with a smallest element, called **root**, and such that the set of predecessors of each element is linearly ordered. So below, *all trees are non-empty and finite*. Maximal elements of the tree order are called **leaves**. We always denote the tree order on T by $\sqsubseteq_T$.

Each tree T carries a binary function $\wedge_T$ that assigns to each $v, w \in T$ the largest with respect to $\sqsubseteq_T$ element $v \wedge_T w$ of T that is a predecessor of both v and w. By convention, we regard every node of a tree as one of its own predecessors and as one of its own successors.

For a tree T and $v \in T$, let $\mathrm{im}_T(v)$ be the set of all **immediate successors** of v, and we do not regard v as one of them. A tree T is called **ordered** if for each $v \in T$ we have a fixed linear order on $\mathrm{im}_T(v)$. Such an assignment of linear orders defines the lexicographic linear order $\leq_T$ on all the nodes of T by stipulating that $v \leq_T w$ if v is a predecessor of w and, in case v is not a predecessor of w and w is not a predecessor of v, that $v \leq_T w$ if the predecessor of v in $\mathrm{im}_T(v \wedge w)$ is less than or equal to the predecessor of w in $\mathrm{im}_T(v \wedge w)$ in the given order on $\mathrm{im}_T(v \wedge w)$.

Let S and T be ordered trees. A function $e\colon S \to T$ is called a **morphism** if the following conditions hold:

(i) $e(v \wedge_S w) = e(v) \wedge_T e(w)$, for all $v, w \in S$;

(ii) e is monotone between $\leq_S$ and $\leq_T$, that is, $v \leq_S w$ implies $e(v) \leq_T e(w)$, for all $v, w \in S$;

(iii) e maps the root of S to the root of T.

Now we give the definition of functions appearing in the dual Ramsey theorem for trees. Let S, T be ordered trees. A function $f\colon T \to S$ is called a **rigid surjection** provided there exists a morphism $e\colon S \to T$ such that equation (3.2) holds. It is not difficult to see that in this situation f determines e uniquely, so the definition above could be stated without invoking e.

Here is the dual Ramsey theorem for trees.

Theorem 3.1 (Solecki [37]). *Let c be a positive integer. Let S, T be ordered trees. There exists an ordered tree U such that for each coloring with c colors of all rigid surjections from U to S there is a rigid surjection $g_0\colon U \to T$ such that*

$$\{f \circ g_0\colon f\colon T \to S \text{ a rigid surjection}\}$$

is monochromatic.

Ramsey theorems for trees proved so far were usually stated in terms of injective morphisms e; see [36] for a survey. (An exception here is the dual Ramsey theorem of Graham–Rothschild, which we discuss below.) Each such injective morphism e is an element of a

unique pair (f, e) with the pair fulfilling (3.2) and with f being a surjective morphism. In this situation, when both e and f are morphisms, e determines f and f determines e. So Ramsey theorems formulated in terms of e can be equivalently stated in terms of pairs (f, e) or in terms of f. One could call the formulation in terms of f dual. Now, it turns out, that on the dual side, surjective morphisms f are part of a much richer family of functions—rigid surjections; one abandons the assumption that f is a morphism and obtains a Ramsey theorem for this larger class of functions. In fact, the statement for the larger class easily implies the statements for morphisms. We discuss it briefly below.

An injective morphism between ordered trees is called an **embedding**. An image of a tree S under an embedding from S to T is called a **copy** of S in T. The following theorem is due to Leeb, see [10].

Theorem 3.2 (Leeb). *Given a positive integer c and ordered trees S and T, there is an ordered tree U such that for each coloring with c colors of all copies of S in U there is a copy T' of T in U such that all copies of S in T' get the same color.*

An embedding uniquely determines a copy which is the image of the embedding, but also vice versa, a copy uniquely determines an embedding of which it is the image. So the theorem above can be restated in terms of embeddings and can be easily seen to be a particular case of Theorem 3.1 by viewing an embedding e as an element of pairs (f, e) fulfilling (3.2).

Theorem 3.1 also generalizes the dual Ramsey theorem of Graham–Rothschild, as we indicate below. A k-**partition** of a set X is a family of k non-empty pairwise disjoint subsets of X whose union is X. A k-partition $\mathcal{P}$ is an k-**subpartition** of an l-partition $\mathcal{Q}$ if each element of $\mathcal{P}$ is the union of some elements of $\mathcal{Q}$. For $m \in \mathbb{N}$, let $[m]$ be the set $\{1, \dots, m\}$. The following is the dual Ramsey theorem of Graham and Rothschild [9]. (We come back to it in the last section of the paper.)

Theorem 3.3 (Graham–Rothschild [9]). *Let c be a positive integer. For each k, l, there exists m such that for each coloring with c colors of all k-partitions of $[m]$ there exists an l-partition $\mathcal{Q}$ of $[m]$ such that all k-subpartitions of $\mathcal{Q}$ get the same color.*

If $\mathcal{P}$ a k-partition of $[m]$, then we can write $\mathcal{P} = \{p_1, \dots, p_k\}$ with $\min p_i < \min p_{i+1}$, for $1 \leq i < k$, and define $f_{\mathcal{P}} \colon [m] \to [k]$ by

$$f_{\mathcal{P}}(x) = \text{ the unique } i \text{ such that } x \in p_i.$$

Note that $[m]$, for $m \in \mathbb{N}$, is an ordered tree if we take $[m]$ with its natural order relation and with the unique trivial ordering of the immediate successors of each vertex. If $[m]$ is treated as a tree, $f_{\mathcal{P}} \colon [m] \to [k]$ is a rigid surjection. This observation leads to a restatement of the Graham–Rothschild theorem in terms of rigid surjections. This restatement follows easily from Theorem 3.1 by considering ordered trees $S = [k]$ and $T = [l]$ and viewing the resulting tree U with its linear order $\leq_U$ only (and forgetting its tree order $\sqsubseteq_U$).

3.3. Description of algebraic structures for the dual Ramsey theorem for trees. We describe here concrete examples of the general structures defined in Section 2 that are used to prove Theorem 3.1. For technical reasons, we consider only a restricted class of rigid surjections. One proves Theorem 3.1 for this restricted class and then derives the full version of the theorem from the restricted one. For ordered trees S, T, a rigid surjection $f \colon T \to S$

is called **sealed** if $f^{-1}(v) = \{w\}$, where v is $\leq_S$-largest in S and w is $\leq_T$-largest in T. For $w \in T$, let

$$T^w = \{v \in T \colon v \leq_T w\},$$

and for $f \colon T \to S$ and $v \in S$, let

$$f^v = f \restriction T^{e(v)},$$

where $e \colon S \to T$ is the unique morphism with (f, e) fulfilling (3.2).

Now we define a normed composition space. Let $\mathcal{L}$ be a family of ordered trees such that for $T \in \mathcal{L}$ and $w \in T$, we have $T^w \in \mathcal{L}$. We will specify $\mathcal{L}$ later. The sets A and X will be equal to each other, as will be the operations $.$ and $\cdot$. We let $A = X$ be the set of all sealed rigid surjections $g \colon T_2 \to T_1$ for $T_1, T_2 \in \mathcal{L}$. Let $f, g \in A = X$. We let $g \cdot f = g \,.\, f$ be defined precisely when $f \colon T^y \to S$ and $g \colon V \to T$ for some ordered trees $S, T, V \in \mathcal{L}$ and a vertex y in T. We let

$$g \cdot f = g \,.\, f = f \circ g^y.$$

For $f \in X$ whose image is a tree S define ∂f as follows. If S consists only of its root, let

$$\partial f = f.$$

If S has a vertex that is not a root, let v be the second $\leq_S$-largest vertex in S, and let

$$\partial f = f^v.$$

Consider $\mathcal{L}$ as a partial order with the partial order relation given by requiring that T_1 be less than T_2 if and only if there exists $w \in T_2$ with $T_1 = T_2^w$. For $f \in X$, let

$$|f| = (\text{domain of } f) \in \mathcal{L}.$$

It is easy to check that the structure $(A, X, \ .\ , \cdot, \partial, |\cdot|)$ defined above is a normed composition space.

Now we define a Ramsey domain over this normed composition space. To specify $\mathcal{L}$, fix a family $\mathcal{T}$ of ordered trees such that each ordered tree has an isomorphic copy in $\mathcal{T}$ and such that $T_1 \cap T_2 = \emptyset$, for $T_1, T_2 \in \mathcal{T}$, and let

$$\mathcal{L} = \{T^w \colon T \in \mathcal{T},\ w \in T\}.$$

We consider non-empty sets $K \subseteq A = X$ for which there exist ordered trees T_1, T_2 such that each element of K has its domain included in T_2 and its image equal to T_1. We require that $T_2 \in \mathcal{T}$. Since the trees in $\mathcal{T}$ are pairwise disjoint, each element of K determines T_2. We define $d(K) = T_2$ and $r(K) = T_1$. Now, let $\mathcal{F}$ consist of all such sets K with $r(K) \in \mathcal{T}$, and let $\mathcal{P}$ consist of all such sets K with $r(K) \in \mathcal{L}$. For $F_1, F_2, F \in \mathcal{F}$ and $P \in \mathcal{P}$, let $F_1 \bullet F_2$ and $F \bullet P$ be defined precisely when $d(F_2) = r(F_1)$ and $d(P) = r(F)$, respectivly. In these cases, we let

$$F_1 \bullet F_2 = F_1 \cdot F_2 \ \text{ and } \ F \bullet P = F \,.\, P.$$

Again one checks that the structure defined above is a Ramsey domain that is linear and vanishing. Condition (R) for it gives the statement of the dual Ramsey theorem for trees (for sealed surjections); condition (LP) for it is proved using a version of the Hales–Jewett theorem, but we will not describe this argument here. For all the proofs the reader may consult [37].

4. Further developments and problems

We present below two groups of problems. Both of them aim at extending, in two different ways, the point of view from Section 2 beyond its original context. The first problem has to do with unifying the approach to finite Ramsey theory of [35], which was described in Section 2, with Todorcevic's infinite Ramsey theory of [39]. Issues in the second group center around proving certain analogous or finding a better understanding of Theorems 1.1, 1.3 and 3.3 presented earlier.

First, there exists a general approach to *infinite* Ramsey theory given by Todorcevic in [39] that incorporates earlier work of Nash-Williams, Ellentuck, and Carlson, among others. Roughly speaking, this is a theory of finding infinite sequences (x_n) such that the set of all infinite sequences formed from (x_n) by, for example, amalgamating or taking subsequences or acting by a semigroup, is monochromatic. The question arises whether one can view the approach to finite Ramsey theory outlined in Section 2 as a starting point, or as the underlying layer, of the infinite Ramsey theory. For example, given a normed composition space $(A, X, \, .\, , \cdot, \partial, |\cdot|)$ as in Section 2, it is natural to consider the space of sequences

$$\varprojlim(X, \partial) = \{(x_n) \in X^{\mathbb{N}} \colon x_n = \partial x_{n+1} \text{ for each } n \in \mathbb{N}\}$$

with the induced partial action of A. It seems plausible that Todorcevic's theory can be recovered in spaces of the form $\varprojlim(X, \partial)$, which would unify the two approaches.

Second, there exist certain Ramsey statements that point to a possible relationship of Ramsey theory with combinatorial tools coming from algebraic topology as in [17] or from fixed point theorems in convex analysis. (A similar view is expressed by Gromov in [11, Introduction to Section 1].) We may recall that Theorem 1.3 is proved using methods that originated with Lovasz's proof of Kneser's conjecture, which is done with the aid of insights coming from algebraic topology around the Lefschetz fixed point theorem. Below, we describe two other purely Ramsey theoretic statements with some intriguing additional features. Both of them merit attention in their own right. It would also be very interesting to see if the combinatorial methods stemming from algebraic topology as in [17] can be incorporated into the approach outlined in Section 2 to shed light on these or similar statements.

Moore [19] carried out an analysis, analogous to the Kechris–Pestov–Todorcevic [15] analysis described in Section 1, of amenability among non-Archimedean groups. As a by-product, he uncovered a Ramsey statement relevant to amenability of well known Thompson's group F. This is the group, under composition, of all piecewise linear increasing homeomorphisms of the interval $[0, 1]$ whose non-differentiability points are dyadic rationals and whose slopes are integer powers of 2. Moore found a Ramsey statement equivalent to amenability of F (establishing which is a major problem concerning this group). This Ramsey statement has a new feature—it involves convex combinations. We reproduce it below.

By a **binary tree** we understand an ordered tree T, as in Section 3.2, with the property that for each vertex $v \in T$ the set of its immediate successors $\mathrm{im}_T(v)$ has size 0 or 2. For $n \in \mathbb{N}$, $n > 0$, let $\mathbb{T}_n$ denote the set of all binary trees with n leaves. Given a sequence of binary trees $\vec{U} = (U_1, \dots, U_m)$ such that the number of leaves in all of them totals n and given a tree T in $\mathbb{T}_m$, let $T(\vec{U})$ be the tree in $\mathbb{T}_n$ that results from T by attaching U_i to the i-th leaf of T, where the leaves of T are numbered according to the linear order $\leq_T$ on T. The root of U_i is identified with the i-th leave of T in the resulting tree. Here is the Ramsey statement formulated by Moore.

For every m there exists $n \geq m$ such that for each coloring $c\colon \mathbb{T}_n \to \{0,1\}$ there exist non-negative numbers $\alpha_{\vec{U}}$, where $\vec{U}$ ranges over all m-tuples $\vec{U} = (U_1, \ldots, U_m)$ of binary trees with a total of n leaves, such that $\sum_{\vec{U}} \alpha_{\vec{U}} = 1$ and

$$\sum_{\vec{U}} \alpha_{\vec{U}} c(T(\vec{U}))$$

is constant as T varies over $\mathbb{T}_m$.

Theorem 4.1 (Moore [19]). *The above Ramsey statement is equivalent to amenability of Thompson's group F.*

More broadly, Moore's analysis of amenability parallel to the analysis of extreme amenability for non-Archimedean groups lead him to a general class of Ramsey statements phrased in terms of convex combinations. At this point, no statements of this form appear to be known that do not follow from ordinary Ramsey statements.

There is another Ramsey statement that seems to fit here. It was formulated by Kechris, Sokić and Todorcevic [16], and was motivated by the desire to give a Ramsey theoretic proof of the theorem of Giordano–Pestov [6] that the group of all measure preserving transformations of the interval $[0,1]$ with Lebesgue measure, taken with the weak topology, is extremely amenable. The original proof in [6] used concentration of measure. What appears to be a minor modification of the Graham–Rothschild theorem, Theorem 3.3 above, yields a Ramsey statement that would imply Giordano–Pestov's result. The statement, which was formulated in [16] and which we reproduce below, is not known to be true.

We say that a partition $\mathcal{Q}$ of a finite set X is **homogeneous** if any two sets in $\mathcal{Q}$ contain the same number of elements of X.

Given a positive integer c, for each k and l there exists m such that for each coloring with c colors of all homogeneous k-partitions of $[m]$ there exists a homogeneous l-partition $\mathcal{Q}$ of $[m]$ such that all homogeneous k-subpartitions of $\mathcal{Q}$ get the same color.

2. Algebra

On finite-dimensional Hopf algebras

Dedicado a Biblioco 34

Nicolás Andruskiewitsch

Abstract. This is a survey on the state-of-the-art of the classification of finite-dimensional complex Hopf algebras. This general question is addressed through the consideration of different classes of such Hopf algebras. Pointed Hopf algebras constitute the class best understood; the classification of those with abelian group is expected to be completed soon and there is substantial progress in the non-abelian case.

Mathematics Subject Classification (2010). 16T05, 16T20, 17B37, 16T25, 20G42.

Keywords. Hopf algebras, quantum groups, Nichols algebras.

1. Introduction

Hopf algebras were introduced in the 1950's from three different perspectives: algebraic groups in positive characteristic, cohomology rings of Lie groups, and group objects in the category of von Neumann algebras. The study of non-commutative non-cocommutative Hopf algebras started in the 1960's. The fundamental breakthrough is Drinfeld's report [25]. Among many contributions and ideas, a systematic construction of solutions of the quantum Yang-Baxter equation (qYBE) was presented. Let V be a vector space. The qYBE is equivalent to the braid equation:

$$(c \otimes \mathrm{id})(\mathrm{id} \otimes c)(c \otimes \mathrm{id}) = (\mathrm{id} \otimes c)(c \otimes \mathrm{id})(\mathrm{id} \otimes c), \qquad c \in GL(V \otimes V). \tag{1.1}$$

If c satisfies (1.1), then (V, c) is called a braided vector space; this is a down-to-the-earth version of a braided tensor category [54]. Drinfeld introduced the notion of quasi-triangular Hopf algebra, meaning a pair (H, R) where H is a Hopf algebra and $R \in H \otimes H$ is invertible and satisfies the appropppriate conditions, so that every H-module V becomes a braided vector space, with c given by the action of R composed with the usual flip. Furthermore, every finite-dimensional Hopf algebra H gives rise to a quasi-triangular Hopf algebra, namely the Drinfeld double $D(H) = H \otimes H^*$ as vector space. If H is not finite-dimensional, some precautions have to be taken to construct $D(H)$, or else one considers Yetter-Drinfeld modules, see §2.2. In conclusion, every Hopf algebra is a source of solutions of the braid equation. Essential examples of quasi-triangular Hopf algebras are the quantum groups $U_q(\mathfrak{g})$ [25, 53] and the finite-dimensional variations $\mathfrak{u}_q(\mathfrak{g})$ [59, 60].

In the approach to the classification of Hopf algebras exposed in this report, braided vector spaces and braided tensor categories play a decisive role; and the finite quantum groups are the main actors in one of the classes that splits off.

Proceedings of the International Congress of Mathematicians, Seoul, 2014

By space limitations, there is a selection of the topics and references included. Particularly, we deal with finite-dimensional Hopf algebras over an algebraically closed field of characteristic zero with special emphasis on description of examples and classifications. Interesting results on Hopf algebras either infinite-dimensional, or over other fields, unfortunately can not be reported. There is no account of the many deep results on tensor categories, see [30]. Various basic fundamental results are not explicitly cited, we refer to [1, 62, 66, 75, 79, 83] for them; classifications of Hopf algebras of fixed dimensions are not evoked, see [21, 71, 86].

2. Preliminaries

Let $\theta \in \mathbb{N}$ and $\mathbb{I} = \mathbb{I}_\theta = \{1, 2, \dots, \theta\}$. The base field is $\mathbb{C}$. If X is a set, then $|X|$ is its cardinal and $\mathbb{C}X$ is the vector space with basis $(x_i)_{i\in X}$. Let G be a group: we denote by $\operatorname{Irr} G$ the set of isomorphism classes of irreducible representations of G and by $\widehat{G}$ the subset of those of dimension 1; by G^x the centralizer of $x \in G$; and by $\mathcal{O}_x^G$ its conjugacy class. More generally we denote by $\operatorname{Irr} \mathfrak{C}$ the set of isomorphism classes of simple objects in an abelian category $\mathfrak{C}$. The group of n-th roots of 1 in $\mathbb{C}$ is denoted $\mathbb{G}_n$; also $\mathbb{G}_\infty = \bigcup_{n\geq 1} \mathbb{G}_n$. The group presented by $(x_i)_{i\in I}$ with relations $(r_j)_{j\in J}$ is denoted $\langle (x_i)_{i\in I} | (r_j)_{j\in J}\rangle$. The notation for Hopf algebras is standard: Δ, ε, $\mathcal{S}$, denote respectively the comultiplication, the counit, the antipode (always assumed bijective, what happens in the finite-dimensional case). We use Sweedler's notation: $\Delta(x) = x_{(1)} \otimes x_{(2)}$. Similarly, if C is a coalgebra and V is a left comodule with structure map $\delta : V \to C \otimes V$, then $\delta(v) = v_{(-1)} \otimes v_{(0)}$. If D, E are subspaces of C, then $D \wedge E = \{c \in C : \Delta(c) \in D \otimes C + C \otimes E\}$; also $\wedge^0 D = D$ and $\wedge^{n+1} D = (\wedge^n D) \wedge D$ for $n > 0$.

2.1. Basic constructions and results. The first examples of finite-dimensional Hopf algebras are the group algebra $\mathbb{C}G$ of a finite group G and its dual, the algebra of functions $\mathbb{C}^G$. Indeed, the dual of a finite-dimensional Hopf algebra is again a Hopf algebra by transposing operations. By analogy with groups, several authors explored the notion of extension of Hopf algebras at various levels of generality; in the finite-dimensional context, every extension $\mathbb{C} \to A \to C \to B \to \mathbb{C}$ can be described as C with underlying vector space $A \otimes B$, via a heavy machinery of actions, coactions and non-abelian cocycles, but actual examples are rarely found in this way (extensions from a different perspective are in [9]). Relevant exceptions are the so-called *abelian extensions* [56] (rediscovered by Takeuchi and Majid): here the input is a matched pair of groups (F, G) with mutual actions $\triangleright, \triangleleft$ (or equivalently, an exact factorization of a finite group). The actions give rise to a Hopf algebra $\mathbb{C}^G \# \mathbb{C}F$. The multiplication and comultiplication can be further modified by compatible cocycles (σ, κ), producing to the abelian extension $\mathbb{C} \to \mathbb{C}^G \to \mathbb{C}^G {}^\kappa\#_\sigma \mathbb{C}F \to \mathbb{C}F \to \mathbb{C}$. Here (σ, κ) turns out to be a 2-cocycle in the total complex associated to a double complex built from the matched pair; the relevant H^2 is computed via the so-called Kac exact sequence.

It is natural to approach Hopf algebras by considering algebra or coalgebra invariants. There is no preference in the finite-dimensional setting but coalgebras and comodules are locally finite, so we privilege the coalgebra ones to lay down general methods. The basic coalgebra invariants of a Hopf algebra H are:

- The group $G(H) = \{g \in H - 0 : \Delta(g) = x \otimes g\}$ of group-like elements of H.

- The space of skew-primitive elements $\mathcal{P}_{g,h}(H)$, $g, h \in G(H)$; $\mathcal{P}(H) := \mathcal{P}_{1,1}(H)$.
- The coradical H_0, that is the sum of all simple subcoalgebras.
- The coradical filtration $H_0 \subset H_1 \subset \dots$, where $H_n = \wedge^n H_0$; then $H = \bigcup_{n\geq 0} H_n$.

2.2. Modules. The category ${}_H\mathcal{M}$ of left modules over a Hopf algebra H is monoidal with tensor product defined by the comultiplication; ditto for the category ${}^H\mathcal{M}$ of left comodules, with tensor product defined by the multiplication. Here are two ways to deform Hopf algebras without altering one of these categories.

- Let $F \in H\otimes H$ be invertible such that $(1\otimes F)(\mathrm{id}\otimes\Delta)(F) = (F\otimes 1)(\Delta\otimes\mathrm{id})(F)$ and $(\mathrm{id}\otimes\varepsilon)(F) = (\varepsilon\otimes\mathrm{id})(F) = 1$. Then H^F (the same algebra with comultiplication $\Delta^F := F\Delta F^{-1}$) is again a Hopf algebra, named the *twisting* of H by F [26]. The monoidal categories ${}_H\mathcal{M}$ and ${}_{H^F}\mathcal{M}$ are equivalent. If H and K are finite-dimensional Hopf algebras with ${}_H\mathcal{M}$ and ${}_K\mathcal{M}$ equivalent as monoidal categories, then there exists F with $K \simeq H^F$ as Hopf algebras (Schauenburg, Etingof-Gelaki). Examples of twistings not mentioned elsewhere in this report are in [31, 65].
- Given a linear map $\sigma : H\otimes H \to \mathbb{C}$ with analogous conditions, there is a Hopf algebra H_σ (same coalgebra, multiplication twisted by σ) such that the monoidal categories ${}^H\mathcal{M}$ and ${}^{H_\sigma}\mathcal{M}$ are equivalent [24].

A Yetter-Drinfeld module M over H is left H-module and left H-comodule with the compatibility $\delta(h.m) = h_{(1)}m_{(-1)}\mathcal{S}(h_{(3)})\otimes h_{(2)}\cdot m_{(0)}$, for all $m \in M$ and $h \in H$. The category ${}^H_H\mathcal{YD}$ of Yetter-Drinfeld modules is braided monoidal. That is, for every $M, N \in {}^H_H\mathcal{YD}$, there is a natural isomorphism $c : M\otimes N \to N\otimes M$ given by $c(m\otimes n) = m_{(-1)}\cdot n\otimes m_{(0)}$, $m \in M$, $n \in N$. When H is finite-dimensional, the category ${}^H_H\mathcal{YD}$ is equivalent, as a braided monoidal category, to ${}_{D(H)}\mathcal{M}$.

The definition of Hopf algebra makes sense in any braided monoidal category. Hopf algebras in ${}^H_H\mathcal{YD}$ are interesting because of the following facts–discovered by Radford and interpreted categorically by Majid, see [62, 75]:

- If R is a Hopf algebra in ${}^H_H\mathcal{YD}$, then $R\#H := R\otimes H$ with semidirect product and coproduct is a Hopf algebra, named the *bosonization* of R by H.
- Let π, ι be Hopf algebra maps as in $K \underset{\pi}{\overset{\iota}{\rightleftarrows}} H$ with $\pi\iota = \mathrm{id}_H$. Then $R = H^{\mathrm{co}\pi} := \{x \in K : (\mathrm{id}\otimes\pi)\Delta(x) = 1\otimes x\}$ is a Hopf algebra in ${}^H_H\mathcal{YD}$ and $K \simeq R\#H$.

For instance, if $V \in {}^H_H\mathcal{YD}$, then the tensor algebra $T(V)$ is a Hopf algebra in ${}^H_H\mathcal{YD}$, by requiring $V \hookrightarrow \mathcal{P}(T(V))$. If $c : V\otimes V \to V\otimes V$ satisfies $c = -\tau$, τ the usual flip, then the exterior algebra $\Lambda(V)$ is a Hopf algebra in ${}^H_H\mathcal{YD}$.

There is a braided adjoint action of a Hopf algebra R in ${}^H_H\mathcal{YD}$ on itself, see e.g. [12, (1.26)]. If $x \in \mathcal{P}(R)$ and $y \in R$, then $\mathrm{ad}_c(x)(y) = xy - \mathrm{mult}\, c(x\otimes y)$.

2.2.1. Triangular Hopf algebras. A quasitriangular Hopf algebra (H, R) is *triangular* if the braiding induced by R is a symmetry: $c_{V\otimes W}c_{W\otimes V} = \mathrm{id}_{W\otimes V}$ for all $V, W \in {}_H\mathcal{M}$. A finite-dimensional triangular Hopf algebra is a twisting of a bosonization $\Lambda(V)\#\mathbb{C}G$, where G is a finite group and $V \in {}^G_G\mathcal{YD}$ has $c = -\tau$ [6]. This lead eventually to the classification of triangular finite-dimensional Hopf algebras [29]; previous work on the semisimple case culminated in [28].

2.3. Semisimple Hopf algebras. The algebra of functions $\mathbb{C}^G$ on a finite group G admits a Haar measure, i.e., a linear function $\int : \mathbb{C}^G \to \mathbb{C}$ invariant under left and right translations, namely $\int =$ sum of all elements in the standard basis of $\mathbb{C}G$. This is adapted as follows: a right integral *on* a Hopf algebra H is a linear function $\int : H \to \mathbb{C}$ which is invariant under the left regular coaction: analogously there is the notion of left integral. The notion has various applications. Assume that H is finite-dimensional. Then an integral *in* H is an integral on H^*; the subspace of left integrals in H has dimension one, and there is a generalization of Maschke's theorem for finite groups: H is semisimple if and only if $\varepsilon(\Lambda) \neq 0$ for any integral $0 \neq \Lambda \in H$. This characterization of semisimple Hopf algebras, valid in any characteristic, is one of several, some valid only in characteristic 0. See [79]. Semisimple Hopf algebras can be obtained as follows:

- ◇ A finite-dimensional Hopf algebra H is semisimple if and only if it is cosemisimple (that is, H^* is semisimple).
- ◇ Given an extension $\mathbb{C} \to K \to H \to L \to \mathbb{C}$, H is semisimple iff K and L are. Notice that there are semisimple extensions that are not abelian [40, 69, 74].
- ◇ If H is semisimple, then so are H^F and H_σ, for any twist F and cocycle σ. If G is a finite simple group, then any twisting of $\mathbb{C}G$ is a simple Hopf algebra (i.e., not a non-trivial extension) [73], but the converse is not true [37].
- ◇ A bosonization $R\#H$ is semisimple iff R and H are.

To my knowledge, all examples of semisimple Hopf algebras arise from group algebras by the preceding constructions; this was proved in [68, 70] in low dimensions and in [32] for dimensions $p^a q^b$, pqr, where p, q and r are primes. See [1, Question 2.6]. An analogous question in terms of fusion categories: is any semisimple Hopf algebra weakly group-theoretical? See [32, Question 2].

There are only finitely many isomorphism classes of *semisimple* Hopf algebras in each dimension [81], but this fails in general [13, 20].

Conjecture 2.1 (Kaplansky). *Let H be a semisimple Hopf algebra. The dimension of every $V \in \operatorname{Irr}{}_H\mathcal{M}$ divides the dimension of H.*

The answer is affirmative for iterated extensions of group algebras and duals of group algebras [67] and notably for semisimple quasitriangular Hopf algebras [27].

3. Lifting methods

3.1. Nichols algebras. Nichols algebras are a special kind of Hopf algebras in braided tensor categories. We are mainly interested in Nichols algebras in the braided category ${}^H_H\mathcal{YD}$, where H is a Hopf algebra, see page 3. In fact, there is a functor $V \mapsto \mathfrak{B}(V)$ from ${}^H_H\mathcal{YD}$ to the category of Hopf algebras in ${}^H_H\mathcal{YD}$. Their first appearence is in the precursor [72]; they were rediscovered in [85] as part of a "quantum differential calculus", and in [61] to present the positive part of $U_q(\mathfrak{g})$. See also [76, 78].

There are several, unrelated at the first glance, alternative definitions. Let $V \in {}^H_H\mathcal{YD}$. The first definition uses the representation of the braid group $\mathbb{B}_n$ in n strands on $V^{\otimes n}$, given by $\varsigma_i \mapsto \mathrm{id}^{\otimes}{}^{n-1} \otimes c \otimes \mathrm{id}^{\otimes}{}^{n-i-1}$, c in $(i, i+1)$ tensorands; here recall that

$$\mathbb{B}_n = \langle \varsigma_1, \dots, \varsigma_{n-1} | \varsigma_i\varsigma_j = \varsigma_j\varsigma_i, |i-j| > 1, \varsigma_i\varsigma_j\varsigma_i = \varsigma_j\varsigma_i\varsigma_j, |i-j| = 1 \rangle.$$

Let $M : \mathbb{S}_n \to \mathbb{B}_n$ be the Matsumoto section and let $\mathcal{Q}_n : V^{\otimes n} \to V^{\otimes n}$ be the quantum symmetrizer, $\mathcal{Q}_n = \sum_{s\in\mathbb{S}_n} M(s) : V^{\otimes n} \to V^{\otimes n}$. Then define

$$\mathfrak{J}^n(V) = \ker \mathcal{Q}_n, \qquad \mathfrak{J}(V) = \oplus_{n\geq 2}\mathfrak{J}^n(V), \qquad \mathfrak{B}(V) = T(V)/\mathfrak{J}(V). \tag{3.1}$$

Hence $\mathfrak{B}(V) = \oplus_{n\geq 0}\mathfrak{B}^n(V)$ is a graded Hopf algebra in ${}^H_H\mathcal{YD}$ with $\mathfrak{B}^0(V) = \mathbb{C}$, $\mathfrak{B}^1(V) \simeq V$; by (3.1) the algebra structure depends only on c. To explain the second definition, let us observe that the tensor algebra $T(V)$ is a Hopf algebra in ${}^H_H\mathcal{YD}$ with comultiplication determined by $\Delta(v) = v\otimes 1 + 1\otimes v$ for $v \in V$. Then $\mathfrak{J}(V)$ coincides with the largest homogeneous ideal of $T(V)$ generated by elements of degree ≥ 2 that is also a coideal. Let now $T = \oplus_{n\geq 0}T^n$ be a graded Hopf algebra in ${}^H_H\mathcal{YD}$ with $T^0 = \mathbb{C}$. Consider the conditions

$$T^1 \text{ generates } T \text{ as an algebra,} \tag{3.2}$$

$$T^1 = \mathcal{P}(T). \tag{3.3}$$

These requirements are dual to each other: if T has finite-dimensional homogeneous components and $R = \oplus_{n\geq 0}R^n$ is the graded dual of T, i.e., $R^n = (T^n)^*$, then T satisfies (3.2) if and only if R satisfies (3.3). These conditions determine $\mathfrak{B}(V)$ up to isomorphisms, as the unique graded connected Hopf algebra T in ${}^H_H\mathcal{YD}$ that satisfies $T^1 \simeq V$, (3.2) and (3.3). There are still other characterizations of $\mathfrak{J}(V)$, e.g. as the radical of a suitable homogeneous bilinear form on $T(V)$, or as the common kernel of some suitable skew-derivations. See [15] for more details.

Despite all these different definitions, Nichols algebras are extremely difficult to deal with, e.g. to present by generators and relations, or to determine when a Nichols algebra has finite dimension or finite Gelfand-Kirillov dimension. It is not even known a priori whether the ideal $\mathfrak{J}(V)$ is finitely generated, except in a few specific cases. For instance, if c is a symmetry, that is $c^2 = \mathrm{id}$, or satisfies a Hecke condition with generic parameter, then $\mathfrak{B}(V)$ is quadratic. By the efforts of various authors, we have some understanding of finite-dimensional Nichols algebras of braided vector spaces either of diagonal or of rack type, see §3.5, 3.6.

3.2. Hopf algebras with the (dual) Chevalley property. We now explain how Nichols algebras enter into our approach to the classification of Hopf algebras. Recall that a Hopf algebra has the *dual Chevalley property* if the tensor product of two simple comodules is semisimple, or equivalently if its coradical is a (cosemisimple) Hopf subalgebra. For instance, a *pointed* Hopf algebra, one whose simple comodules have all dimension one, has the dual Chevalley property and its coradical is a group algebra. Also, a *copointed* Hopf algebra (one whose coradical is the algebra of functions on a finite group) has the dual Chevalley property. The Lifting Method is formulated in this context [13]. Let H be a Hopf algebra with the dual Chevalley property and set $K := H_0$. Under this assumption, the graded coalgebra $\operatorname{gr} H = \oplus_{n\in\mathbb{N}_0} \operatorname{gr}^n H$ associated to the coradical filtration becomes a Hopf algebra and considering the homogeneous projection π as in $R = H^{\operatorname{co}\pi} \hookrightarrow \operatorname{gr} H \underset{\pi}{\rightleftarrows} K$ we see that $\operatorname{gr} H \simeq R\#K$. The subalgebra of coinvariants R is a graded Hopf algebra in ${}^K_K\mathcal{YD}$ that inherits the grading with $R^0 = \mathbb{C}$; it satisfies (3.3) since the grading comes from the coradical filtration. Let R' be the subalgebra of R generated by $V := R^1$; then $R' \simeq \mathfrak{B}(V)$. The braided vector space V is a basic invariant of H called its *infinitesimal braiding*. Let us fix then a semisimple Hopf algebra K. To classify all finite-dimensional Hopf algebras H with $H_0 \simeq K$ as Hopf algebras, we have to address the following questions.

(a) Determine those $V \in {}^K_K\mathcal{YD}$ such that $\mathfrak{B}(V)$ is finite-dimensional, and give an efficient defining set of relations of these.
(b) Investigate whether any *finite-dimensional* graded Hopf algebra R in ${}^K_K\mathcal{YD}$ satisfying $R^0 = \mathbb{C}$ and $P(R) = R^1$, is a Nichols algebra.
(c) Compute all Hopf algebras H such that $\operatorname{gr} H \simeq \mathfrak{B}(V)\#K$, V as in (a).

Since the Nichols algebra $\mathfrak{B}(V)$ depends as an algebra (and as a coalgebra) only on the braiding c, it is convenient to restate Question (a) as follows:

(a_1) Determine those braided vector spaces (V,c) in a suitable class such that $\dim \mathfrak{B}(V) < \infty$, and give an efficient defining set of relations of these.
(a_2) For those V as in (a_1), find in how many ways, if any, they can be realized as Yetter-Drinfeld modules over K.

For instance, if $K = \mathbb{C}\Gamma$, Γ a finite abelian group, then the suitable class is that of braided vector spaces of diagonal type. In this context, Question (a_2) amounts to solve systems of equations in Γ. The answer to (a) is instrumental to attack (b) and (c). Question (b) can be rephrased in two equivalent statements:

(b_1) Investigate whether any *finite-dimensional* graded Hopf algebra T in ${}^K_K\mathcal{YD}$ with $T^0 = \mathbb{C}$ and generated as algebra by T^1, is a Nichols algebra.
(b_2) Investigate whether any *finite-dimensional* Hopf algebra H with $H_0 = K$ is generated as algebra by H_1.

We believe that the answer to (b) is affirmative at least when K is a group algebra. In other words, by the reformulation (b_2):

Conjecture 3.1 ([14]). *Every finite-dimensional pointed Hopf algebra is generated by group-like and skew-primitive elements.*

As we shall see in §3.7, the complete answer to (a) is needed in the approach proposed in [14] to attack Conjecture 3.1. It is plausible that the answer of (b_2) is affirmative for every semisimple Hopf algebra K. Question (c), known as *lifting* of the relations, also requires the knowledge of the generators of $\mathfrak{J}(V)$, see §3.8.

3.3. Generalized lifting method. Before starting with the analysis of the various questions in §3.2, we discuss a possible approach to more general Hopf algebras [5]. Let H be a Hopf algebra; we consider the following invariants of H:

- The *Hopf coradical* $H_{[0]}$ is the subalgebra generated by H_0.
- The *standard filtration* $H_{[0]} \subset H_{[1]} \subset \dots$, $H_{[n]} = \wedge^{n+1} H_{[0]}$; then $H = \bigcup_{n\geq 0} H_{[n]}$.

If H has the dual Chevalley property, then $H_{[n]} = H_n$ for all $n \in \mathbb{N}_0$. In general, $H_{[0]}$ is a Hopf subalgebra of H with coradical H_0 and we may consider the graded Hopf algebra $\operatorname{gr} H = \oplus_{n\geq 0} H_{[n]}/H_{[n-1]}$. As before, if $\pi : \operatorname{gr} H \to H_{[0]}$ is the homogeneous projection, then $R = (\operatorname{gr} H)^{\operatorname{co}\pi}$ is a Hopf algebra in ${}^{H_{[0]}}_{H_{[0]}}\mathcal{YD}$ and $\operatorname{gr} H \cong R\#H_{[0]}$. Furthermore, $R = \oplus_{n\geq 0} R^n$ with grading inherited from $\operatorname{gr} H$. This discussion raises the following questions.

(A) Let C be a finite-dimensional cosemisimple coalgebra and $S : C \to C$ a bijective anti-coalgebra map. Classify all finite-dimensional Hopf algebras L generated by C, such that $\mathcal{S}|_C = S$.

(B) Given L as in the previous item, classify all finite-dimensional connected graded Hopf algebras R in ${}^L_L\mathcal{YD}$.

(C) Given L and R as in previous items, classify all deformations or liftings, that is, classify all Hopf algebras H such that $\operatorname{gr} H \cong R\#L$.

Question (A) is largely open, except for the remarkable [82, Theorem 1.5]: if H is a Hopf algebra generated by an $\mathcal{S}$-invariant 4-dimensional simple subcoalgebra C, such that $1 < \operatorname{ord}(\mathcal{S}^2|_C) < \infty$, then H is a Hopf algebra quotient of the quantized algebra of functions on SL_2 at a root of unity ω. Nichols algebras enter into the picture in Question (B); if $V = R^1$, then $\mathfrak{B}(V)$ is a subquotient of R. Question (C) is completely open, as it depends on the previous Questions.

3.4. Generalized root systems and Weyl groupoids. Here we expose two important notions introduced in [51].

Let $\theta \in \mathbb{N}$ and $\mathbb{I} = \mathbb{I}_\theta$. A *basic datum* of type $\mathbb{I}$ is a pair $(\mathcal{X}, \rho)$, where $\mathcal{X} \neq \emptyset$ is a set and $\rho : \mathbb{I} \to \mathbb{S}_\mathcal{X}$ is a map such that $\rho_i^2 = \mathrm{id}$ for all $i \in \mathbb{I}$. Let $\mathcal{Q}_\rho$ be the quiver $\{\sigma_i^x := (x, i, \rho_i(x)) : i \in \mathbb{I}, x \in \mathcal{X}\}$ over $\mathcal{X}$, with $t(\sigma_i^x) = x$, $s(\sigma_i^x) = \rho_i(x)$ (here t means target, s means source). Let $F(\mathcal{Q}_\rho)$ be the free groupoid over $\mathcal{Q}_\rho$; in any quotient of $F(\mathcal{Q}_\rho)$, we denote

$$\sigma_{i_1}^x \sigma_{i_2} \cdots \sigma_{i_t} = \sigma_{i_1}^x \sigma_{i_2}^{\rho_{i_1}(x)} \cdots \sigma_{i_t}^{\rho_{i_{t-1}} \cdots \rho_{i_1}(x)}; \tag{3.4}$$

i.e., the implicit superscripts are those allowing compositions.

3.4.1. Coxeter groupoids. A *Coxeter datum* is a triple $(\mathcal{X}, \rho, \mathbf{M})$, where $(\mathcal{X}, \rho)$ is a basic datum of type $\mathbb{I}$ and $\mathbf{M} = (\mathbf{m}^x)_{x \in \mathcal{X}}$ is a family of Coxeter matrices $\mathbf{m}^x = (m_{ij}^x)_{i,j \in \mathbb{I}}$ with

$$s((\sigma_i^x \sigma_j)^{m_{ij}^x}) = x, \qquad i, j \in \mathbb{I}, \qquad x \in \mathcal{X}. \tag{3.5}$$

The *Coxeter groupoid* $\mathcal{W}(\mathcal{X}, \rho, \mathbf{M})$ associated to $(\mathcal{X}, \rho, \mathbf{M})$ [51, Definition 1] is the groupoid presented by generators $\mathcal{Q}_\rho$ with relations

$$(\sigma_i^x \sigma_j)^{m_{ij}^x} = \mathrm{id}_x, \qquad i, j \in \mathbb{I}, x \in \mathcal{X}. \tag{3.6}$$

3.4.2. Generalized root system. A generalized root system (GRS for short) is a collection $\mathcal{R} := (\mathcal{X}, \rho, \mathcal{C}, \Delta)$, where $\mathcal{C} = (C^x)_{x \in \mathcal{X}}$ is a family of generalized Cartan matrices $C^x = (c_{ij}^x)_{i,j \in \mathbb{I}}$, cf. [57], and $\Delta = (\Delta^x)_{x \in \mathcal{X}}$ is a family of subsets $\Delta^x \subset \mathbb{Z}^\mathbb{I}$. We need the following notation: Let $\{\alpha_i\}_{i \in \mathbb{I}}$ be the canonical basis of $\mathbb{Z}^\mathbb{I}$ and define $s_i^x \in GL(\mathbb{Z}^\mathbb{I})$ by $s_i^x(\alpha_j) = \alpha_j - c_{ij}^x \alpha_i$, $i, j \in \mathbb{I}$, $x \in \mathcal{X}$. The collection should satisfy the following axioms:

$$c_{ij}^x = c_{ij}^{\rho_i(x)} \qquad \text{for all } x \in \mathcal{X},\ i, j \in \mathbb{I}. \tag{3.7}$$

$$\Delta^x = \Delta_+^x \cup \Delta_-^x, \qquad \Delta_\pm^x := \pm(\Delta^x \cap \mathbb{N}_0^\mathbb{I}) \subset \pm\mathbb{N}_0^\mathbb{I}; \tag{3.8}$$

$$\Delta^x \cap \mathbb{Z}\alpha_i = \{\pm\alpha_i\}; \tag{3.9}$$

$$s_i^x(\Delta^x) = \Delta^{\rho_i(x)}; \tag{3.10}$$

$$(\rho_i\rho_j)^{m_{ij}^x}(x) = (x), \qquad m_{ij}^x := |\Delta^x \cap (\mathbb{N}_0\alpha_i + \mathbb{N}_0\alpha_j)|, \tag{3.11}$$

for all $x \in \mathcal{X}$, $i \neq j \in \mathbb{I}$. We call Δ_+^x, respectively Δ_-^x, the set of *positive*, respectively *negative*, roots. Let $\mathcal{G} = \mathcal{X} \times GL_\theta(\mathbb{Z}) \times \mathcal{X}$, $\varsigma_i^x = (x,\, s_i^x,\, \rho_i(x))$, $i \in \mathbb{I}$, $x \in \mathcal{X}$, and $\mathcal{W} = \mathcal{W}(\mathcal{X}, \rho, \mathcal{C})$ the subgroupoid of $\mathcal{G}$ generated by all the ς_i^x, i.e., by the image of the morphism of quivers $\mathcal{Q}_\rho \to \mathcal{G}$, $\sigma_i^x \mapsto \varsigma_i^x$. There is a Coxeter matrix $\mathbf{m}^x = (m_{ij}^x)_{i,j\in\mathbb{I}}$, where m_{ij}^x is the smallest natural number such that $(\varsigma_i^x\varsigma_j)^{m_{ij}^x} = \mathrm{id}\, x$. Then $\mathbf{M} = (\mathbf{m}^x)_{x\in\mathcal{X}}$ fits into a Coxeter datum $(\mathcal{X}, \rho, \mathbf{M})$, and there is an isomorphism of groupoids $\mathcal{W}(\mathcal{X}, \rho, \mathbf{M}) \twoheadrightarrow \mathcal{W} = \mathcal{W}(\mathcal{X}, \rho, \mathcal{C})$ [51]; this is called the *Weyl groupoid* of $\mathcal{R}$. If $w \in \mathcal{W}(x, y)$, then $w(\Delta^x) = \Delta^y$, by (3.10). The sets of *real* roots at $x \in \mathcal{X}$ are $(\Delta^{\mathrm{re}})^x = \bigcup_{y\in\mathcal{X}}\{w(\alpha_i) : i \in \mathbb{I},\, w \in \mathcal{W}(y, x)\}$; correspondingly the *imaginary* roots are $(\Delta^{\mathrm{im}})^x = \Delta^x - (\Delta^{\mathrm{re}})^x$. Assume that $\mathcal{W}$ is connected. Then the following conditions are equivalent [22, Lemma 2.11]:

- Δ^x is finite for some $x \in \mathcal{X}$,
- Δ^x is finite for all $x \in \mathcal{X}$,
- $(\Delta^{\mathrm{re}})^x$ is finite for all $x \in \mathcal{X}$,
- $\mathcal{W}$ is finite.

If these hold, then all roots are real [22]; we say that $\mathcal{R}$ is *finite*. We now discuss two examples of GRS, central for the subsequent discussion.

Example 3.2 ([2]). Let $\mathbf{k}$ be a field of characteristic $\ell \geq 0$, $\theta \in \mathbb{N}$, $\mathbf{p} \in \mathbb{G}_2^\theta$ and $A = (a_{ij}) \in \mathbf{k}^{\theta\times\theta}$. We assume $\ell \neq 2$ for simplicity. Let $\mathfrak{h} = \mathbf{k}^{2\theta - \mathrm{rk}\, A}$. Let $\mathfrak{g}(A, \mathbf{p})$ be the Kac-Moody Lie superalgebra over $\mathbf{k}$ defined as in [57]; it is generated by $\mathfrak{h}$, e_i and f_i, $i \in \mathbb{I}$, and the parity is given by $|e_i| = |f_i| = p_i$, $i \in \mathbb{I}$, $|h| = 0$, $h \in \mathfrak{h}$. Let $\Delta^{A,\mathbf{p}}$ be the root system of $\mathfrak{g}(A, \mathbf{p})$. We make the following technical assumptions:

$$a_{jk} = 0 \implies a_{kj} = 0, \qquad j \neq k; \tag{3.12}$$

$$\mathrm{ad}\, f_i \text{ is locally nilpotent in } \mathfrak{g}(A, \mathbf{p}), \qquad i \in \mathbb{I}. \tag{3.13}$$

The matrix A is *admissible* if (3.13) holds [80]. Let $C^{A,\mathbf{p}} = (c_{ij}^{A,\mathbf{p}})_{i,j\in\mathbb{I}}$ be given by

$$c_{ij}^{A,\mathbf{p}} := -\min\{m \in \mathbb{N}_0 : (\mathrm{ad}\, f_i)^{m+1} f_j = 0\}, i \neq j \in \mathbb{I}, \qquad c_{ii}^{A,\mathbf{p}} := 2. \tag{3.14}$$

We need the following elements of $\mathbf{k}$:

$$\text{if } p_i = 0, \qquad d_m = m\, a_{ij} + \binom{m}{2} a_{ii}; \tag{3.15}$$

$$\text{if } p_i = 1; \qquad d_m = \begin{cases} k\, a_{ii}, & m = 2k, \\ k\, a_{ii} + a_{ij}, & m = 2k+1; \end{cases} \tag{3.16}$$

$$\nu_{j,0} = 1, \qquad \nu_{j,n} = \prod_{t=1}^{n} (-1)^{p_i((t-1)p_i + p_j)} d_t; \tag{3.17}$$

$$\mu_{j,0} = 0, \qquad \mu_{j,n} = (-1)^{p_i p_j} n \left(\prod_{t=2}^{n} (-1)^{p_i((t-1)p_i + p_j)} d_t \right) a_{ji}. \tag{3.18}$$

With the help of these scalars, we define a reflection $r_i(A,\mathbf{p}) = (r_iA, r_i\mathbf{p})$, where $r_i\mathbf{p} = (\overline{p}_j)_{j\in\mathbb{I}}$, with $\overline{p}_j = p_j - c_{ij}^{A,\mathbf{p}}p_i$, and $r_iA = (\overline{a}_{jk})_{j,k\in\mathbb{I}}$, with

$$\overline{a}_{jk} = \begin{cases} -c_{ik}^{A,\mathbf{p}}\mu_{j,-c_{ij}^{A,\mathbf{p}}}a_{ii} + \mu_{j,-c_{ij}^{A,\mathbf{p}}}a_{ik} \\ \qquad -c_{ik}^{A,\mathbf{p}}\nu_{j,-c_{ij}^{A,\mathbf{p}}}a_{ji} + \nu_{j,-c_{ij}^{A,\mathbf{p}}}a_{jk}, & j,k\neq i; \\ c_{ik}^{A,\mathbf{p}}a_{ii} - a_{ik}, & j = i \neq k; \\ -\mu_{j,-c_{ij}^{A,\mathbf{p}}}a_{ii} - \nu_{j,-c_{ij}^{A,\mathbf{p}}}a_{ji}, & j \neq k = i; \\ a_{ii}, & j = k = i. \end{cases} \tag{3.19}$$

Theorem 3.3. *There is an isomorphism $T_i^{A,\mathbf{p}} : \mathfrak{g}(r_i(A,\mathbf{p})) \to \mathfrak{g}(A,\mathbf{p})$ of Lie superalgebras given (for an appropppriate basis (h_i) of $\mathfrak{h}$) by*

$$T_i^{A,\mathbf{p}}(e_j) = \begin{cases} (\operatorname{ad} e_i)^{-c_{ij}^{A,\mathbf{p}}}(e_j), & i\neq j\in\mathbb{I}, \\ f_i, & j = i \end{cases}$$
$$T_i^{A,\mathbf{p}}(f_j) = \begin{cases} (\operatorname{ad} f_i)^{-c_{ij}^{A,\mathbf{p}}}f_j, & j\in\mathbb{I}, j\neq i, \\ (-1)^{p_i}e_i, & j = i, \end{cases} \tag{3.20}$$
$$T_i^{A,\mathbf{p}}(h_j) = \begin{cases} \mu_{j,-c_{ij}^{A,\mathbf{p}}}h_i + \nu_{j,-c_{ij}^{A,\mathbf{p}}}h_j, & i\neq j\in\mathbb{I} \\ -h_i, & j = i, \\ h_j, & \theta+1\leq j\leq 2\theta - \operatorname{rk} A. \end{cases}$$

Assume that $\dim\mathfrak{g}(A,\mathbf{p}) < \infty$; then (3.12) and (3.13) hold. Let

$$\mathcal{X} = \{r_{i_1}\cdots r_{i_n}(A,\mathbf{p}) \,|\, n\in\mathbb{N}_0, i_1,\dots,i_n\in\mathbb{I}\}.$$

Then $(\mathcal{X}, r, \mathcal{C}, \Delta)$, where $\mathcal{C} = (C^{(B,\mathbf{q})})_{(B,\mathbf{q})\in\mathcal{X}}$ and $\Delta = (\Delta^{(B,\mathbf{q})})_{(B,\mathbf{q})\in\mathcal{X}}$, is a finite GRS, an invariant of $\mathfrak{g}(A,\mathbf{p})$.

Example 3.4. Let H be a Hopf algebra, assumed semisimple for easiness. Let $M\in {}^H_H\mathcal{YD}$ be finite-dimensional, with a fixed decomposition $M = M_1\oplus\cdots\oplus M_\theta$, where $M_1,\dots,M_\theta\in \operatorname{Irr}{}^H_H\mathcal{YD}$. Then $T(M)$ and $\mathfrak{B}(M)$ are $\mathbb{Z}^\theta$-graded, by $\deg x = \alpha_i$ for all $x\in M_i$, $i\in\mathbb{I}_\theta$. Recall that $\mathbb{Z}^\theta_{\geq 0} = \sum_{i\in\mathbb{I}_\theta}\mathbb{Z}_{\geq 0}\alpha_i$.

Theorem 3.5 ([46, 48]). *If $\dim\mathfrak{B}(M) < \infty$, then M has a finite GRS.*

We discuss the main ideas of the proof. Let $i\in\mathbb{I} = \mathbb{I}_\theta$. We define $M_i' = V_i^*$,

$$c_{ij}^M = -\sup\{h\in\mathbb{N}_0 : \operatorname{ad}_c^h(M_i)(M_j)\neq 0 \text{ in } \mathfrak{B}(M)\}, \qquad i\neq j, \quad c_{ii}^M = 2;$$
$$M_j' = \operatorname{ad}_c^{-c_{ij}}(M_i)(M_j), \qquad \rho_i(M) = M_1'\oplus\cdots\oplus M_\theta'.$$

Then $\dim\mathfrak{B}(M) = \dim\mathfrak{B}(\rho_i(M))$ and $C^M = (c_{ij}^M)_{i,j\in\mathbb{I}}$ is a generalized Cartan matrix [12]. Also, M_j' is irreducible [12, 3.8], [46, 7.2]. Let $\mathcal{X}$ be the set of objects in ${}^H_H\mathcal{YD}$ with fixed decomposition (up to isomorphism) of the form

$$\{\rho_{i_1}\cdots\rho_{i_n}(M) \,|\, n\in\mathbb{N}_0, i_1,\dots,i_n\in\mathbb{I}\}.$$

Then $(\mathcal{X}, \rho, \mathcal{C})$, where $\mathcal{C} = (C^N)_{N\in\mathcal{X}}$, satisfies (3.7). Next we need:

- [46, Theorem 4.5]; [42] There exists a totally ordered index set $(L, \leq)$ and families $(W_l)_{l\in L}$ in $\operatorname{Irr} {}^H_H\mathcal{YD}$, $(\beta_l)_{l\in L}$ such that $\mathfrak{B}(M) \simeq \otimes_{l\in L}\mathfrak{B}(W_l)$ as $\mathbb{Z}^\theta$-graded objects in ${}^H_H\mathcal{YD}$, where $\deg x = \beta_l$ for all $x \in W_l$, $l \in L$.

Let $\Delta^M_\pm = \{\pm\beta_l : l \in L\}$, $\Delta^M = \Delta^M_+ \cup \Delta^M_-$, $\Delta = (\Delta^N)_{N\in\mathcal{X}(M)}$. Then $\mathcal{R} = (\mathcal{X}, \rho, \mathcal{C}, \Delta)$ is a finite GRS.

Theorem 3.6 ([23]). *The classification of all finite GRS is known.*

The proof is a combinatorial tour-de-force and requires computer calculations. It is possible to recover from this result the classification of the finite-dimensional contragredient Lie superalgebras in arbitrary characteristic [2]. However, the list of [23] is substantially larger than the classifications of the alluded Lie superalgebras or the braidings of diagonal type with finite-dimensional Nichols algebra.

3.5. Nichols algebras of diagonal type. Let G be a finite group. We denote ${}^G_G\mathcal{YD} = {}^H_H\mathcal{YD}$ for $H = \mathbb{C}G$. So $M \in {}^G_G\mathcal{YD}$ is a left G-module with a G-grading $M = \oplus_{g\in G}M_g$ such that $t \cdot M_g = M_{tgt^{-1}}$, for all $g, t \in G$. If $M, N \in {}^G_G\mathcal{YD}$, then the braiding $c : M \otimes N \to N \otimes M$ is given by $c(m \otimes n) = g \cdot n \otimes m$, $m \in M_g$, $n \in N$, $g \in G$. Now assume that $G = \Gamma$ is a finite abelian group. Then every $M \in {}^\Gamma_\Gamma\mathcal{YD}$ is a Γ-graded Γ-module, hence of the form $M = \oplus_{g\in\Gamma,\chi\in\widehat{\Gamma}}M^\chi_g$, where M^χ_g is the χ-isotypic component of M_g. So ${}^\Gamma_\Gamma\mathcal{YD}$ is just the category of $\Gamma \times \widehat{\Gamma}$-graded modules, with the braiding $c : M \otimes N \to N \otimes M$ given by $c(m \otimes n) = \chi(g)n \otimes m$, $m \in M^\eta_g$, $n \in N^\chi_t$, $g, t \in G$, $\chi, \eta \in \widehat{\Gamma}$. Let $\theta \in \mathbb{N}$, $\mathbb{I} = \mathbb{I}_\theta$.

Definition 3.7. Let $\mathbf{q} = (q_{ij})_{i,j\in\mathbb{I}}$ be a matrix with entries in $\mathbb{C}^\times$. A braided vector space (V, c) is of *diagonal type* with matrix $\mathbf{q}$ if V has a basis $(x_i)_{i\in\mathbb{I}}$ with

$$c(x_i \otimes x_j) = q_{ij}x_j \otimes x_i, \qquad i, j \in \mathbb{I}. \tag{3.21}$$

Thus, every finite-dimensional $V \in {}^\Gamma_\Gamma\mathcal{YD}$ is a braided vector space of diagonal type. Question (a), more precisely (a_1), has a complete answer in this setting. First we can assume that $q_{ii} \neq 1$ for $i \in \mathbb{I}$, as otherwise $\dim \mathfrak{B}(V) = \infty$. Also, let $\mathbf{q}' = (q'_{ij})_{i,j\in\mathbb{I}} \in (\mathbb{C}^\times)^{\mathbb{I}\times\mathbb{I}}$ and V' a braided vector space with matrix $\mathbf{q}'$. If $q_{ii} = q'_{ii}$ and $q_{ij}q_{ji} = q'_{ij}q'_{ji}$ for all $j \neq i \in \mathbb{I}_\theta$, then $\mathfrak{B}(V) \simeq \mathfrak{B}(V')$ as braided vector spaces.

Theorem 3.8 ([44]). *The classification of all braided vector spaces of diagonal type with finite-dimensional Nichols algebra is known.*

The proof relies on the Weyl groupoid introduced in [43], a particular case of Theorem 3.5. Another fundamental ingredient is the following result, generalized at various levels in [42, 46, 48].

Theorem 3.9 ([58]). *Let V be a braided vector space of diagonal type. Every Hopf algebra quotient of $T(V)$ has a PBW basis.*

The classification in Theorem 3.8 can be organized as follows:

- ◇ For most of the matrices $\mathbf{q} = (q_{ij})_{i,j\in\mathbb{I}_\theta}$ in the list of [44] there is a field $\mathbf{k}$ and a pair $(A, \mathbf{p})$ as in Example 3.2 such that $\dim \mathfrak{g}(A, \mathbf{p}) < \infty$, and $\mathfrak{g}(A, \mathbf{p})$ has the same GRS as the Nichols algebra corresponding to $\mathbf{q}$ [2].
- ◇ Besides these, there are 12 (yet) unidentified examples.

We believe that Theorem 3.8 can be proved from Theorem 3.6, via Example 3.2.

Theorem 3.10 ([18, 19]). *An efficient set of defining relations of each finite-dimensional Nichols algebra of a braided vector space of diagonal type is known.*

The proof uses most technical tools available in the theory of Nichols algebras; of interest in its own is the introduction of the notion of convex order in Weyl groupoids. As for other classifications above, it is not possible to state precisely the list of relations. We just mention different types of relations that appear.

- Quantum Serre relations, i.e., $\mathrm{ad}_c(x_i)^{1-a_{ij}}(x_j)$ for suitable $i \neq j$.
- Powers of root vectors, i.e., $x_\beta^{N_\beta}$, where the x_β's are part of the PBW basis.
- More exotic relations; they involve 2, 3, or at most 4 i's in $\mathbb{I}$.

3.6. Nichols algebras of rack type. We now consider Nichols algebras of objects in ${}^G_G\mathcal{YD}$, where G is a finite not necessarily abelian group. The category ${}^G_G\mathcal{YD}$ is semisimple and the simple objects are parametrized by pairs $(\mathcal{O}, \rho)$, where $\mathcal{O}$ is a conjugacy class in G and $\rho \in \operatorname{Irr} G^x$, for a fixed $x \in \mathcal{O}$; the corresponding simple Yetter-Drinfeld module $M(\mathcal{O}, \rho)$ is $\operatorname{Ind}_{G^x}^G \rho$ as a module. The braiding c is described in terms of the conjugation in $\mathcal{O}$. To describe the related suitable class, we recall that a rack is a set $X \neq \emptyset$ with a map $\triangleright : X \times X \to X$ satisfying

- $\varphi_x := x \triangleright \_\_$ is a bijection for every $x \in X$.
- $x \triangleright (y \triangleright z) = (x \triangleright y) \triangleright (x \triangleright z)$ for all $x, y, z \in X$ (self-distributivity).

For instance, a conjugacy class $\mathcal{O}$ in G with the operation $x \triangleright y = xyx^{-1}$, $x, y \in \mathcal{O}$ is a rack; actually we only consider racks realizable as conjugacy classes. Let X be a rack and $\mathfrak{X} = (X_k)_{k\in I}$ a decomposition of X, i.e., a disjoint family of subracks with $X_l \triangleright X_k = X_k$ for all $k, l \in I$.

Definition 3.11. [10] A *2-cocycle of degree* $\mathbf{n} = (n_k)_{k\in I}$, associated to $\mathfrak{X}$, is a family $\mathbf{q} = (q_k)_{k\in I}$ of maps $q_k : X \times X_k \to \mathbf{GL}(n_k, \mathbb{C})$ such that

$$q_k(i, j \triangleright h) q_k(j, h) = q_k(i \triangleright j, i \triangleright h) q_k(i, h), \qquad i, j \in X,\ h \in X_k,\ k \in I. \tag{3.22}$$

Given such $\mathbf{q}$, let $V = \oplus_{k\in I} \mathbb{C}X_k \otimes \mathbb{C}^{n_k}$ and let $c^{\mathbf{q}} \in \mathbf{GL}(V \otimes V)$ be given by

$$c^{\mathbf{q}}(x_i v \otimes x_j w) = x_{i \triangleright j} q_k(i, j)(w) \otimes x_i v, \qquad i \in X_l,\ j \in X_k,\ v \in \mathbb{C}^{n_l},\ w \in \mathbb{C}^{n_k}.$$

Then $(V, c^{\mathbf{q}})$ is a braided vector space called of *rack type*; its Nichols algebra is denoted $\mathfrak{B}(X, \mathbf{q})$. If $\mathfrak{X} = (X)$, then we say that $\mathbf{q}$ is *principal*.

Every finite-dimensional $V \in {}^G_G\mathcal{YD}$ is a braided vector space of rack type [10, Theorem 4.14]. Question (a_1) in this setting has partial answers in three different lines: computation of some finite-dimensional Nichols algebras, Nichols algebras of reducible Yetter-Drinfeld modules and collapsing of racks.

3.6.1. Finite-dimensional Nichols algebras of rack type. The algorithm to compute a Nichols algebra $\mathfrak{B}(V)$ is as follows: compute the space $\mathfrak{J}^i(V) = \ker \mathcal{Q}_i$ of relations of degree i, for $i = 2, 3, \dots, m$; then compute the m-th partial Nichols algebra $\widehat{\mathfrak{B}_m(V)} =$

$T(V)/\langle \oplus_{2\le i\le m}\mathfrak{J}^i(V)\rangle$, say with a computer program. If lucky enough to get $\dim \widehat{\mathfrak{B}_m}(V) < \infty$, then check whether it is a Nichols algebra, e.g. via skew-derivations; otherwise go to $m+1$. The description of $\mathfrak{J}^2(V) = \ker(\mathrm{id}+c)$ is not difficult [38] but for higher degrees it turns out to be very complicated. We list all known examples of finite-dimensional Nichols algebras $\mathfrak{B}(X,\mathbf{q})$ with X indecomposable and $\mathbf{q}$ principal and abelian ($n_1 = 1$).

Example 3.12. Let $\mathcal{O}_d^m$ be the conjugacy class of d-cycles in $\mathbb{S}_m$, $m \ge 3$. We start with the rack of transpositions in $\mathbb{S}_m$ and the cocycles -1, χ that arise from the $\rho \in \operatorname{Irr}\mathbb{S}_m^{(12)}$ with $\rho(12) = -1$, see [64, (5.5), (5.9)]. Let V be a vector space with basis $(x_{ij})_{(ij)\in\mathcal{O}_2^m}$ and consider the relations

$$x_{ij}^2 = 0, \qquad (ij) \in \mathcal{O}_2^m; \tag{3.23}$$

$$x_{ij}x_{kl} + x_{kl}x_{ij} = 0, \qquad (ij),(kl) \in \mathcal{O}_2^m,\ |\{i,j,k,l\}| = 4; \tag{3.24}$$

$$x_{ij}x_{kl} - x_{kl}x_{ij} = 0, \qquad (ij),(kl) \in \mathcal{O}_2^m,\ |\{i,j,k,l\}| = 4; \tag{3.25}$$

$$x_{ij}x_{ik} + x_{jk}x_{ij} + x_{ik}x_{jk} = 0, \qquad (ij),(ik),(jk) \in \mathcal{O}_2^m,\ |\{i,j,k\}| = 3; \tag{3.26}$$

$$x_{ij}x_{ik} - x_{jk}x_{ij} - x_{ik}x_{jk} = 0, \qquad (ij),(ik),(jk) \in \mathcal{O}_2^m,\ |\{i,j,k\}| = 3. \tag{3.27}$$

The quadratic algebras $\mathfrak{B}_m := \widehat{\mathfrak{B}_2}(\mathcal{O}_2^m, -1) = T(V)/\langle (3.23), (3.24), (3.26)\rangle$ and $\mathcal{E}_m := \widehat{\mathfrak{B}_2}(\mathcal{O}_2^m, \chi) = T(V)/\langle (3.23), (3.25), (3.27)\rangle$ were considered in [64], [36] respectively; $\mathcal{E}_m$ are named the *Fomin-Kirillov algebras*. It is known that

- The Nichols algebras $\mathfrak{B}(\mathcal{O}_2^m, -1)$ and $\mathfrak{B}(\mathcal{O}_2^m, \chi)$ are twist-equivalent, hence have the same Hilbert series. Ditto for the algebras $\mathfrak{B}_m$ and $\mathcal{E}_m$ [84].
- If $3 \le m \le 5$, then $\mathfrak{B}_m = \mathfrak{B}(\mathcal{O}_2^m, -1)$ and $\mathcal{E}_m = \mathfrak{B}(\mathcal{O}_2^m, \chi)$ are finite-dimensional [36, 38, 64] (for $m = 5$ part of this was done by Graña). In fact

$$\dim \mathfrak{B}_3 = 12, \qquad \dim \mathfrak{B}_4 = 576, \qquad \dim \mathfrak{B}_5 = 8294400.$$

  But for $m \ge 6$, it is not known whether the Nichols algebras $\mathfrak{B}(\mathcal{O}_2^m, -1)$ and $\mathfrak{B}(\mathcal{O}_2^m, \chi)$ have finite dimension or are quadratic.

Example 3.13 ([10]). The Nichols algebra $\mathfrak{B}(\mathcal{O}_4^4, -1)$ is quadratic, has the same Hilbert series as $\mathfrak{B}(\mathcal{O}_2^4, -1)$ and is generated by $(x_\sigma)_{\sigma\in\mathcal{O}_4^4}$ with defining relations

$$x_\sigma^2 = 0, \tag{3.28}$$

$$x_\sigma x_{\sigma^{-1}} + x_{\sigma^{-1}}x_\sigma = 0, \tag{3.29}$$

$$x_\sigma x_\kappa + x_\nu x_\sigma + x_\kappa x_\nu = 0, \qquad \sigma\kappa = \nu\sigma,\ \kappa \ne \sigma \ne \nu \in \mathcal{O}_4^4. \tag{3.30}$$

Example 3.14 ([41]). Let A be a finite abelian group and $g \in \operatorname{Aut} A$. The *affine* rack (A, g) is the set A with product $a \triangleright b = g(b) + (\mathrm{id} - g)(a)$, $a, b \in A$. Let $p \in \mathbb{N}$ be a prime, $q = p^{v(q)}$ a power of p, $A = \mathbb{F}_q$ and g the multiplication by $N \in \mathbb{F}_q^\times$; let $X_{q,N} = (A, g)$. Assume that $q = 3$, 4, 5, or 7, with $N = 2$, $\omega \in \mathbb{F}_4 - \mathbb{F}_2$, 2 or 3, respectively. Then $\dim \mathfrak{B}(X_{q,N}, -1) = q\varphi(q)(q-1)^{q-2}$, φ being the Euler function, and $\mathfrak{J}(X_{q,N}, -1) = \langle \mathfrak{J}^2 + \mathfrak{J}^{v(q)(q-1)}\rangle$, where $\mathfrak{J}^2$ is generated by

$$x_i^2, \qquad \text{always} \tag{3.31}$$

$$x_i x_j + x_{-i+2j}x_i + x_j x_{-i+2j}, \qquad \text{for } q = 3, \tag{3.32}$$

$$x_ix_j + x_{(\omega+1)i+\omega j}x_i + x_jx_{(\omega+1)i+\omega j}, \qquad \text{for } q = 4, \tag{3.33}$$
$$x_ix_j + x_{-i+2j}x_i + x_{3i-2j}x_{-i+2j} + x_jx_{3i-2j}, \qquad \text{for } q = 5, \tag{3.34}$$
$$x_ix_j + x_{-2i+3j}x_i + x_jx_{-2i+3j}, \qquad \text{for } q = 7, \tag{3.35}$$

with $i, j \in \mathbb{F}_q$; and $\mathfrak{J}^{v(q)(q-1)}$ is generated by $\sum_h T^h(V)\mathfrak{J}^2T^{v(q)(q-1)-h-2}(V)$ and

$$(x_\omega x_1x_0)^2 + (x_1x_0x_\omega)^2 + (x_0x_\omega x_1)^2, \qquad \text{for } q = 4, \tag{3.36}$$
$$(x_1x_0)^2 + (x_0x_1)^2, \qquad \text{for } q = 5, \tag{3.37}$$
$$(x_2x_1x_0)^2 + (x_1x_0x_2)^2 + (x_0x_2x_1)^2, \qquad \text{for } q = 7. \tag{3.38}$$

Of course $X_{3,2} = \mathcal{O}_2^3$; also $\dim \mathfrak{B}(X_{4,\omega}, -1) = 72$. By duality, we get

$$\dim \mathfrak{B}(X_{5,3}, -1) = \dim \mathfrak{B}(X_{5,2}, -1) = 1280,$$
$$\dim \mathfrak{B}(X_{7,5}, -1) = \dim \mathfrak{B}(X_{7,3}, -1) = 326592.$$

Example 3.15 ([45]). There is another finite-dimensional Nichols algebra associated to $X_{4,\omega}$ with a cocycle $\mathbf{q}$ with values $\pm\xi$, where $1 \neq \xi \in \mathbb{G}_3$. Concretely, $\dim \mathfrak{B}(X_{4,\omega}, \mathbf{q}) = 5184$ and $\mathfrak{B}(X_{4,\omega}, \mathbf{q})$ can be presented by generators $(x_i)_{i\in\mathbb{F}_4}$ with defining relations

$$x_0^3 = x_1^3 = x_\omega^3 = x_{\omega^2}^3 = 0,$$
$$\xi^2x_0x_1 + \xi x_1x_\omega - x_\omega x_0 = 0, \quad \xi^2x_0x_\omega + \xi x_\omega x_{\omega^2} - x_{\omega^2}x_0 = 0,$$
$$\xi x_0x_{\omega^2} - \xi^2x_1x_0 + x_{\omega^2}x_1 = 0, \quad \xi x_1x_{\omega^2} + \xi^2x_\omega x_1 + x_{\omega^2}x_\omega = 0,$$
$$x_0^2x_1x_\omega x_1^2 + x_0x_1x_\omega x_1^2x_0 + x_1x_\omega x_1^2x_0^2 + x_\omega x_1^2x_0^2x_1 + x_1^2x_0^2x_1x_\omega + x_1x_0^2x_1x_\omega x_1$$
$$+x_1x_\omega x_1x_0^2x_\omega + x_\omega x_1x_0x_1x_0x_\omega + x_\omega x_1^2x_0x_\omega x_0 = 0.$$

3.6.2. Nichols algebras of decomposable Yetter-Drinfeld modules over groups. The ideas of Example 3.4 in the context of decomposable Yetter-Drinfeld modules over groups were pushed further in a series of papers culminating with a remarkable classification result [50]. Consider the groups

$$\Gamma_n = \langle a, b, \nu | ba = \nu ab, \quad \nu a = a\nu^{-1}, \quad \nu b = b\nu, \quad \nu^n = 1\rangle, \quad n \geq 2; \tag{3.39}$$
$$T = \langle \zeta, \chi_1, \chi_2 | \zeta\chi_1 = \chi_1\zeta, \quad \zeta\chi_2 = \chi_2\zeta, \quad \chi_1\chi_2\chi_1 = \chi_2\chi_1\chi_2, \quad \chi_1^3 = \chi_2^3\rangle. \tag{3.40}$$

- [47] Let G be a suitable quotient of Γ_2. Then there exist $V_1, W_1 \in \operatorname{Irr}{}^G_G\mathcal{YD}$ such that $\dim V_1 = \dim W_1 = 2$ and $\dim \mathfrak{B}(V_1 \oplus W_1) = 64 = 2^6$.
- [50] Let G be a suitable quotient of Γ_3. Then there exist V_2, V_3, V_4, $W_2, W_3, W_4 \in \operatorname{Irr}{}^G_G\mathcal{YD}$ such that $\dim V_2 = 1$, $\dim V_3 = \dim V_4 = 2$, $\dim W_2 = \dim W_3 = \dim W_4 = 3$ and $\dim \mathfrak{B}(V_2 \oplus W_2) = \dim \mathfrak{B}(V_3 \oplus W_3) = 10368 = 2^7 3^4$, $\dim \mathfrak{B}(V_4 \oplus W_4) = 2304 = 2^{18}$.
- [49] Let G be a suitable quotient of Γ_4. Then there exist V_5, $W_5 \in \operatorname{Irr}{}^G_G\mathcal{YD}$ such that $\dim V_5 = 2$, $\dim W_5 = 4$ and $\dim \mathfrak{B}(V_5 \oplus W_5) = 262144 = 2^{18}$.
- [49] Let G be a suitable quotient of T. Then there exist V_6, $W_6 \in \operatorname{Irr}{}^G_G\mathcal{YD}$ such that $\dim V_6 = 1$, $\dim W_6 = 4$ and $\dim \mathfrak{B}(V_6 \oplus W_6) = 80621568 = 2^{12}3^9$.

Theorem 3.16 ([50]). *Let G be a non-abelian group and $V, W \in \operatorname{Irr}{}^G_G\mathcal{YD}$ such that G is generated by the support of $V \oplus W$. Assume that $c^2_{|V\otimes W} \neq \mathrm{id}$ and that $\dim \mathfrak{B}(V \oplus W) < \infty$. Then $V \oplus W$ is one of $V_i \oplus W_i$, $i \in \mathbb{I}_6$, above, and correspondingly G is a quotient of either Γ_n, $2 \leq n \leq 4$, or T.*

3.6.3. Collapsing racks. Implicit in Question (a_1) in the setting of racks is the need to compute all non-principal 2-cocycles for a fixed rack X. Notably, there exist criteria that dispense of this computation. To state them and explain their significance, we need some terminology. All racks below are finite.

- A rack X is *abelian* when $x \triangleright y = y$, for all $x, y \in X$.
- A rack is *indecomposable* when it is not a disjoint union of two proper subracks.
- A rack X with $|X| > 1$ is *simple* when for any projection of racks $\pi : X \to Y$, either π is an isomorphism or Y has only one element.

Theorem 3.17 ([10, 3.9, 3.12], [55]). *Every simple rack is isomorphic to one of:*

(1) *Affine racks $(\mathbb{F}_p^t, T)$, where p is a prime, $t \in \mathbb{N}$, and T is the companion matrix of a monic irreducible polynomial $f \in \mathbb{F}_p[\mathtt{X}]$ of degree t, $f \neq \mathtt{X}, \mathtt{X} - 1$.*

(2) *Non-trivial (twisted) conjugacy classes in simple groups.*

(3) *Twisted conjugacy classes of type (G, u), where $G = L^t$, with L a simple non-abelian group and $1 < t \in \mathbb{N}$; and $u \in \operatorname{Aut}(L^t)$ acts by $u(\ell_1, \ell_2, \dots, \ell_t) = (\theta(\ell_t), \ell_1, \ell_2, \dots, \ell_{t-1})$, where $\theta \in \operatorname{Aut}(L)$.*

Definition 3.18 ([7, 3.5]). We say that a finite rack X is *of type D* when there are a decomposable subrack $Y = R \coprod S$, $r \in R$ and $s \in S$ such that $r \triangleright (s \triangleright (r \triangleright s)) \neq s$.

Also, X is *of type F* [4] if there are a disjoint family of subracks $(R_a)_{a\in\mathbb{I}_4}$ and a family $(r_a)_{a\in\mathbb{I}_4}$ with $r_a \in R_a$, such that $R_a \triangleright R_b = R_b$, $r_a \triangleright r_b \neq r_b$, for all $a \neq b \in \mathbb{I}_4$.

An indecomposable rack X *collapses* when $\dim \mathfrak{B}(X, \mathbf{q}) = \infty$ for every finite *faithful* 2-cocycle $\mathbf{q}$ (see [7] for the definition of faithful).

Theorem 3.19 ([7, 3.6]; [4, 2.8]). *If a rack is of type D or F, then it collapses.*

The proofs use results on Nichols algebras from [12, 23, 46].

If a rack projects onto a rack of type D (or F), then it is also of type D (or F), hence it collapses by Theorem 3.19. Since every indecomposable rack X, $|X| > 1$, projects onto a simple rack, it is natural to ask for the determination of all *simple* racks of type D or F. A rack is *cthulhu* if it is neither of type D nor F; it is *sober* if every subrack is either abelian or indecomposable [4]. Sober implies cthulhu.

- Let $m \geq 5$. Let $\mathcal{O}$ be either $\mathcal{O}^{\mathbb{S}_m}_\sigma$, if $\sigma \in \mathbb{S}_m - \mathbb{A}_m$, or else $\mathcal{O}^{\mathbb{A}_m}_\sigma$ if $\sigma \in \mathbb{A}_m$. The type of σ is formed by the lengths of the cycles in its decomposition.
  - ◇ [7, 4.2] If the type of σ is (3^2), $(2^2, 3)$, $(1^n, 3)$, (2^4), $(1^2, 2^2)$, $(2, 3)$, (2^3), or $(1^n, 2)$, then $\mathcal{O}$ is cthulhu. If the type of σ is $(1, 2^2)$, then $\mathcal{O}$ is sober.
  - ◇ [33] Let $p \in \mathbb{N}$ be a prime. Assume the type of σ is (p). If $p = 5, 7$ or not of the form $(r^k - 1)/(r - 1)$, r a prime power, then $\mathcal{O}$ is sober; otherwise $\mathcal{O}$ is of type D. Assume the type of σ is $(1, p)$. If $p = 5$ or not of the form $(r^k - 1)/(r - 1)$, r a prime power, then $\mathcal{O}$ is sober; otherwise $\mathcal{O}$ is of type D.

Table 3.1. Classes in sporadic simple groups not of type D

Group	Classes	Group	Classes
T	2A	Co_3	23A, 23B
M_{11}	8A, 8B, 11A, 11B	J_1	15A, 15B, 19A, 19B, 19C
M_{12}	11A, 11B	J_2	2A, 3A
M_{22}	11A, 11B	J_3	5A, 5B, 19A, 19B
M_{23}	23A, 23B	J_4	29A, 43A, 43B, 43C
M_{24}	23A, 23B	Ly	37A, 37B, 67A, 67B, 67C
Ru	29A, 29B	$O'N$	31A, 31B
Suz	3A	Fi_{23}	2A
HS	11A, 11B	Fi_{22}	2A, 22A, 22B
McL	11A, 11B	Fi'_{24}	29A, 29B
Co_1	3A	B	2A, 46A, 46B, 47A, 47B
Co_2	2A, 23A, 23B		

- ◇ [7, 4.1] For all other types, $\mathcal{O}$ is of type D, hence it collapses.
- ○ [4] Let $n \geq 2$ and q be a prime power. Let $x \in \mathbf{PSL}_n(q)$ not semisimple and $\mathcal{O} = \mathcal{O}_x^{\mathbf{PSL}_n(q)}$. The type of a unipotent element are the sizes of its Jordan blocks.
- ◇ Assume x is unipotent. If x is either of type (2) and q is even or not a square, or of type (3) and $q = 2$, then $\mathcal{O}$ is sober. If x is either of type $(2,1)$ and q is even, or of type $(2,1,1)$ and $q = 2$ then $\mathcal{O}$ is cthulhu. If x is of type $(2,1,1)$ and $q > 2$ is even, then $\mathcal{O}$ is not of type D, but it is open if it is of type F.
- ◇ Otherwise, $\mathcal{O}$ is either of type D or of type F, hence it collapses.
- ○ [8, 35] Let $\mathcal{O}$ be a conjugacy class in a sporadic simple group G. If $\mathcal{O}$ appears in Table 3.1, then $\mathcal{O}$ is not of type D. If $G = M$ is the Monster and $\mathcal{O}$ is one of 32A, 32B, 41A, 46A, 46B, 47A, 47B, 59A, 59B, 69A, 69B, 71A, 71B, 87A, 87B, 92A, 92B, 94A, 94B, then it is open whether $\mathcal{O}$ is of type D. Otherwise, $\mathcal{O}$ is of type D.

3.7. Generation in degree one. Here is the scheme of proof proposed in [14] to attack Conjecture 3.1: Let T be a finite-dimensional graded Hopf algebra in ${}^K_K\mathcal{YD}$ with $T^0 = \mathbb{C}$ and generated as algebra by T^1. We have a commutative diagram of Hopf algebra maps $\begin{array}{ccc} T & \xrightarrow{\pi} & \mathfrak{B}(V) \\ & {\scriptstyle p}\nwarrow \quad \nearrow & \\ & T(V) & \end{array}$. To show that π is injective, take a generator r (or a family of generators) of $\mathfrak{J}(V)$ such that $r \in \mathcal{P}(T(V))$ and consider the Yetter-Drinfeld submodule $U = \mathbb{C}r \oplus V$ of $T(V)$; if $\dim \mathfrak{B}(U) = \infty$, then $p(r) = 0$. Then p factorizes through $T(V)/\mathfrak{J}_1(V)$, where $\mathfrak{J}_1(V)$ is the ideal generated by primitive generators of $\mathfrak{J}(V)$, and so on.

The Conjecture has been verified in all known examples in characteristic 0 (it is false in positive characteristic or for infinite-dimensional Hopf algebras).

Theorem 3.20. *A finite-dimensional pointed Hopf algebra H is generated by group-like and skew-primitive elements if either of the following holds:*

- ◇ [19] *The infinitesimal braiding is of diagonal type, e. g. $G(H)$ is abelian.*
- ◇ [11, 38]. *The infinitesimal braiding of H is any of $(\mathcal{O}_2^m, -1)$, $(\mathcal{O}_2^m, \chi)$ $(m = 3, 4, 5)$, $(X_{4,\omega}, -1)$, $(X_{5,2}, -1)$, $(X_{5,3}, -1)$, $(X_{7,3}, -1)$, $(X_{7,5}, -1)$.*

3.8. Liftings. We address here Question (c) in §3.2. Let X be a finite rack and $q : X \times X \to \mathbb{G}_\infty$ a 2-cocycle. A Hopf algebra H is a *lifting* of (X, q) if H_0 is a Hopf subalgebra, H is generated by H_1 and its infinitesimal braiding is a realization of $(\mathbb{C}X, c^q)$. See [39] for liftings in the setting of copointed Hopf algebras.

We start discussing realizations of braided vector spaces as Yetter-Drinfeld modules. Let $\theta \in \mathbb{N}$ and $\mathbb{I} = \mathbb{I}_\theta$. First, a *YD-datum of diagonal type* is a collection

$$\mathcal{D} = ((q_{ij})_{i,j\in\mathbb{I}}, G, (g_i)_{i\in\mathbb{I}}, (\chi_i)_{i\in\mathbb{I}}), \tag{3.41}$$

where $q_{ij} \in \mathbb{G}_\infty$, $q_{ii} \neq 1$, $i, j \in \mathbb{I}$; G is a finite group; $g_i \in Z(G)$; $\chi_i \in \widehat{G}$, $i \in \mathbb{I}$; such that $q_{ij} := \chi_j(g_i)$, $i, j \in \mathbb{I}$. Let (V, c) be the braided vector space of diagonal type with matrix (q_{ij}) in the basis $(x_i)_{i\in\mathbb{I}_\theta}$. Then $V \in {}^G_G\mathcal{YD}$ by declaring $x_i \in V^{\chi_i}_{g_i}$, $i \in \mathbb{I}$. More generally, a *YD-datum of rack type* [11, 64] is a collection

$$\mathcal{D} = (X, q, G, \cdot, g, \chi), \tag{3.42}$$

where X is a finite rack; $q : X \times X \to \mathbb{G}_\infty$ is a 2-cocycle; G is a finite group; $\cdot$ is an action of G on X; $g : X \to G$ is equivariant with respect to the conjugation in G; and $\chi = (\chi_i)_{i\in X}$ is a family of 1-cocycles $\chi_i : G \to \mathbb{C}^\times$ (that is, $\chi_i(ht) = \chi_i(t)\chi_{t\cdot i}(h)$, for all $i \in X$, $h, t \in G$) such that $g_i \cdot j = i \triangleright j$ and $\chi_i(g_j) = q_{ij}$ for all $i, j \in X$. Let $(V, c) = (\mathbb{C}X, c^q)$ be the associated braided vector space. Then V becomes an object in ${}^G_G\mathcal{YD}$ by $\delta(x_i) = g_i \otimes x_i$ and $t \cdot x_i = \chi_i(t)x_{t\cdot i}$, $t \in G$, $i \in X$.

Second, let $\mathcal{D}$ be a YD-datum of either diagonal or rack type and $V \in {}^G_G\mathcal{YD}$ as above; let $\mathcal{T}(V) := T(V)\#\mathbb{C}G$. The desired liftings are quotients of $\mathcal{T}(V)$; write a_i in these quotients instead of x_i to distinguish them from the elements in $\mathfrak{B}(V)\#\mathbb{C}G$. Let $\mathcal{G}$ be a minimal set of generators of $\mathfrak{J}(V)$, assumed homogeneous both for the $\mathbb{N}$- and the G-grading. Roughly speaking, the deformations will be defined by replacing the relations $r = 0$ by $r = \phi_r$, $r \in \mathcal{G}$, where $\phi_r \in \mathcal{T}(V)$ belongs to a lower term of the coradical filtration, and the ideal $\mathfrak{J}_\phi(V)$ generated by ϕ_r, $r \in \mathcal{G}$, is a Hopf ideal. The problem is to describe the ϕ_r's and to check that $\mathcal{T}(V)/\mathfrak{J}_\phi(V)$ has the right dimension. If $r \in \mathcal{P}(T(V))$ has G-degree g, then $\phi_r = \lambda(1 - g)$ for some $\lambda \in \mathbb{C}$; depending on the action of G on r, it may happen that λ should be 0. In some cases, all $r \in \mathcal{G}$ are primitive, so all deformations can be described; see [13] for quantum linear spaces (their liftings can also be presented as Ore extensions [20]) and the Examples 3.21 and 3.22. But in most cases, not all $r \in \mathcal{G}$ are primitive and some recursive construction of the deformations is needed. This was achieved in [15] for diagonal braidings of Cartan type A_n, with explicit formulae, and in [16] for diagonal braidings of finite Cartan type, with recursive formulae. Later it was observed that the so obtained liftings are cocycle deformations of $\mathfrak{B}(V)\#\mathbb{C}G$, see e.g. [63]. This led to the strategy in [3]: pick an adapted stratification $\mathcal{G} = \mathcal{G}_0 \cup \mathcal{G}_1 \cup \cdots \cup \mathcal{G}_N$ [3, 5.1]; then construct recursively the deformations of $T(V)/\langle \mathcal{G}_0 \cup \mathcal{G}_1 \cup \cdots \cup \mathcal{G}_{k-1}\rangle$ by determining the cleft extensions of the deformations in the previous step and applying the theory of Hopf bi-Galois extensions [77]. In the Examples below, $\chi_i = \chi \in \widehat{G}$ for all $i \in X$ by [11, 3.3 (d)].

Example 3.21 ([11, 39]). Let $\mathcal{D} = (\mathcal{O}_2^3, -1, G, \cdot, g, \chi)$ be a YD-datum. Let $\lambda \in \mathbb{C}^2$ be such that

$$\lambda_1 = \lambda_2 = 0, \qquad \text{if } \chi^2 \neq \varepsilon; \tag{3.43}$$

$$\lambda_1 = 0, \qquad \text{if } g_{12}^2 = 1; \qquad \lambda_2 = 0, \qquad \text{if } g_{12}g_{13} = 1. \tag{3.44}$$

Let $\mathfrak{u} = \mathfrak{u}(\mathcal{D}, \lambda)$ be the quotient of $\mathcal{T}(V)$ by the relations

$$a_{12}^2 = \lambda_1(1 - g_{12}^2), \tag{3.45}$$

$$a_{12}a_{13} + a_{23}a_{12} + a_{13}a_{23} = \lambda_2(1 - g_{12}g_{13}). \tag{3.46}$$

Then $\mathfrak{u}$ is a pointed Hopf algebra, a cocycle deformation of $\operatorname{gr}\mathfrak{u} \simeq \mathfrak{B}(V)\#\mathbb{C}G$ and $\dim \mathfrak{u} = 12|G|$; $\mathfrak{u}(\mathcal{D}, \lambda) \simeq \mathfrak{u}(\mathcal{D}, \lambda')$ iff $\lambda = c\lambda'$ for some $c \in \mathbb{C}^\times$. Conversely, any lifting of $(\mathcal{O}_2^3, -1)$ is isomorphic to $\mathfrak{u}(\mathcal{D}, \lambda)$ for some YD-datum $\mathcal{D} = (\mathcal{O}_2^3, -1, G, \cdot, g, \chi)$ and $\lambda \in \mathbb{C}^2$ satisfying (3.43), (3.44).

Example 3.22 ([11]). Let $\mathcal{D} = (\mathcal{O}_2^4, -1, G, \cdot, g, \chi)$ be a YD-datum. Let $\lambda \in \mathbb{C}^3$ be such that

$$\lambda_i = 0, \quad i \in \mathbb{I}_3, \qquad \text{if } \chi^2 \neq \varepsilon; \tag{3.47}$$

$$\lambda_1 = 0, \quad \text{if } g_{12}^2 = 1; \qquad \lambda_2 = 0, \quad \text{if } g_{12}g_{34} = 1; \quad \lambda_3 = 0, \quad \text{if } g_{12}g_{13} = 1. \tag{3.48}$$

Let $\mathfrak{u} = \mathfrak{u}(\mathcal{D}, \lambda)$ be the quotient of $\mathcal{T}(V)$ by the relations

$$a_{12}^2 = \lambda_1(1 - g_{12}^2), \tag{3.49}$$

$$a_{12}a_{34} + a_{34}a_{12} = \lambda_2(1 - g_{12}g_{34}), \tag{3.50}$$

$$a_{12}a_{13} + a_{23}a_{12} + a_{13}a_{23} = \lambda_3(1 - g_{12}g_{13}). \tag{3.51}$$

Then $\mathfrak{u}$ is a pointed Hopf algebra, a cocycle deformation of $\mathfrak{B}(V)\#\mathbb{C}G$ and $\dim \mathfrak{u} = 576|G|$; $\mathfrak{u}(\mathcal{D}, \lambda) \simeq \mathfrak{u}(\mathcal{D}, \lambda')$ iff $\lambda = c\lambda'$ for some $c \in \mathbb{C}^\times$. Conversely, any lifting of $(\mathcal{O}_2^4, -1)$ is isomorphic to $\mathfrak{u}(\mathcal{D}, \lambda)$ for some YD-datum $\mathcal{D} = (\mathcal{O}_2^4, -1, G, \cdot, g, \chi)$ and $\lambda \in \mathbb{C}^3$ satisfying (3.47), (3.48).

Example 3.23 ([39]). Let $\mathcal{D} = (X_{4,\omega}, -1, G, \cdot, g, \chi)$ be a YD-datum. Let $\lambda \in \mathbb{C}^3$ be such that

$$\lambda_1 = \lambda_2 = 0, \qquad \text{if } \chi^2 \neq \varepsilon; \qquad \lambda_3 = 0, \text{ if } \chi^6 \neq \varepsilon; \tag{3.52}$$

$$\lambda_1 = 0, \text{ if } g_0^2 = 1, \qquad \lambda_2 = 0, \text{ if } g_0g_1 = 1, \qquad \lambda_3 = 0, \text{ if } g_0^3g_1^3 = 1. \tag{3.53}$$

Let $\mathfrak{u} = \mathfrak{u}(\mathcal{D}, \lambda)$ be the quotient of $\mathcal{T}(V)$ by the relations

$$x_0^2 = \lambda_1(1 - g_0^2), \tag{3.54}$$

$$x_0x_1 + x_\omega x_0 + x_1x_\omega = \lambda_2(1 - g_0g_1) \tag{3.55}$$

$$(x_\omega x_1 x_0)^2 + (x_1x_0x_\omega)^2 + (x_0x_\omega x_1)^2 = \zeta_6 - \lambda_3(1 - g_0^3g_1^3), \qquad \text{where} \tag{3.56}$$

$$\zeta_6 = \lambda_2(x_\omega x_1x_0x_\omega + x_1x_0x_\omega x_1 + x_0x_\omega x_1x_0) - \lambda_2^3(g_0g_1 - g_0^3g_1^3)$$

$$
\begin{aligned}
&+\lambda_1^2 g_0^2\big(g_{1+\omega}^2(x_\omega x_3 + x_0 x_\omega) + g_1 g_{1+\omega}(x_\omega x_1 + x_1 x_3) + g_1^2(x_1 x_0 + x_0 x_3)\big)\\
&-2\lambda_1^2 g_0^2(x_0 x_3 - x_\omega x_3 - x_1 x_\omega + x_1 x_0) - 2\lambda_1^2 g_\omega^2(x_\omega x_3 - x_1 x_3 + x_0 x_\omega - x_0 x_1)\\
&-2\lambda_1^2 g_1^2(x_\omega x_1 + x_1 x_3 + x_1 x_\omega - x_0 x_3 + x_0 x_1)\\
&+\lambda_2\lambda_1(g_\omega^2 x_0 x_3 + g_1^2 x_\omega x_3 + g_0^2 x_1 x_3) + \lambda_2^2 g_0 g_1(x_\omega x_1 + x_1 x_0 + x_0 x_\omega - \lambda_1)\\
&-\lambda_2\lambda_1^2(3g_0^3 g_{1+\omega} - 2g_0 g_1^3 - g_0^2 g_\omega^2 - 2g_0^3 g_1 + g_\omega^2 - g_1^2 + g_0^2)\\
&-\lambda_2(\lambda_1 - \lambda_2)\big(\lambda_1\, g_0^2(g_{1+\omega}^2 + g_1 g_{1+\omega} + g_1^2 + 2g_0 g_1^3) + x_\omega x_1 + x_1 x_0 + x_0 x_\omega\big).
\end{aligned}
$$

Then $\mathfrak{u}$ is a pointed Hopf algebra, a cocycle deformation of $\operatorname{gr}\mathfrak{u} \simeq \mathfrak{B}(V)\#\mathbb{C}G$ and $\dim \mathfrak{u} = 72|G|$; $\mathfrak{u}(\mathcal{D},\lambda) \simeq \mathfrak{u}(\mathcal{D},\lambda')$ iff $\lambda = c\lambda'$ for some $c \in \mathbb{C}^\times$. Conversely, any lifting of $(X_{4,\omega}, -1)$ is isomorphic to $\mathfrak{u}(\mathcal{D},\lambda)$ for some YD-datum $\mathcal{D} = (X_{4,\omega}, -1, G, \cdot, g, \chi)$ and $\lambda \in \mathbb{C}^3$ satisfying (3.52), (3.53).

Example 3.24 ([39]). Let $\mathcal{D} = (X_{5,2}, -1, G, \cdot, g, \chi)$ be a YD-datum. Let $\lambda \in \mathbb{C}^3$ be such that

$$
\lambda_1 = \lambda_2 = 0, \qquad \text{if } \chi^2 \neq \varepsilon; \qquad \lambda_3 = 0, \text{ if } \chi^4 \neq \varepsilon; \tag{3.57}
$$

$$
\lambda_1 = 0, \text{ if } g_0^2 = 1, \qquad \lambda_2 = 0, \text{ if } g_0 g_1 = 1, \qquad \lambda_3 = 0, \text{ if } g_0^2 g_1 g_2 = 1. \tag{3.58}
$$

Let $\mathfrak{u} = \mathfrak{u}(\mathcal{D},\lambda)$ be the quotient of $\mathcal{T}(V)$ by the relations

$$
x_0^2 = \lambda_1(1 - g_0^2), \tag{3.59}
$$

$$
x_0 x_1 + x_2 x_0 + x_3 x_2 + x_1 x_3 = \lambda_2(1 - g_0 g_1), \tag{3.60}
$$

$$
(x_1 x_0)^2 + (x_0 x_1)^2 = \zeta_4 - \lambda_3(1 - g_0^2 g_1 g_2), \quad \text{where} \tag{3.61}
$$

$\zeta_4 = \lambda_2\,(x_1 x_0 + x_0 x_1) + \lambda_1\, g_1^2(x_3 x_0 + x_2 x_3) - \lambda_1\, g_0^2(x_2 x_4 + x_1 x_2) + \lambda_2\lambda_1\, g_0^2(1 - g_1 g_2)$.
Then $\mathfrak{u}$ is a pointed Hopf algebra, a cocycle deformation of $\operatorname{gr}\mathfrak{u} \simeq \mathfrak{B}(V)\#\mathbb{C}G$ and $\dim \mathfrak{u} = 1280|G|$; $\mathfrak{u}(\mathcal{D},\lambda) \simeq \mathfrak{u}(\mathcal{D},\lambda')$ iff $\lambda = c\lambda'$ for some $c \in \mathbb{C}^\times$. Conversely, any lifting of $(X_{5,2}, -1)$ is isomorphic to $\mathfrak{u}(\mathcal{D},\lambda)$ for some YD-datum $\mathcal{D} = (X_{5,2}, -1, G, \cdot, g, \chi)$ and $\lambda \in \mathbb{C}^3$ satisfying (3.57), (3.58).

Example 3.25 ([39]). Let $\mathcal{D} = (X_{5,3}, -1, G, \cdot, g, \chi)$ be a YD-datum. Let $\lambda \in \mathbb{C}^3$ be such that

$$
\lambda_1 = \lambda_2 = 0, \qquad \text{if } \chi^2 \neq \varepsilon; \qquad \lambda_3 = 0, \text{ if } \chi^4 \neq \varepsilon; \tag{3.62}
$$

$$
\lambda_1 = 0, \text{ if } g_0^2 = 1, \qquad \lambda_2 = 0, \text{ if } g_1 g_0 = 1, \qquad \lambda_3 = 0, \text{ if } g_0^2 g_1 g_3 = 1. \tag{3.63}
$$

Let $\mathfrak{u} = \mathfrak{u}(\mathcal{D},\lambda)$ be the quotient of $\mathcal{T}(V)$ by the relations

$$
x_0^2 = \lambda_1(1 - g_0^2), \tag{3.64}
$$

$$
x_1 x_0 + x_0 x_2 + x_2 x_3 + x_3 x_1 = \lambda_2(1 - g_1 g_0) \tag{3.65}
$$

$$
x_0 x_2 x_3 x_1 + x_1 x_4 x_3 x_0 = \zeta_4' - \lambda_3(1 - g_0^2 g_1 g_3), \quad \text{where} \tag{3.66}
$$

$\zeta_4' = \lambda_2\,(x_0 x_1 + x_1 x_0) - \lambda_1\, g_1^2(x_3 x_2 + x_0 x_3) - \lambda_1\, g_0^2(x_3 x_4 + x_1 x_3) + \lambda_1\lambda_2(g_1^2 + g_0^2 - 2g_0^2 g_1 g_3)$.
Then $\mathfrak{u}$ is a pointed Hopf algebra, a cocycle deformation of $\operatorname{gr}\mathfrak{u} \simeq \mathfrak{B}(V)\#\mathbb{C}G$ and $\dim \mathfrak{u} = 1280|G|$; $\mathfrak{u}(\mathcal{D},\lambda) \simeq \mathfrak{u}(\mathcal{D},\lambda')$ iff $\lambda = c\lambda'$ for some $c \in \mathbb{C}^\times$. Conversely, any lifting of $(X_{5,3}, -1)$ is isomorphic to $\mathfrak{u}(\mathcal{D},\lambda)$ for some YD-datum $\mathcal{D} = (X_{5,3}, -1, G, \cdot, g, \chi)$ and $\lambda \in \mathbb{C}^3$ satisfying (3.62), (3.63).

4. Pointed Hopf algebras

4.1. Pointed Hopf algebras with abelian group. Here is a classification from [16]. Let $\mathcal{D} = ((q_{ij})_{i,j\in\mathbb{I}_\theta}, \Gamma, (g_i)_{i\in\mathbb{I}_\theta}, (\chi_i)_{i\in\mathbb{I}_\theta})$ be a YD-datum of diagonal type as in (3.41) with Γ a finite abelian group and let $V \in {}^\Gamma_\Gamma\mathcal{YD}$ be the corresponding realization. We say that $\mathcal{D}$ is a *Cartan datum* if there is a Cartan matrix (of finite type) $\mathbf{a} = (a_{ij})_{i,j\in\mathbb{I}_\theta}$ such that $q_{ij}q_{ji} = q_{ii}^{a_{ij}}$, $i \neq j \in \mathbb{I}_\theta$.

Let Φ be the root system associated to $\mathbf{a}$, $\alpha_1, \dots, \alpha_\theta$ a choice of simple roots, $\mathcal{X}$ the set of connected components of the Dynkin diagram of Φ and set $i \sim j$ whenever α_i, α_j belong to the same $J \in \mathcal{X}$. We consider two classes of parameters:

- $\lambda = (\lambda_{ij})_{i<j\in\mathbb{I}_\theta,\ i\not\sim j}$, is a family in $\{0,1\}$ with $\lambda_{ij} = 0$ when $g_ig_j = 1$ or $\chi_i\chi_j \neq \varepsilon$.
- $\mu = (\mu_\alpha)_{\alpha\in\Phi^+}$ is a family in $\mathbb{C}$ with $\mu_\alpha = 0$ when $\operatorname{supp}\alpha \subset J$, $J \in \mathcal{X}$, and $g_\alpha^{N_J} = 1$ or $\chi_\alpha^{N_J} \neq \varepsilon$. Here $N_J = \operatorname{ord} q_{ii}$ for an arbitrary $i \in J$.

We attach a family $(u_\alpha(\mu))_{\alpha\in\Phi^+}$ in $\mathbb{C}\Gamma$ to the parameter μ , defined recursively on the length of α, starting by $u_{\alpha_i}(\mu) = \mu_{\alpha_i}(1 - g_i^{N_i})$. From all these data we define a Hopf algebra $\mathfrak{u}(\mathcal{D}, \lambda, \mu)$ as the quotient of $\mathcal{T}(V) = T(V)\#\mathbb{C}\Gamma$ by the relations

$$ga_ig^{-1} = \chi_i(g)a_i, \tag{4.1}$$

$$\operatorname{ad}_c(a_i)^{1-a_{ij}}(a_j) = 0, \qquad i \neq j, i \sim j, \tag{4.2}$$

$$\operatorname{ad}_c(a_i)(a_j) = \lambda_{ij}(1 - g_ig_j), \qquad i < j, i \not\sim j, \tag{4.3}$$

$$a_\alpha^{N_J} = u_\alpha(\mu). \tag{4.4}$$

Theorem 4.1. *The Hopf algebra $\mathfrak{u}(\mathcal{D}, \lambda, \mu)$ is pointed, $G(\mathfrak{u}(\mathcal{D}, \lambda, \mu)) \simeq \Gamma$ and $\dim \mathfrak{u}(\mathcal{D}, \lambda, \mu) = \prod_{J\in\mathcal{X}} N_J^{|\Phi_J^+|}|\Gamma|$. Let H be a pointed finite-dimensional Hopf algebra and set $\Gamma = G(H)$. Assume that the prime divisors of $|\Gamma|$ are > 7. Then there exists a Cartan datum $\mathcal{D}$ and parameters λ and μ such that $H \simeq \mathfrak{u}(\mathcal{D}, \lambda, \mu)$. It is known when two Hopf algebras $\mathfrak{u}(\mathcal{D}, \lambda, \mu)$ and $\mathfrak{u}(\mathcal{D}', \lambda', \mu')$ are isomorphic.*

The proof offered in [16] relies on [14, 43, 59, 60]. Some comments: the hypothesis on $|\Gamma|$ forces the infinitesimal braiding V of H to be of Cartan type, and the relations of $\mathfrak{B}(V)$ to be just quantum Serre and powers of root vectors. The quantum Serre relations are not deformed in the liftings, except those linking different components of the Dynkin diagram; the powers of the root vectors are deformed to the $u_\alpha(\mu)$ that belong to the coradical. All this can fail without the hypothesis, see [52] for examples in rank 2.

4.2. Pointed Hopf algebras with non-abelian group. We present some classification results of pointed Hopf algebras with non-abelian group. We say that a finite group G *collapses* whenever any finite-dimensional pointed Hopf algebra H with $G(H) \simeq G$ is isomorphic to $\mathbb{C}G$.

- [7, 8] Let G be either $\mathbb{A}_m$, $m \geq 5$, or a sporadic simple group, different from Fi_{22}, the Baby Monster B or the Monster M. Then G collapses.

  The proof uses §3.6.3; the remaining Yetter-Drinfeld modules are discarded considering abelian subracks of the supporting conjugacy class and the list in [44].

- [12] Let $V = M(\mathcal{O}_2^3, \operatorname{sgn})$ and let $\mathcal{D}$ be the corresponding YD-datum. Let H be a finite-dimensional pointed Hopf algebra with $G(H) \simeq \mathbb{S}_3$. Then H is isomorphic either to $\mathbb{CS}_3$, or to $\mathfrak{u}(\mathcal{D}, 0) = \mathfrak{B}(V)\#\mathbb{CS}_3$, or to $\mathfrak{u}(\mathcal{D}, (0,1))$, cf. Example 3.21.
- [38] Let $H \not\simeq \mathbb{CS}_4$ be a finite-dimensional pointed Hopf algebra with $G(H) \simeq \mathbb{S}_4$. Let $V_1 = M(\mathcal{O}_2^4, \operatorname{sgn} \otimes \operatorname{id})$, $V_2 = M(\mathcal{O}_2^4, \operatorname{sgn} \otimes \operatorname{sgn})$, $W = M(\mathcal{O}_4^4, \operatorname{sgn} \otimes \operatorname{id})$, with corresponding data $\mathcal{D}_1$, $\mathcal{D}_2$ and $\mathcal{D}_3$. Then H is isomorphic to one of

$$\mathfrak{u}(\mathcal{D}_1, (0,\mu)), \quad \mu \in \mathbb{C}^2; \qquad \mathfrak{u}(\mathcal{D}_2, t), \quad t \in \{0,1\}; \qquad \mathfrak{u}(\mathcal{D}_3, \lambda), \quad \lambda \in \mathbb{C}^2.$$

  Here $\mathfrak{u}(\mathcal{D}_1, (0,\mu))$ is as in Example 3.22; $\mathfrak{u}(\mathcal{D}_2, t)$ is the quotient of $\mathcal{T}(V_2)$ by the relations $a_{12}^2 = 0$, $a_{12}a_{34} - a_{34}a_{12} = 0$, $a_{12}a_{23} - a_{13}a_{12} - a_{23}a_{13} = t(1 - g_{(12)}g_{(23)})$ and $\mathfrak{u}(\mathcal{D}_3, \lambda)$ is the quotient of $\mathcal{T}(W)$ by the relations

$$a_{(1234)}^2 = \lambda_1(1 - g_{(13)}g_{(24)}); \qquad a_{(1234)}a_{(1432)} + a_{(1432)}a_{(1234)} = 0;$$
$$a_{(1234)}a_{(1243)} + a_{(1243)}a_{(1423)} + a_{(1423)}a_{(1234)} = \lambda_2(1 - g_{(12)}g_{(13)}).$$

  Clearly $\mathfrak{u}(\mathcal{D}_1, 0) = \mathfrak{B}(V_1)\#\mathbb{CS}_4$, $\mathfrak{u}(\mathcal{D}_2, 0) = \mathfrak{B}(V_2)\#\mathbb{CS}_4$, $\mathfrak{u}(\mathcal{D}_3, 0) = \mathfrak{B}(W)\#\mathbb{CS}_4$. Also $\mathfrak{u}(\mathcal{D}_1, (0,\mu)) \simeq \mathfrak{u}(\mathcal{D}_1, (0,\nu))$ iff $\mu = c\nu$ for some $c \in \mathbb{C}^\times$, and $\mathfrak{u}(\mathcal{D}_3, \lambda) \simeq \mathfrak{u}(\mathcal{D}_3, \kappa)$ iff $\lambda = c\kappa$ for some $c \in \mathbb{C}^\times$.
- [7, 38] Let H be a finite-dimensional pointed Hopf algebra with $G(H) \simeq \mathbb{S}_5$, but $H \not\simeq \mathbb{CS}_5$. It is not known whether $\dim \mathfrak{B}(\mathcal{O}_{2,3}^5, \operatorname{sgn} \otimes \varepsilon) < \infty$. Let $\mathcal{D}_1$, $\mathcal{D}_2$ be the data corresponding to $V_1 = M(\mathcal{O}_2^5, \operatorname{sgn} \otimes \operatorname{id})$, $V_2 = M(\mathcal{O}_2^5, \operatorname{sgn} \otimes \operatorname{sgn})$. If the infinitesimal braiding of H is not $M(\mathcal{O}_{2,3}^5, \operatorname{sgn} \otimes \varepsilon)$, then H is isomorphic to one of $\mathfrak{u}(\mathcal{D}_1, (0,\mu))$, $\mu \in \mathbb{C}^2$ (defined as in Example 3.22), or $\mathfrak{B}(V_2)\#\mathbb{CS}_5$, or $\mathfrak{u}(\mathcal{D}_2, 1)$ (defined as above).
- [7] Let $m > 6$. Let $H \not\simeq \mathbb{CS}_m$ be a finite-dimensional pointed Hopf algebra with $G(H) \simeq \mathbb{S}_m$. Then the infinitesimal braiding of H is $V = M(\mathcal{O}, \rho)$, where the type of σ is $(1^{m-2}, 2)$ and $\rho = \rho_1 \otimes \operatorname{sgn}$, $\rho_1 = \operatorname{sgn}$ or ε; it is an open question whether $\dim \mathfrak{B}(V) < \infty$, see Example 3.12. If $m = 6$, there are two more Nichols algebras with unknown dimension corresponding to the class of type (2^3), but they are conjugated to those of type $(1^4, 2)$ by the outer automorphism of $\mathbb{S}_6$.
- [34] Let $m \geq 12$, $m = 4h$ with $h \in \mathbb{N}$. Let $G = \mathbb{D}_m$ be the dihedral group of order $2m$. Then there are infinitely many finite-dimensional Nichols algebras in ${}^G_G\mathcal{YD}$; all of them are exterior algebras as braided Hopf algebras. Let H be a finite-dimensional pointed Hopf algebra with $G(H) \simeq \mathbb{D}_m$, but $H \not\simeq \mathbb{CD}_m$. Then H is a lifting of an exterior algebra, and there infinitely many such liftings.

4.2.1. Copointed Hopf algebras. We say that a semisimple Hopf algebra K *collapses* if any finite-dimensional Hopf algebra H with $H_0 \simeq K$ is isomorphic to K. Thus, if G collapses, then $\mathbb{C}^G$ and $(\mathbb{C}G)^F$ collapse, for any twist F. Next we state the classification of the finite-dimensional copointed Hopf algebras over $\mathbb{S}_3$ [17]. Let $V = M(\mathcal{O}_2^3, \operatorname{sgn})$ as a Yetter-Drinfeld module over $\mathbb{C}^{\mathbb{S}_3}$. Let $\lambda \in \mathbb{C}^{\mathcal{O}_2^3}$ be such that $\sum_{(ij) \in \mathcal{O}_2^3} \lambda_{ij} = 0$. Let $\mathfrak{v} = \mathfrak{v}(V, \lambda)$ be the quotient of $T(V)\#\mathbb{C}^{\mathbb{S}_3}$ by the relations $a_{(13)}a_{(23)} + a_{(12)}a_{(13)} + a_{(23)}a_{(12)} = 0$, $a_{(23)}a_{(13)} + a_{(13)}a_{(12)} + a_{(12)}a_{(23)} = 0$, $a_{(ij)}^2 = \sum_{g \in \mathbb{S}_3} (\lambda_{ij} - \lambda_{g^{-1}(ij)g})\delta_g$, for $(ij) \in \mathcal{O}_2^3$. Then $\mathfrak{v}$ is a Hopf algebra of dimension 72 and $\operatorname{gr} \mathfrak{v} \simeq \mathfrak{B}(V)\#\mathbb{C}^{\mathbb{S}_3}$. Any finite-dimensional

copointed Hopf algebra H with $H_0 \simeq \mathbb{C}^{\mathbb{S}_3}$ is isomorphic to $\mathfrak{v}(V, \lambda)$ for some λ as above; $\mathfrak{v}(V, \lambda) \simeq \mathfrak{v}(V, \lambda')$ iff λ and λ' are conjugated under $\mathbb{C}^\times \times \operatorname{Aut} \mathbb{S}_3$.

Acknowledgements. This work was partially supported by ANPCyT-Foncyt, CONICET, Secyt (UNC). I thank all my coauthors for pleasant and fruitful collaborations. I am particularly in debt with Hans-Jürgen Schneider, Matías Graña and Iván Angiono for sharing their ideas on pointed Hopf algebras with me.

Excision, descent, and singularity in algebraic K-theory

Guillermo Cortiñas

Abstract. Algebraic K-theory is a homology theory that behaves very well on sufficiently nice objects such as stable C^*-algebras or smooth algebraic varieties, and very badly in singular situations. This survey explains how to exploit this to detect singularity phenomena using K-theory and cyclic homology.

Mathematics Subject Classification (2010). Primary 19D55; Secondary 19D50, 19E08.

Keywords. Algebraic K-theory, cyclic homology, topological algebras, singular varieties.

1. Introduction

A homology theory of rings associates groups $H_n(R)$ ($n \in \mathbb{Z}$) depending covariantly on the ring R. We say that H is (polynomially) *homotopy invariant* if the map $H_n(R) \to H_n(R[t])$ is an isomorphism. A homology theory also associates groups $H_n(R : I)$ to every two-sided ideal $I \lhd R$, which fit into a long exact sequence

$$H_{n+1}(R/I) \to H_n(R : I) \to H_n(R) \to H_n(R/I).$$

We say that H is *nilinvariant* if $H_*(R : I) = 0$ when I is nilpotent. The homology theory is said to satisfy *excision* if whenever $f : R \to S$ is a ring homomorphism sending an ideal $I \lhd R$ isomorphically onto an ideal of S, the map $H_*(R : I) \to H_*(S : f(I))$ is an isomorphism. Similarly, a cohomology theory of algebraic varieties over a field (schemes of finite type) associates groups $H_n(X : Y)$ with every closed immersion $Y \to X$, depending contravariantly on $(X : Y)$. In particular if $\tilde{X}$ is the blowup of X along Y and $\tilde{Y}$ is the exceptional fiber, we have a map $H_*(X : Y) \to H_*(\tilde{X} : \tilde{Y})$; this map is an isomorphism whenever H satisfies *cdh-descent*. For example, Quillen's *algebraic K-theory* K is a (co)homology theory of rings and schemes which has none of the aforementioned properties. For another example, Weibel's *homotopy algebraic K-theory* KH is also defined for rings and schemes, and satisfies all of them. There is a natural map $K_n(R) \to KH_n(R)$ which is an isomorphism when R is K_n*-regular*; this means that the map $K_n(R) \to K_n(R[t_1, \dots, t_p])$ is an isomorphism for all p. For instance Noetherian regular rings such as rings of polynomial functions on smooth varieties, and stable C^*-algebras such as the algebra $\mathcal{K}$ of compact operators, are K_n-regular for all n. In general the map $K \to KH$ is part of a long exact sequence

$$KH_{n+1}(R) \to K_n^{\mathrm{nil}}(R) \to K_n(R) \to KH_n(R).$$

Proceedings of International Congress of Mathematicians, 2014, Seoul

In this article we survey a series of results that help describe the groups K_*^{nil} in terms of cyclic homology, and explain how this description has helped make significant progress in several long standing problems, ranging from the comparison of algebraic and topological K-theory of topological algebras to the relation between K-regularity and nonsingularity of algebraic varieties.

The article is organized as follows. In Section 2 we recall (from Goodwillie's paper [29] and from [6]) two key properties of the Chern character $ch_* : K_*(R) \to HN_*(R)$ to negative cyclic homology of $\mathbb{Q}$-algebras. They can be summarized by saying that *infinitesimal K-theory* is nilinvariant and satisfies excision (Theorem 2.4); the infinitesimal K-groups fit into a long exact sequence

$$HN_{n+1}(R) \to K_n^{\mathrm{inf}}(R) \to K_n(R) \xrightarrow{ch_n} HN_n(R).$$

In Section 3 we explain how the results of the previous one were used in [15] to compare the algebraic and the topological K-theory of a stable locally convex algebra L. The main result reviewed in this section is Theorem 3.2, which says that for such L, $KH_*(L) = K_*^{\mathrm{top}}(L)$ and $K_n^{\mathrm{nil}}(L) = HC_{n-1}(L)$ is cyclic homology. In Section 4 we recall the notions of descent and Mayer-Vietories properties. We review Thomason's theorems that K-theory satisfies Nisnevich descent and has the Mayer-Vietoris property for blow-ups along regularly embedded closed subschemes (Theorem 4.1), and their analogues for cyclic homology and infinitesimal K-theory of schemes of finite type over a field of characteristic zero (Theorem 4.2). In Section 5 we review Haesemeyer's theorem on cdh-descent and its generalization (Theorems 5.1 and 5.2) and derive from them a long exact sequence (Theorem 5.3)

$$KH_{n+1}(X) \to \mathcal{F}_{n-1}^{HC}(X) \to K_n(X) \to KH_n(X), \tag{1.1}$$

for every scheme X of finite type over a field of characteristic zero. Up to extension, the groups $\mathcal{F}_*^{HC}(X)$ are computed from the cyclic homology groups of X and of an array of smooth schemes that appear in its desingularization process. In Section 6 we show how these results were used to prove Weibel's dimension conjecture for schemes of finite type over a field of characteristic zero (Theorem 6.3). In Section 7 we begin by explaining how the sequence 1.1 can be used to compute the obstruction to K_n-regularity (Proposition 7.1). Then we review several results on K-regularity, including that Vorst's regularity conjecture and Gubeladze's nilpotence conjecture hold for algebras and coefficient rings containing a field of characteristic zero (Theorems 7.3 and 7.8), and the answer to Bass' question on whether $K_n(R) = K_n(R[t])$ implies that $K_n(R) = K_n(R[t_1, t_2])$ (Theorem 7.5). Versions of some of these results in characteristic $p > 0$ are reviewed in Section 8. They are based on the good properties of the Bökstedt-Hsiang-Madsen cyclotomic trace $\mathrm{tr} : K \to TC$, which takes values in topological cyclic homology [3]. Theorems of McCarthy and Geisser-Hesselholt (8.1 and 8.2) say that tr computes the obstruction groups to nilinvariance and excision up to p-adic completion. The results of Geisser-Hesselholt extending Haesemeyer's theorem (Theorem 8.4) and proving Weibel's dimension conjecture (Theorem 8.5) and Vorst's regularity conjecture (Theorem 8.6) over a perfect field of characteristic $p > 0$ which admits strong resolution of singularities are reviewed, as well as the solution of Gubeladze's nilpotence conjecture over a field of charactristic p (Theorem 8.8).

2. The obstructions to excision and nilinvariance

Quillen's algebraic K-theory associates groups $K_n(R)$ ($n \in \mathbb{Z}$) to each associative, not necessarily unital ring R. These groups are defined as the stable homotopy groups of a functorial spectrum $K(R)$. If $I \lhd R$ is an ideal, the relative K-theory spectrum is $K(R:I) = \mathrm{hofiber}(K(R) \to K(R/I))$. The spectrum $K(R:I)$ is defined so as to fit into a *homotopy fibration sequence*

$$K(R:I) \to K(R) \to K(R/I).$$

Thus taking homotopy groups we obtain a long exact sequence

$$K_{n+1}(R/I) \to K_n(R:I) \to K_n(R) \to K_n(R/I).$$

Observe that the failure of the map $K_*(R) \to K_*(R/I)$ to be an isomorphism is measured by the relative groups $K_*(R:I)$. If I is nilpotent, the groups $K_n(R:I)$ vanish for $n \leq 0$. Thus $K_n(R) \to K_n(R/I)$ is an isomorphism for $n \leq 0$; because of this, we say that K-theory is *nilinvariant* in nonpositive degrees. For $n \geq 1$ the groups $K_n(R:I)$ may be nonzero for nilpotent I; if R is a $\mathbb{Q}$-algebra they are $\mathbb{Q}$-vector spaces ([49, Consequence 1.4]). For general R, the groups $K_n(R:I) \otimes \mathbb{Q}$ are computed by means of the Chern character [29]

$$ch : K_*(R) \to HN_*(R \otimes \mathbb{Q}). \tag{2.1}$$

Negative cyclic homology is connected with cyclic and periodic cyclic homology by means of Connes' SBI-sequence

$$HP_{n+1}(R) \xrightarrow{S} HC_{n-1}(R) \xrightarrow{B} HN_n(R) \xrightarrow{I} HP_n(R). \tag{2.2}$$

Theorem 2.1 (Goodwillie, [28, Theorem II.5.1], [29, Main Theorem]). *Let R be a ring and $I \lhd R$ a nilpotent ideal. Then*

$$HP_n(R \otimes \mathbb{Q} : I \otimes \mathbb{Q}) = 0,$$

and the Chern character induces an isomorphism

$$K_n(R:I) \otimes \mathbb{Q} \cong HN_n(R \otimes \mathbb{Q} : I \otimes \mathbb{Q}) \cong HC_{n-1}(R \otimes \mathbb{Q} : I \otimes \mathbb{Q}).$$

In particular, $K_n(R:I) \otimes \mathbb{Q} \cong K_n(R \otimes \mathbb{Q} : I \otimes \mathbb{Q})$.

Remark 2.2. Goodwillie states his results for unital R; the nonunital case follows from the unital case (see [5, Lemma 6.1], e.g.).

If $I \lhd R$ is an ideal and $f : R \to S$ is a ring homomorphism such that $f(I) \lhd S$ is an ideal and $f : I \to f(I)$ is bijective, we put

$$K(R, S : I) = \mathrm{hofiber}(K(R:I) \to K(S : f(I))).$$

The groups $K_n(R, S : I)$ are zero for $n \leq -1$. Thus for $n \leq 0$ the groups $K_n(R:I)$ depend only on I and not on the ideal embedding $I \lhd R$. Because of this, we say that K-theory satisfies *excision* (or that it is *excisive*) in nonpositive degrees. If R is a $\mathbb{Q}$-algebra, the groups $K_n(R, S : I)$ are $\mathbb{Q}$-vector spaces ([49, Consequence 1.5]). For general R, the

groups $K_n(R, S : I) \otimes \mathbb{Q}$ are again computed by means of the Chern character; this is the content of Theorem 2.3 below. First let us recall the Cuntz-Quillen excision theorem [18, Theorem 5.3], which says that HP *satisfies excision* in the category of $\mathbb{Q}$-algebras; this means that if in the situation just described f is a $\mathbb{Q}$-algebra homomorphism, then

$$HP_*(R, S : I) = 0. \tag{2.3}$$

It follows that the B-map in the SBI sequence (2.2) induces an isomorphism

$$HC_{*-1}(R, S : I) \cong HN_*(R, S : I).$$

Theorem 2.3 ([6, Theorem 0.1]). *Let $I \lhd R$ be an ideal and let $f : R \to S$ be a ring homomorphism. Assume that $f(I) \lhd S$ is an ideal and that $f : I \to f(I)$ is bijective. Then the Chern character induces an isomorphism*

$$\begin{aligned} K_*(R, S : I) \otimes \mathbb{Q} &\cong HN_*(R \otimes \mathbb{Q}, S \otimes \mathbb{Q} : I \otimes \mathbb{Q}) \\ &\cong HC_{*-1}(R \otimes \mathbb{Q}, S \otimes \mathbb{Q} : I \otimes \mathbb{Q}). \end{aligned}$$

In particular, $K_*(R, S : I) \otimes \mathbb{Q} \cong K_*(R \otimes \mathbb{Q}, S \otimes \mathbb{Q} : I \otimes \mathbb{Q})$.

In the case of $\mathbb{Q}$-algebras Theorem 2.3 confirmed a conjecture formulated in the mid 1980's by Geller-Reid-Weibel ([24, 25]). Its proof combines the techniques developed by Cuntz-Quillen to prove their excision theorem with those used by Suslin-Wodzicki to characterize those nonunital rings I such that $K_*(-, - : I) \otimes \mathbb{Q} = 0$ [44, Theorem A].

In the applications considered in the next sections, all the rings involved are $\mathbb{Q}$-algebras. In this case we will find it useful to formulate the results above in terms of infinitesimal K-theory. The Chern character (2.1) comes from a map of spectra $K \to HN$; *infinitesimal K-theory* is the homotopy fiber of this map:

$$K^{\inf}(R) = \operatorname{hofiber}(K(R) \to HN(R)).$$

In terms of $K^{\inf}$, Theorems 2.1 and 2.3 can be expressed as follows.

Theorem 2.4. *Infinitesimal K-theory of $\mathbb{Q}$-algebras is nilinvariant and satisfies excision.*

3. $K^{\inf}$-regularity and algebraic K-theory of topological algebras.

Let A be a ring and $F : \mathrm{Rings} \to \mathfrak{Ab}$ a functor. We say that A is *F-regular* if the map induced by the canonical inclusion

$$F(A) \to F(A[t_1, \dots, t_n])$$

is an isomorphism for all $n \geq 1$. The functor F is called *invariant under polynomial homotopy* (homotopy invariant, for short) on a subcategory $\mathfrak{C} \subset \mathrm{Rings}$ if every ring $A \in \mathfrak{C}$ is F-regular. A *homology theory* of rings is a covariant functor E from rings to spectra; we write $E_n(R) = \pi_n E(R)$ for the stable homotopy group. If E is a homology theory of rings, we call a ring *E-regular* if it is E_n-regular for all n. We call E *homotopy invariant* if each E_n is homotopy invariant. There is a well-known procedure $E \to EH$, the *homotopization procedure* that transforms E to a homotopy invariant homology

theory EH. This construction comes with a natural map $E(A) \to EH(A)$ and setting $E^{\mathrm{nil}}(A) = \mathrm{hofiber}(E(A) \to EH(A))$ one obtains a long exact sequence

$$EH_{n+1}(A) \to E_n^{\mathrm{nil}}(A) \to E_n(A) \to EH_n(A). \tag{3.1}$$

If A is E_m-regular for all $m \leq n$, then $E_m(A) \to EH_m(A)$ is an isomorphism for $m \leq n$ and is onto for $m = n+1$. Applying this procedure to Quillen's K-theory yields Weibel's homotopy K-theory KH [50]. The following theorem summarizes two key properties of KH.

Theorem 3.1 (Weibel, [50, Theorems 2.1 and 2.3]). *Homotopy algebraic K-theory KH is nilinvariant and satisfies excision.*

If A is a $\mathbb{Q}$-algebra, then A is HP-regular (e.g. by [28, Corollary II.4.4] or by [38, Equation 3.13]). Geller and Weibel showed in [26, Theorem 4.1] that if A is a $\mathbb{Q}$-algebra then $HNH_*(A) \cong HP_*(A)$, and (3.1) identifies with Connes' SBI-sequence (2.2). If A is a $\mathbb{Q}$-algebra, set

$$K^{\mathrm{ninf}}(A) = K^{\mathrm{inf,nil}}(A).$$

The homotopization procedure preserves fibration sequences. Hence we have a homotopy commutative diagram whose rows and columns are homotopy fibration sequences:

$$\begin{array}{ccccc} K^{\mathrm{ninf}}(A) & \longrightarrow & K^{\mathrm{inf}}(A) & \longrightarrow & K^{\mathrm{inf}}H(A) \\ \downarrow & & \downarrow & & \downarrow \\ K^{\mathrm{nil}}(A) & \longrightarrow & K(A) & \longrightarrow & KH(A) \\ \downarrow & & \downarrow & & \downarrow \\ HC(A)[-1] & \longrightarrow & HN(A) & \longrightarrow & HP(A). \end{array} \tag{3.2}$$

By the discussion above,

$$A \;\; K^{\mathrm{inf}} - \text{regular} \;\Rightarrow K_*^{\mathrm{nil}}(A) \xrightarrow{\cong} HC_{*-1}(A). \tag{3.3}$$

A *locally convex algebra* is a complete locally convex $\mathbb{C}$-vector space L equipped with a jointly continuous, associative multiplication $L \otimes_{\mathbb{C}} L \to L$. The following theorem concerns the K-theory of a large class of stable locally convex algebras. It computes the obstruction for the map $K \to K^{\mathrm{top}}$ to be an isomorphism. Here $K_*^{\mathrm{top}}(L) = kk_*^{lc}(\mathbb{C}, L)$ is the covariant part of Cuntz' bivariant K-theory for locally convex algebras [17]. As expected of a bivariant K-theory of complex topological algebras, it is periodic of period two:

$$kk_*^{lc}(L, M) = kk_{*+2}^{lc}(L, M). \tag{3.4}$$

Thus there are only two covariant topological K-groups, K_0^{top} and K_1^{top}.

Let $\mathcal{B} = \mathcal{B}(\ell^2(\mathbb{N}))$ be the C^*-algebra of bounded operators in an infinite dimensional, separable Hilbert space. An ideal $I \lhd \mathcal{B}$ is a *Fréchet operator ideal* if it carries a complete metrizable locally convex topology such that the inclusion $I \to \mathcal{B}$ is continuous.

Theorem 3.2 ([15, Theorems 6.2.1 and 6.3.1]). *Let L be a locally convex $\mathbb{C}$-algebra and let I be a Fréchet operator ideal. Write $\hat{\otimes}$ for the projective tensor product. Then:*

(i) $L\hat{\otimes}I$ *is* $K^{\inf}$*-regular.*

(ii) $KH_*(L\hat{\otimes}I) = K_*^{\mathrm{top}}(L\hat{\otimes}I)$.

(iii) *For each* $n \in \mathbb{Z}$*, there is a natural* 6*-term exact sequence of abelian groups as follows:*

$$\begin{array}{ccccc} K_1^{\mathrm{top}}(L\hat{\otimes}I) & \longrightarrow & HC_{2n-1}(L\hat{\otimes}I) & \longrightarrow & K_{2n}(L\hat{\otimes}I) \\ \uparrow & & & & \downarrow \\ K_{2n-1}(L\hat{\otimes}I) & \longleftarrow & HC_{2n-2}(L\hat{\otimes}I) & \longleftarrow & K_0^{\mathrm{top}}(L\hat{\otimes}I). \end{array}$$

Sketch of the proof of Theorem 3.2. Call a Banach ideal $I \lhd \mathcal{B}$ *harmonic* if it contains an operator whose sequence of singular values is the harmonic sequence $\{1/n\}$. Results of Cuntz-Thom [19, Theorems 4.2.1 and 5.1.2] imply that if H is a homology theory which satisfies excision and $I \lhd \mathcal{B}$ is harmonic, then $H(-\hat{\otimes}I)$ is invariant under C^∞ homotopies, also called *diffotopies*. It is shown in [15, Theorem 6.16] that if in addition H is nilinvariant, then $H(-\hat{\otimes}I)$ is diffotopy invariant for any Fréchet ideal I. In particular this applies to $K^{\inf}$ and KH by Theorems 2.4 and 3.1. Part i) of the theorem follows from the fact that $K^{\inf}(-\hat{\otimes}I)$ is diffotopy invariant, using the argument of [42, Theorem 3.4]. By [15, Lemma 3.2.1], $K^{\inf}$-regular $\mathbb{Q}$-algebras are K_n-regular for $n \leq 0$. Hence we have $KH_n(L\hat{\otimes}I) = K_n(L\hat{\otimes}I)$ for $n \leq 0$. Cuntz and Thom proved in [19, Theorem 6.2.1] that $K_0(L\hat{\otimes}I) = K_0^{\mathrm{top}}(L\hat{\otimes}I)$ when I is harmonic; by the argument of [15, Theorem 6.16], this extends to all Fréchet ideals. Summing up $KH(-\hat{\otimes}I)$ is an excisive and diffotopy invariant homology theory in $\mathfrak{Loc}\mathfrak{Alg}$ which agrees with $K^{\mathrm{top}}(-\hat{\otimes}I)$ in dimension 0. A standard argument now shows that they must agree in all dimensions ([16, Abschnitt 6]). This proves ii). Part iii) follows from what we have already done, using (3.3), (3.4), and diagram (3.2). □

The following theorem can be proved using Theorem 3.2.

Theorem 3.3 ([15, Theorem 8.3.3]). *Let* $\mathcal{K} \lhd \mathcal{B}$ *be the ideal of compact operators and let* L *be a Fréchet algebra whose topology is generated by a countable family of submultiplicative seminorms and which has a uniformly bounded, one-sided approximate unit. Then the map*

$$K_*(L\hat{\otimes}\mathcal{K}) \to K_*^{\mathrm{top}}(L\hat{\otimes}\mathcal{K})$$

is an isomorphism.

The particular case of the theorem above when L is a Banach algebra with a one-sided approximate unit confirms a conjecture formulated by Karoubi in [37]. Wodzicki announced a proof of the latter case in [54, Theorem 1]; he told us he has also proved the general case of Theorem 3.3. The proof of Theorem 3.3 given in [15] consists of showing that $HC_*(L\hat{\otimes}\mathcal{K}) = 0$, and then using Theorem 3.2. For a different proof see [7, Theorem 12.1.1]. Karoubi also proved that if $\mathfrak{A}$ is a C^*-algebra and $\otimes$ is the spatial tensor product, then the comparison map

$$K_*(\mathfrak{A}\otimes\mathcal{K}) \to K_*^{\mathrm{top}}(\mathfrak{A}\otimes\mathcal{K}) \tag{3.5}$$

is an isomorphism for $* \leq 0$, and conjectured that it is also an isomorphism for $* \geq 1$. This conjecture was proved by Suslin-Wodzicki ([44, Theorem 10.9]). We remark that the analog of Theorem 3.2 for $\mathfrak{A}\otimes\mathcal{K}$ also holds. Indeed a theorem of Higson ([42, Theorem 20]) says that $\mathfrak{A}\otimes\mathcal{K}$ is K-regular, so $KH_*(\mathfrak{A}\otimes\mathcal{K}) = K_*^{\mathrm{top}}(\mathfrak{A}\otimes\mathcal{K})$, since (3.5) is an isomorphism; a

similar argument as that of [42, Theorem 20] shows that $\mathfrak{A}\underset{\sim}{\otimes}\mathcal{K}$ is also $K^{\inf}$-regular. Finally it is not hard to see that $HC_*(\mathfrak{A}\underset{\sim}{\otimes}\mathcal{K}) = 0$ (the argument is similar to that of [15, Lemma 8.2.3]).

Remark 3.4. No nonzero commutative unital $\mathbb{Q}$-algebra is $K^{\inf}$-regular. Indeed [15, Proposition 3.3.1] says that if a unital algebra R is $K_n^{\inf}$-regular for some $n \geq 1$, then every element $a \in R$ can be written as a finite linear combination

$$a = \sum_{i=1}^{m} b_i(x_i y_i - y_i x_i)c_i \qquad (b_i, c_i, x_i, y_i \in R).$$

4. Mayer-Vietoris sequences and descent

Fix a field k. Let Sch/k be the category of schemes essentially of finite type over $\mathrm{Spec}(k)$. A *k-scheme* is an object of Sch/k. A *cohomology theory* (also called *presheaf of spectra*) is a functor $(\mathrm{Sch}/k)^{op} \to \mathrm{Spt}$. Let

$$\begin{array}{ccc} Y' & \longrightarrow & X' \\ \downarrow & & \downarrow{\scriptstyle p} \\ Y & \xrightarrow[i]{} & X \end{array} \tag{4.1}$$

be a cartesian square in Sch/k. A cohomology theory E of k-schemes is said to have the *Mayer-Vietoris* property with respect to (4.1) if it sends (4.1) to a homotopy cartesian diagram of spectra. This implies that we have a long exact sequence of Mayer-Vietoris type:

$$E_{n+1}(Y') \to E_n(X) \to E_n(Y) \oplus E_n(X') \to E_n(Y').$$

In the sequence above, we have used subscript notation; we will switch to superscripts when needed, following the usual convention $E_* = E^{-*}$.

We consider classes of cartesian squares in Sch/k which are closed under isomorphism. We call such a class a *cd-structure*. Each such class generates a Grothendieck topology on Sch/k. We shall consider the following cd-structures; note that each of them is contained in the next one:

- The cd-structure of elementary *Zariski* squares. A square (4.1) is an elementary Zariski square if i and p are open immersions and $X = Y' \cup X'$. We write *zar* for the Grothendieck topology generated by this structure.
- The cd-structure of elementary *Nisnevich* squares. A square (4.1) is an elementary Nisnevich square if i is an open embedding, p is étale, and $p : (X' \setminus Y')_{\mathrm{red}} \to (X \setminus Y)_{\mathrm{red}}$ is an isomorphism. Here X_{red} is the reduced scheme. We remark that in the particular case when p is an open immersion, the latter condition is equivalent to the condition that $Y' \cup X' = X$; thus every elementary Zariski square is an elementary Nisnevich square. We write *nis* for the Nisnevich topology.
- Voevodsky's *combined cd-structure*. It consists of the elementary Nisnevich squares and the *abstract blow-up squares*. A square (4.1) is an abstract blow-up if p is proper, i is a closed embedding and $p : (X' \setminus Y') \to (X \setminus Y)$ is an isomorphism. We write *cdh* for the corresponding topology.

Let c be one of the above cd-structures on Sch/k and let t be the Grothendieck topology it generates. A cohomology theory E of k-schemes satisfies *descent* with respect to t if it has the Mayer-Vietoris property for every square in c. There is a construction $(E,t)\mapsto \mathbb{H}_t(-,E)$ which given a topology t and a cohomology theory E produces a cohomology theory $\mathbb{H}_t(-,E)$ which satisfies t-descent, and a natural transformation ([36])

$$E\to \mathbb{H}_t(-,E). \tag{4.2}$$

The case when t comes from a cd-structure was studied in depth by Voevodsky, who obtained several key results in his fundamental article [47]. Using Voevodsky's results, one can show that if t comes from a cd-structure which meets some technical conditions [8, Theorem 3.4], which are satisfied in all the examples we consider here, then E satisfies t-descent if and only if the map (4.2) is a *global weak equivalence*; this means that

$$E_*(X)\to \mathbb{H}_t^{-*}(X,E)$$

is an isomorphism for all X.

A cohomology theory of schemes E which satisfies Zariski descent is determined by its value on affine schemes, and

$$E(R):=E(\operatorname{Spec} R) \tag{4.3}$$

is a homology theory of commutative rings which satisfies Zariski descent. Each of the homology theories of rings considered in the previous sections extends to a cohomology theory of schemes which satisfies Zariski descent so that (4.3) holds. Moreover, we have the following landmark results of Thomason. Recall that a closed immersion is *regular* if it is locally defined by a regular sequence. A closed subscheme $Y\subset X$ is of *pure codimension* when all its irreducible components have the same codimension. The square (4.1) is a *regular blow-up* if i is a regular closed immersion of pure codimension and p is the blow-up along i.

Theorem 4.1 (Thomason, [45, Theorem 10.8], [46, Théorème 2.1]). *K-theory of schemes satisfies Nisnevich descent and has the Mayer-Vietoris property for regular blow-up squares.*

Thomason defined the K-theory of a quasi-compact and separated scheme X in terms of the complicial category of perfect complexes of quasi-coherent sheaves; the main technical tool for proving Theorem 4.1 is the Thomason-Waldhausen localization theorem ([45, Theorems 1.8.2 and 1.9.8]) which roughly says that K-theory maps sequences of complicial categories which induce exact sequences of derived categories into homotopy fibration sequences of spectra. Weibel introduced cyclic homology of schemes as the hyperhomology of the sheafified Connes' complex [52]. He and Geller showed in [27, Theorem 4.8] that HC satisfies Nisnevich descent. Keller proved a version of the Thomason-Waldhausen localization theorem for cyclic homology [40, Theorem 2.4] and showed [39, Section 5.2] that for quasi-compact separated schemes the cyclic homology of schemes introduced by Weibel in [52] admits a categorical description analogous to that of K-theory. The proof given in [8] of the following theorem uses the latter result of Keller and the argument of Thomason's proof of Theorem 4.1.

Theorem 4.2 ([27, Theorem 4.8], [8, Theorems 2.9 and 2.10]). *Cyclic, negative cyclic and periodic cyclic homology satisfy Nisnevich descent and have the Mayer-Vietoris property for regular blow-ups.*

Corollary 4.3. *Let $E \in \{HC, HN, HP, K\}$ and let $X \in \mathrm{Sch}/k$. Assume that X is smooth. Then the map $E_*(X) \to H^{-*}_{\mathrm{cdh}}(X, E)$ is an isomorphism.*

Proof. By [8, Corollary 3.9], any cohomology theory on Sch/k which satisfies Nisnevich descent and has the Mayer-Vietoris property for regular blow-ups also satisfies this. □

A homology theory of k-schemes E is *invariant under infinitesimal thickenings* if $E_*(X) \to E_*(X_{\mathrm{red}})$ is an isomorphism for all X. An abstract blow-up square is a *finite blow-up* if p is a finite morphism. If E satisfies Zariski descent then E is invariant under infinitesimal thickenings (resp. has the Mayer-Vietoris property for finite blow-ups) if and only if the associated homology of commutative algebras (4.3) is nilinvariant (resp. satisfies excision).

The Chern character (2.1) extends to schemes. If $X \in \mathrm{Sch}/k$ and k is of characteristic zero it is given by a map of spectra $ch : K(X) \to HN(X)$; infinitesimal K-theory is defined as $K^{\mathrm{inf}}(X) = \mathrm{hofiber}(K(X) \to HN(X))$.

The following is an immediate corollary of Theorems 2.4, 4.1 and 4.2.

Corollary 4.4 ([8, Theorems 4.3 and 4.4]). *Let k be a field of characteristic zero. Then the infinitesimal K-theory of k-schemes is invariant under infinitesimal thickenings, satifies Nisnevich descent, and has the Mayer-Vietoris property for regular blow-ups and for finite blow-ups.*

5. Haesemeyer's theorem

In this section k is a field of characteristic zero. If E is a cohomology theory of k-schemes, we write $\mathcal{F}^E(X) = \mathrm{hofiber}(E(X) \to H_{cdh}(X, E))$. Thus we have a homotopy fibration sequence

$$\mathcal{F}^E(X) \to E(X) \to \mathbb{H}_{\mathrm{cdh}}(X, E). \tag{5.1}$$

Both $\mathbb{H}_{\mathrm{cdh}}(X, -)$ and $\mathcal{F}^-(X)$ preserve homotopy fibration sequences; this fact is used in diagram 5.2 below.

Theorem 5.1 (Haesemeyer, [34, Theorem 6.4]). *Let k be a field of characteristic zero and $X \in \mathrm{Sch}/k$. Then $KH(X) \xrightarrow{\sim} \mathbb{H}_{\mathrm{cdh}}(X, K)$.*

It follows from the theorem above that for $E = K$ and $X = \mathrm{Spec}\, A$, the sequence (5.1) is equivalent to the middle row of diagram (3.2). For $X \in \mathrm{Sch}/k$ we have a homotopy commutative diagram whose rows and columns are homotopy fibration sequences:

$$\begin{array}{ccccc}
\mathcal{F}^{K^{\mathrm{inf}}}(X) & \longrightarrow & K^{\mathrm{inf}}(X) & \longrightarrow & H_{\mathrm{cdh}}(X, K^{\mathrm{inf}}) \\
\downarrow & & \downarrow & & \downarrow \\
\mathcal{F}^{K}(X) & \longrightarrow & K(X) & \longrightarrow & KH(X) \\
\downarrow & & \downarrow & & \downarrow \\
\mathcal{F}^{HN}(X) & \longrightarrow & HN(X) & \longrightarrow & H_{\mathrm{cdh}}(X, HN).
\end{array} \tag{5.2}$$

Theorem 5.1 implies that KH satisfies cdh-descent. On the other hand we know from [50, Theorem 1.2] that it is also *homotopy invariant*, that is, it sends the projection $X \times \mathbb{A}^1 \to X$

to an isomorphism $KH_*(X) \cong KH_*(X \times \mathbb{A}^1)$. For the proof of Theorem 5.1, Haesemayer first showed that KH has the Mayer-Vietoris property for regular blow-ups ([34, Theorem 3.6]). In almost all the rest of the proof, the only other properties of KH that are used are excision and invariance under infinitesimal thickenings. Homotopy invariance is used only once, in [34, Proposition 3.7]. It was found later that homotopy invariance is not needed; this led to the following generalization of Haesemeyer's theorem.

Theorem 5.2 ([8, Theorem 3.12]). *Let k be a field of characteristic zero and let E be a cohomology theory of k-schemes. Assume that E satisfies excision, is invariant under infinitesimal thickenings, satisfies Nisnevich descent, and has the Mayer-Vietoris property for regular blow-ups. Then E satisfies* cdh*-descent.*

By Corollary 4.4, Theorem 5.2 applies to K^{inf}. It follows that $\mathcal{F}_*^{K^{\mathrm{inf}}}(X) = 0$ in diagram (5.2), and therefore we have a weak equivalence

$$\mathcal{F}^K(X) \xrightarrow{\sim} \mathcal{F}^{HN}(X).$$

By Cuntz-Quillen's theorem (2.3) and by Theorems 2.1 and 4.2, HP also satisfies the hypothesis of Theorem 5.2. It follows from this and the SBI-sequence that there is a weak equivalence

$$\mathcal{F}^{HC}(X)[-1] \xrightarrow{\sim} \mathcal{F}^{HN}(X).$$

Summing up, we have proved the following.

Theorem 5.3 ([14, Theorem 1.6], see also [8, Corollary 3.13 and Theorem 4.6]). *Let k be a field of characteristic zero and $X \in \mathrm{Sch}/k$. Then there is a homotopy fibration sequence*

$$\mathcal{F}^{HC}(X)[-1] \to K(X) \to KH(X).$$

Theorems 5.1 and 5.3 together say that the obstruction to cdh-descent in algebraic K-theory is measured by $\mathcal{F}^{HC}$. By Corollary 4.3 and Hironaka's desingularization theorem [35] the groups $\mathcal{F}_*^{HC}(X)$ can be computed in terms of the cyclic homology of X and of the cyclic homology of a finite array (called a hyperresolution) of smooth schemes that appear in the desingularization process. In this sense we can say that the fiber of $K(X) \to KH(X)$ can be computed in terms of cyclic homology. Note that this represents a lot of progress from our starting point. Indeed regarding KH as K-theory made homotopic lead us to a map $K_*^{\mathrm{nil}} \to HC_{*-1}$ (see (3.2)) that is never an isomorphism in the commutative case (see Remark 3.4); regarding it instead as a version of K-theory with cdh-descent lead us to a character $K_*^{\mathrm{nil}} = \mathcal{F}_*^K \to \mathcal{F}_{*-1}^{HC}$ which is always an isomorphism. Haesemeyer's theorem made all the difference.

Theorems 5.1 and 5.3 are powerful tools for studying the K-theory of singular schemes. In the next sections we review a number of results whose proofs used these tools.

Remark 5.4. Building on work of Ayoub and ideas of Voevodsky, Cisinski proved in [4, Théorème 3.9] that KH satisfies cdh-descent in the category of Noetherian schemes of finite dimension. Since the latter category includes the schemes of finite type over a field of any characteristic, Cisinki's result is far more general than Haesemeyer's Theorem 5.1. However, Cisinski's proof relies heavily on homotopy invariance, and therefore no analog of Theorem 5.2 can be derived from his argument. A version of Theorem 5.2 for schemes of finite type over a perfect field which admits strong resolution of singularities, due to Geisser-Hesselholt, is given in Theorem 8.4 below.

6. Weibel's dimension conjecture

Conjecture 6.1 (Weibel's dimension conjecture [51, Questions 2.9]). *Let X be a Noetherian scheme of dimension d. Then $K_m(X) = 0$ for $m < -d$ and X is K_{-d}-regular.*

The KH-version of the conjecture for schemes over a field of characteristic zero was settled by Haesemeyer:

Theorem 6.2 (Haesemeyer, [34, Theorem 7.1]). *Let k be a field of characteristic zero and let $X \in \mathrm{Sch}/k$. Then $KH_m(X) = 0$ for $m < -\dim X$.*

Proof. By Theorem 5.1 and [34, Theorem 2.8] there is a spectral sequence

$$E_2^{p,q} = H^p_{\mathrm{cdh}}(X, aK_{-q}) \Rightarrow KH_{-p-q}(X).$$

The E_2-term is the cohomology of the cdh sheaf associated to the K-theory groups. We have $aK_{-q} = 0$ for $q > 0$ by Hironaka's desingularization theorem and the fact that negative K-theory vanishes on smooth schemes. By a result of Suslin-Voevodsky [43, Theorem 5.13], if $n > d = \dim X$ then $H^n_{\mathrm{cdh}}(X, \mathcal{S}) = 0$ for every cdh sheaf $\mathcal{S}$; thus $E_2^{p,q} = 0$ if either $p > d$ or $q > 0$. The theorem is immediate from this. □

Theorem 6.3 ([8, Theorem 6.2]). *Weibel's conjecture holds for schemes essentially of finite type over a field of characteristic zero.*

The vanishing part of Theorem 6.3 can be proved using Theorems 5.3 and 6.2 and a similar spectral sequence argument; the regularity part requires more work (see [8, Section 6]).

7. Singularity and the obstruction to K-regularity

Let $F : \mathrm{Rings} \to \mathfrak{Ab}$ be a functor from rings to abelian groups. If A is a ring, then the inclusion $A \subset A[t]$ is split by evaluation at zero. Hence for

$$NF(A) = \mathrm{coker}(F(A) \to F(A[t]))$$

we have a direct sum decomposition

$$F(A[t]) = F(A) \oplus NF(A).$$

Similarly,

$$F(A[t_1, t_2]) = F(A) \oplus NF(A) \oplus NF(A) \oplus N^2F(A),$$

where $N^2F = N(NF)$. Iterating this process one obtains an expression for $F(A[t_1, \ldots, t_n])$ in terms of $F(A)$ and of the groups $N^jF(A)$ for $j \geq 1$. Hence A is F-regular if and only if $N^jF(A) = 0$ for all $j \geq 1$.

Kassel proved ([38, Example 3.3]) that if A is a unital associative $\mathbb{Q}$-algebra, then

$$NHC_n(A) = HH_n(A) \otimes t\mathbb{Q}[t]. \tag{7.1}$$

Here HH is *Hochschild homology*; it is related to cyclic homology by Connes' SBI-sequence

$$HC_{n-1}(A) \xrightarrow{B} HH_n(A) \xrightarrow{I} HC_n(A) \xrightarrow{S} HC_{n-2}(A).$$

For example if A is commutative, then $HH_0(A) = A$ and

$$HH_1(A) = \Omega^1_A \tag{7.2}$$

is the module of absolute *Kähler* 1-*differential forms*. Using (7.1), (7.2), and the Künneth formula for Hochschild homology [53, Proposition 9.4.1], we obtain

$$\begin{aligned} N^2HC_n(A) =& NHH_n(A) \otimes t\mathbb{Q}[t] \\ =& HH_n(A) \otimes \mathbb{Q}[t] \otimes \mathbb{Q}[t] \oplus HH_{n-1}(A) \otimes \Omega^1_{\mathbb{Q}[t]} \otimes \mathbb{Q}[t]. \end{aligned} \tag{7.3}$$

Iterating this process one obtains a formula for $N^jHC_n(A)$ for all j in terms of $HH_{n-p}(A)$ $(p \leq j)$ (see [9, Formula 1.5]). Like cyclic homology, Hochschild homology is defined for schemes (see [52]) and has all the properties stated for cyclic homology in Theorem 4.2 and Corollary 4.3 ([8, Theorem 2.9]). Formulas (7.1) and (7.3) generalize to schemes. Moreover if k is a field of characteristic zero and $X \in \mathrm{Sch}/k$, then for $V = t\mathbb{Q}[t]$ and $dV = \Omega^1_{\mathbb{Q}[t]}$, we have ([9, Lemma 3.2 and Corollary 3.3]

$$\begin{aligned} N\mathcal{F}^{HC}_n(X) =& \mathcal{F}^{HH}_n(X) \otimes V, \\ N^2\mathcal{F}^{HC}_n(X) =& \big(\mathcal{F}^{HH}_n(X) \otimes V \otimes V\big) \oplus \big(\mathcal{F}^{HH}_{n-1}(X) \otimes V \otimes dV\big). \end{aligned}$$

In view of Theorem 5.3 and of the fact that KH is homotopy invariant, we obtain the following formulas:

$$\begin{aligned} NK_n(X) =& \mathcal{F}^{HH}_{n-1}(X) \otimes V \\ N^2K_n(X) =& \big(\mathcal{F}^{HH}_{n-1}(X) \otimes V \otimes V\big) \oplus \big(\mathcal{F}^{HH}_{n-2}(X) \otimes V \otimes dV\big). \end{aligned}$$

Of course we can iterate this to produce formulas for $N^jK_n(X)$ in terms of $\mathcal{F}^{HH}_{n-p}(X)$ $(p \leq j-1)$. Summing up, we obtain the following.

Proposition 7.1. *Let k be a field of characteristic zero, let $X \in \mathrm{Sch}/k$ and let $n \in \mathbb{Z}$. Then X is K_n-regular if and only if $\mathcal{F}^{HH}_m(X) = 0$ for all $m \leq n-1$.*

In view of (5.1), the equivalent conditions of the proposition are also equivalent to the assertion that the map

$$HH_m(X) \to \mathbb{H}^{-m}_{\mathrm{cdh}}(X, HH)$$

is an isomorphism for $m \leq n-1$ and a surjection for $m = n$. By [14, Proposition 2.1 and Theorem 2.2], $\mathbb{H}^*_{\mathrm{cdh}}(X, HH)$ decomposes as follows:

$$\mathbb{H}^{-m}_{\mathrm{cdh}}(X, HH) = \bigoplus_{i \geq 0} H^{i-m}_{\mathrm{cdh}}(X, a\Omega^i).$$

Here $H^*_{\mathrm{cdh}}(X, a\Omega^i)$ is the cohomology of the cdh-sheaf associated to Kähler i-differential forms. Summing up, K-regularity questions translate into comparing Hochschild homology with cdh cohomology of differential forms. This point of view has been useful for solving the following old questions about K-regularity.

Conjecture 7.2 (Vorst's regularity conjecture [48]). *Let R be a commutative unital ring of dimension d, essentially of finite type over a field k. If R is K_{d+1}-regular then R is a regular ring.*

For $d = 0$, the conjecture is trivial; the case $d = 1$ was proved by Vorst [48, Theorem 3.6]. Recall that a commutative unital ring R is *regular in codimension* d if the local ring $R_{\mathfrak{p}}$ is regular for each prime $\mathfrak{p}$ of codimension d. A Noetherian ring of dimension d is regular if and only if it is regular in codimension d.

Theorem 7.3 ([14, Theorem 0.1]). *Let R be a commutative unital ring which is essentially of finite type over a field k of characteristic zero. Assume that R is K_n-regular. Then R is regular in codimension $< n$. In particular, if R is $K_{\dim R+1}$-regular, then it is regular.*

Question 7.4 (Bass' question [1, Question $(VI)_n$]). *Does $NK_n(R) = 0$ imply $N^2K_n(R) = 0$?*

Theorem 7.5 ([9, Corollary 6.7], [10, Theorem 4.1]).

a) *For any field F algebraic over $\mathbb{Q}$, the 2-dimensional normal algebra*

$$R = F[x, y, z]/(z^2 + y^3 + x^{10} + x^7 y)$$

has $NK_0(R) = 0$ but $N^2K_0(R) \neq 0$.

b) *Suppose R is essentially of finite type over a field of infinite transcendence degree over $\mathbb{Q}$. Then $NK_n(R) = 0$ implies that R is K_n-regular.*

The proof in *loc.cit.* of the theorem above employs the method described in the paragraph after Proposition 7.1. Gubeladze gave a different proof of part b) in [33, Theorem 1].

The next conjecture concerns abelian monoids; we shall use multiplicative notation. An abelian monoid is called *cancellative* if $ac = bc$ implies $a = b$, and *torsion-free* if $a^n = b^n$ with $n \in \mathbb{Z}_{\geq 1}$ implies $a = b$. An element $u \in M$ is called a *unit* if it has an inverse in M. If k is a commutative ring and M a commutative monoid, then the *monoid k-algebra* $k[M]$ is the set of finitely supported functions $M \to k$ equipped with pointwise addition and convolution product. Any element of $k[M]$ can be written uniquely as a finite k-linear combination $\sum_a \lambda_a \chi_a$ where χ_a is the characteristic function $\chi_a(b) = \delta_{a,b}$. Each integer $c \geq 2$ defines a k-algebra homomorphism

$$\theta_c : k[M] \to k[M], \qquad \theta_c(\chi_a) = \chi_{a^c}.$$

The map θ_c is called the *dilation* of ratio c. If $F : \mathrm{Rings} \to \mathfrak{Ab}$ is a functor and $\mathfrak{c} = (c_1, c_2, \dots)$ is a sequence of integers $c_i \geq 2$, then we have an inductive system $\{\theta_{c_n} : F(k[M]) \to F(k[M]) : n \geq 1\}$. We write

$$F(k[M])^{\mathfrak{c}} = \operatorname*{colim}_{\theta_{c_n}} F(k[M])$$

for its colimit.

Conjecture 7.6 (Gubeladze's nilpotence conjecture, [30, Conjecture 2.1]). *Let k be a commutative ring, M an abelian monoid and $\mathfrak{c} = (c_1, c_2, \dots)$ a sequence of integers $c_i \geq 2$. Assume that k is regular Noetherian and that M is cancellative and torsion-free and has no non-trivial units. Then*

$$K_*(k[M])^{\mathfrak{c}} = K_*(k).$$

Remark 7.7. Under the conditions of the conjecture, the map $k[M] \to k$ is a polynomial homotopy equivalence (see the proof of [13, Corollary 8.4]). Thus Gubeladze's conjecture is a homotopy invariance statement.

Theorem 7.8 (Gubeladze, [31, Theorem 1.2], [32, Theorem 1]). *Conjecture 7.6 holds if k contains a field of characteristic zero.*

Gubeladze's proof uses relies on Theorem 2.3 and on his previous work on special cases of the conjecture. A different proof, using Theorem 5.2, was given in [11, Corollary 6.10] for the particular case when k is a field. The general case when k is a regular ring containing a field (of any characteristic) was proved in [13, Theorem 0.2]; this is discussed in Section 8.

8. A glimpse at characteristic $p > 0$.

We have seen in Section 2 that the obstructions to nilinvariance and excision with rational coefficients are computed by the Chern character to negative cyclic homology. To compute these obstructions in the p-adically complete case for a prime p, one has to replace the Chern character by the *cyclotomic trace* of Bökstedt-Hsiang-Madsen [3]

$$\mathrm{tr} : K(R) \to TC(R),$$

which takes values in *topological cyclic homology*.

Theorem 8.1 (McCarthy, [41, Main Theorem]). *Let R be a unital ring, $I \lhd R$ a nilpotent ideal and $p > 0$ a prime. Then $\mathrm{tr} : K(R : I) \to TC(R : I)$ becomes a weak equivalence after p-completion.*

The topological cyclic homology spectrum TC is the homotopy limit of a pro-spectrum TC^n; the following theorem is formulated in terms of the latter pro-spectrum. It implies that $K(R, S : I) \to TC(R, S : I)$ becomes a weak equivalence after p-completion.

Theorem 8.2 (Geisser-Hesselholt [21, Theorem 1]). *Let $f : R \to S$ be a homomorphism of unital associative rings, let $I \lhd R$ be a two-sided ideal and assume that $f : I \to f(I)$ is an isomorphism onto a two-sided ideal of S. Then the map induced by the cyclotomic trace map*

$$K_q(R, S : I, \mathbb{Z}/p^\nu) \to TC^n_q(R, S : I, \mathbb{Z}/p^\nu)$$

is an isomorphism of pro-abelian groups, for all integers q, all primes p, and all positive integers ν.

Remark 8.3. In their recent article [20], Dundas and Kittang have shown that Goodwillie's global cyclotomic trace $K \to \mathcal{TC}$ induces an integral isomorphism $K_*(R, S : I) \to \mathcal{TC}_*(R, S : I)$.

The following is a version of Theorem 5.2 for perfect fields which admit *strong resolution of singularities*. This means that for every integral scheme X separated and of finite type over k, there exists a sequence of blow-ups

$$X_r \to X_{r-1} \to \cdots \to X_1 \to X_0 = X$$

such that the reduced scheme X_r^{red} is smooth over k; the center Y_i of the blow-up $X_{i+1} \to X_i$ is connected and smooth over k; the closed embedding of Y_i in X_i is normally flat; and Y_i is nowhere dense in X_i.

Theorem 8.4 (Geisser-Hesselholt, [22, Theorem 1.1]). *Let k be an infinite perfect field such that strong resolution of singularities holds over k, and let $\{F^n(-)\}$ be a presheaf of pro-spectra on the category of schemes essentially of finite type over k. Assume that $\{F^n(-)\}$ takes infinitesimal thickenings to weak equivalences and finite abstract blow-up squares to homotopy cartesian squares. Assume further that each $F^n(-)$ takes elementary Nisnevich squares and squares associated with blow-ups along regular embeddings to homotopy cartesian squares. Then the canonical map defines a weak equivalence of pro-spectra*

$$\{F^n(X)\} \xrightarrow{\sim} \{\mathbb{H}^{\cdot}_{\mathrm{cdh}}(X, F^n(-))\}$$

for every scheme X essentially of finite type over k.

By Theorems 3.1, 8.1, and 8.2, the theorem above applies to KH and to the fiber of the cyclotomic trace. Using this, Geisser and Hesselholt obtained the following result about Weibel's dimension conjecture.

Theorem 8.5 (Geisser-Hesselholt, [22, Theorem A]). *Let k be an infinite perfect field of characteristic $p > 0$ such that strong resolution of singularities holds over k, and let X be a d-dimensional scheme essentially of finite type over k. Then $K_q(X)$ vanishes for $q < -d$.*

Geisser and Hesselholt also obtained the following result about Vorst's conjecture.

Theorem 8.6 (Geisser-Hesselholt, [23, Theorem A]). *Let k be an infinite perfect field of characteristic $p > 0$ such that strong resolution of singularities holds over k. Let R be a localization of a d-dimensional commutative k-algebra of finite type and suppose that R is K_{d+1}-regular. Then R is a regular ring.*

If we restrict our attention to toric varieties, the assumption that the ground field admits strong resolution of singularities can be dropped. The Bierstone-Milman theorem [2, Thm. 1.1] provides a chacteristic-free resolution of singularities for such varieties that is sufficient to prove the following toric version of Haesemeyer's theorem.

Theorem 8.7 ([12, Theorem 1.1]). *Assume k is an infinite field and let $\mathcal{G}$ be a cohomology theory on Sch/k. If $\mathcal{G}$ satisfies the Mayer-Vietoris property for Zariski covers, finite abstract blow-up squares, and blow-ups along regularly embedded closed subschemes, then $\mathcal{G}$ satisfies the Mayer-Vietoris property for all abstract blow-up squares of toric k-varieties.*

Theorems 8.2 and 8.7 were used to prove the following.

Theorem 8.8 ([13, Theorem 0.2]). *Gubeladze's conjecture 7.6 holds if k contains a field of characteristic $p > 0$.*

As we saw in Theorem 7.8, the case when $k \supset \mathbb{Q}$ of the theorem above had already been proved by Gubeladze in [32]. A different proof of Gubeladze's theorem, using Theorem 8.7, was also given in [13, Theorem 7.5].

Applications of the classification of finite simple groups

Dedicated to the memory of my friend and mentor Robert Steinberg

Robert Guralnick

Abstract. We discuss how the classification of finite simple groups is used and mention some specific applications to various other fields of mathematics as well as to group theory.

Mathematics Subject Classification (2010). Primary 20D05; Secondary 20B15, 14H30, 12F05.

Keywords. Finite groups, finite simple groups, applications of simple groups, Brauer groups, Riemann surfaces, polynomials, function fields.

1. Introduction

Recall that a subgroup N of a group G is normal in G if it is closed under conjugation. A *simple group* is a nontrivial group in which the only normal subgroups are the group itself and the identity subgroup. The first step in understanding groups is to understand the simple groups. This is much too hard for general groups and so one wants to focus on special types of groups. The classification of simple Lie groups turned out to have a beautiful theory (and has been amazingly fruitful). The classification of simple affine algebraic groups turns out to have essentially the same description albeit with a more difficult proof.

The classification of finite simple groups is one of the most amazing theorems in mathematics. See [55] for a very nice history. It is probably the longest and most complicated single proof in mathematics and involved contributions by many different mathematicians. Perhaps the most significant breakthrough came in John Thompson's series of papers on N-groups [56]. This built upon the earlier groundbreaking work of Feit and Thompson proving that all groups of odd order are solvable (recall that a finite group is solvable if and only if for K a normal subgroup of H with $K < H < G$ and H/K simple, then H/K is cyclic of prime order – this is equivalent to saying the derived series of G terminates in the identity subgroup). Thompson classified all finite simple groups such that the normalizer of any nontrivial prime power order subgroup is solvable. In particular, he classified all the minimal finite simple groups.

Much of the structure of the proof of the classification was based on the strategy used in the Thompson papers. In the early 1970's, Gorenstein realized that based on Thompson's ideas (and others) a proof of the classification was feasible. As Gorenstein has remarked, Aschbacher came along and started proving one amazing result after another and as a result

Proceedings of the International Congress of Mathematicians, Seoul, 2014

sped up the process significantly. Although the result was announced in the early 1980's, it was only completed with the publication of the books of Aschbacher and Smith in 2004 [6]. The original proof is scattered throughout the literature and there is a second generation proof that is being worked on. See the article [3] for a summary of the ideas. This second generation proof is being published by the AMS. Several volumes (plus some preliminary material and the two Aschbacher-Smith volumes) have already been published.

One major advantage of the second generation proof is that one wants to prove that there is no minimal counterexample to the theorem. Thus, one can assume that all proper subgroups of a possible counterexample only involve the known simple groups. This allows one to prove properties of simple groups and use them in the proof.

Indeed, there are other approaches being worked as on well – including one by Meiefrankenfeld et al (see [49]). Also, recently an approach using fusion systems which allows more topological tools to be used has been intensively studied and shown to be a useful way of thinking. Some parts of the classification have been recast in this language.

The tools and techniques in the proof are an amazing array of deep and clever ideas. Results about generators and relations, representation theory, amalgamated products and local subgroup structure are just a few of the ideas involved in the proof. One key result which finally settled a problem which many thought might not be resolved for quite a while was obtained by Bombieri [8] following work of Thompson. Bombieri used elimination theory to show that groups of Ree type are actually Ree groups.

The classification allows one to reduce many problems to questions of simple groups. Some of these reduction theorems could have been proved much earlier but there was not much point as the state of knowledge about arbitrary finite simple groups was quite limited before Thompson came on the scene.

There has also been some thought that with the completion of the classification, finite group theory does not have much of a future. To the contrary, with the tools we now have, one can prove some beautiful results in group theory and in other areas as well. When Richard Brauer was asked whether the classification of finite simple groups would be the end of finite group theory, he answered that it was only the beginning.

Recall that the classification of finite simple groups essentially says:

Theorem 1.1. *Let G be a finite simple group. Then one of the following holds:*

(1) *G is cyclic of prime order;*

(2) *G is an alternating group of degree $n \geq 5$;*

(3) *G is one of 26 sporadic groups; or*

(4) *G is a finite group of Lie type.*

The 26 sporadic groups are a fascinating subject and there have been thousands of pages written about them (and some amazing computations). The smallest of these is the Mathieu group of degree 11 and order 7920 while the largest is the Monster of order approximately 8×10^{53} and has some very interesting connections with modular functions. The first five of these groups were constructed by Mathieu during latter part of the nineteenth century. The remaining sporadic groups were exhibited in the 1960's and 70's.

The simple algebraic groups over an algebraically closed field k of characteristic p are classified (up to isogeny) by the irreducible Dynkin diagrams. The ones of types A, B, C and D correspond to classical groups (i.e. linear, orthogonal and symplectic groups) while the groups of type G_2, F_4 and $E_n, n = 6, 7, 8$ are called exceptional groups. If F is an

endomorphism of a simple algebraic group X such that the fixed set $G := X^F$ is finite, then G is close to being a finite simple (with just a few exceptions, the derived group of G modulo its center is simple). The simplest example is to let F be the q-Frobenius map on k (i.e. it is the map $x \to x^q$ for $q = p^e$). Then F is an automorphism of k and we can extend this to matrices and so to any group of matrices that is invariant under F. For example, if $X = \mathrm{SL}_n(k)$ and F is the q-Frobenius, then $X^F = \mathrm{SL}_n(q)$ and this modulo its center (of order $\gcd(n, q-1)$) is simple for $n \geq 3$ or $n = 2$ and $q \geq 4$. If the Dynkin diagram has graph automorphisms, then we get more examples. For example if we take $F = \sigma\tau$ on $X := \mathrm{SL}_n(k), n \geq 3$ where σ is the q-Frobenius and τ is a graph automorphism (which we can take as transpose inverse), then $X^F = \mathrm{SU}_n(q)$, the special unitary group. Again, almost always this is simple modulo its center (of order $\gcd(n, q+1)$). If $p > 3$, it turns out that these are the only such endomorphisms (note these maps are actually bijections but the inverses are not morphisms in the category of algebraic groups).

In characteristic 2 for the algebraic groups of type B_2 and F_4 and in characteristic 3 for the group G_2, one gets more exotic endomorphisms. This gives the complete list of the finite simple groups of Lie type. Special cases of these constructions were observed but Chevalley, Steinberg and Ree proved the general cases.

See the wonderful book [17] for many more properties of the finite simple groups. One crucial fact about the classification of finite simple groups is not just that gives the full list but that the typical finite simple group is of Lie type and this often allows one to use the theory of algebraic groups and its rich structure to deduce results about finite simple groups. We give some examples of results which use the classification below.

2. Using the classification

The classification of finite simple groups has had many consequences in different areas of mathematics. Many problems in number theory and algebraic geometry can be translated to problems in group theory and very often these involve permutation groups. Typically, one reduces the problem first to transitive groups and then to primitive permutation groups (recall we say that a group G acts primitively on a set S of cardinality larger than 1 if G preserves no nontrivial equivalence relation on S – this is equivalent to G being transitive on S and the stabilizer of a point being a maximal subgroup; these are the simple objects in the category of G-sets).

Note that even if one is trying to prove a result about a known simple group, often one needs to know about subgroups. The classification of simple groups is typically needed for this.

There is a very useful theorem that describes the structure of finite primitive permutation groups due to Aschbacher, O'Nan and Scott [4]. See also [21, 45]. We will not state the theorem but just note that finite primitive permutation groups have a very restricted structure. In particular:

Theorem 2.1. *If G is a finite primitive permutation group, then either G has a unique minimal normal subgroup or G has exactly 2 minimal normal subgroups which are isomorphic and act regularly on the set.*

The Aschbacher-O'Nan-Scott theorem reduces the study of primitive permutation groups to questions about (almost) simple groups and irreducible faithful representations of finite

groups (and the cohomology of such).

Aschbacher [1] gives a very nice description of the subgroups of the classical (almost) simple groups. Basically, the result says that any subgroup of a classical group either preserves some natural structure on the space or is almost simple (modulo the center). Similarly, Liebeck and Seitz [47] give a description of the maximal subgroups of the finite exceptional groups of Lie type. The maximal subgroups of symmetric and alternating groups are described in [46].

Linear representations of finite groups (both complex and over finite fields) also come into various applications. Fortunately, there have been major advances in recent years in both cases. In particular, the Deligne-Lusztig theory has played an important role in many applications.

There is a beautiful paper of Larsen and Pink [42] (see also an earlier related paper by Nori [51]) which asserts in particular that there are only finitely many sporadic groups which have a linear representation of fixed dimension. This can be used as a replacement for the classification for certain types of asymptotic results.

3. Coverings of Riemann Surfaces

Zariski in his thesis answered a conjecture of Enrique and proved:

Theorem 3.1. *Let X be a generic Riemann surface of genus $g > 6$. Let $n > 1$ be a positive integer. There are no solvable rational maps $f : X \to Y$ of degree n.*

If $f : X \to Y$ is a nonconstant map of Riemann surfaces, let $\mathrm{Mon}(f)$ denote the monodromy group of f (i.e the Galois group of the Galois closure of the field extension $\mathbb{C}(X)/\mathbb{C}(Y)$). A solvable map is one whose monodromy group is solvable.

One needs to define generic appropriately (basically, it means that the set of Riemann surfaces of genus g which admit a degree n solvable map to another Riemann surface is contained in a proper closed subvariety of the moduli space of genus g Riemann surfaces). Note that any Riemann surface of genus $g \leq 6$ admits a map of degree at most 4 to $\mathbb{P}^1$ and in particular a solvable map and so $g > 6$ is necessary in the theorem.

In fact, Zariski's proof was mostly about finite primitive solvable groups. In [31], the hypothesis of n being fixed was removed (for $n > 1$, one obtains a proper subvariety but in fact the countable union of these subvarieties is again contained in a proper subvariety).

Using the classification of finite simple groups, one can extend Zariski's result considerably. The following is proved in a series of papers [27, 31, 35]:

Theorem 3.2. *Let X be a generic Riemann surface of genus $g > 3$. Suppose that there exists an indecomposable map f of degree n from X to another Riemann surface Y. Then $Y = \mathbb{P}^1$ and one of the following holds:*

(1) *The monodromy group of f is S_n with $n \geq (g+2)/2$; or*

(2) *The monodromy group of f is A_n with $n > 2g$.*

The indecomposable case is the critical case to consider (any generic map is a composition of an indecomposable map and a rational function on $\mathbb{P}^1$). The key fact about primitive permutation groups that is required is the classification of primitive permutation groups

containing an element that fixes at least $1/2$ the points (a problem that was considered extensively already in the late 1800's).

It is a classical result that the first case in the previous theorem could arise. It was only relatively recently [48] that it was shown the second case can occur as well. There is a similar result for $g = 3$ [27]. The possibilities for $g \leq 2$ have not been worked out. Note that for $g = 0$, we just saying that f is a rational function. However, we do have the following theorem that is a result of the work of a dozen or so authors. This project was completed in [15].

Theorem 3.3. *Let g be a positive integer with X and Y Riemann surfaces with X of genus g. Suppose that $f : X \to Y$ is a rational map. Let S be any simple composition factor of the monodromy group of f. Then there exists a positive integer $N(g)$ such that one of the following holds:*

(1) *S is cyclic of prime order;*

(2) *S is an alternating group; or*

(3) *$|S| < N(g)$.*

Of course, the first two cases do occur. If $g = 0$ then essentially the complete list of possible composition factors of monodromy groups of rational functions has been worked out (indeed, Frohardt, Guralnick and Magaard are working on a project to describe all indecomposable rational functions of degree n whose monodromy groups are not alternating or symmetric groups of degree n).

4. Division Algebras

One of the earliest consequences of the classification of finite simple groups was pointed out by Fein, Kantor and Schacher [12]. Recall that a number field is a finite extension of the rational field.

Theorem 4.1. *Let L/K be a finite nontrivial extension of number fields. There are infinitely many non-isomorphic finite dimensional division algebras D with center K such that $L \otimes D$ is a full matrix ring over L*

The Brauer group $\mathrm{Br}(L)$ of a field is the set of equivalence classes of finite dimensional central division algebras over L (with the multiplication coming from tensor product). The theorem says that the relative Brauer group $\mathrm{Br}(L|K)$ is infinite ($\mathrm{Br}(L|K)$ is the kernel of the natural map from $\mathrm{Br}(K) \to \mathrm{Br}(L)$ given by extension of scalars). If L/K is Galois this follows easily from the description of division algebras over a number field. In the general case, it turns out [12] that one has the following equivalences:

Theorem 4.2. *The following are equivalent:*

(1) *$\mathrm{Br}(L|K)$ is infinite for any nontrivial extension of number fields;*

(2) *$\mathrm{Br}(L|K)$ is nonzero for any nontrivial extension of number fields;*

(3) *If G is a finite group acting transitively on a set S of cardinality $n > 1$, then there exists an element $x \in G$ of prime power order not fixing any points of S.*

Another equivalent condition is that the image of the norm map from L^* to K^* has infinite index. The fact there always exists a fixed point free element in a finite transitive group of degree $n > 1$, is quite elementary (going back to Jordan) but the only known proof to date of the existence of an element of prime power order with no fixed points depends on the classification of finite simple groups.

A proof of a more general result (again with a number theoretic consequence) is given in [19]. We state the number theoretic result.

Theorem 4.3. *Let L/K be a degree $n \geq 1$ extension of number fields. Assume that the Galois group of the Galois closure of L/K is S_n. If L'/K is an extension of number fields (of any degree) and $\mathrm{Br}(L|K)$ is commensurable with $\mathrm{Br}(L'|K)$, then L' and L are K-conjugate fields.*

Recall that two subgroups of a group are said to be commensurable if their intersection has finite index in each subgroup.

An easy corollary of the previous result also gives:

Corollary 4.4. *Let L/K be a degree $n \geq 1$ extension of number fields. Assume that the Galois group of the Galois closure of L/K is S_n. If L'/K is an extension of number fields (of any degree) and the set of degree 1 primes of K with respect to L and L' are the same (up to a finite set), then L' and L are K-conjugate fields.*

We say that a prime P of K (i.e. a prime ideal of the ring $\mathcal{O}_K$ of algebraic integers of K) is a degree 1 prime with respect to L, if some prime ideal of $\mathcal{O}_L$ laying over P has the same residue field as P. For $n = 1$, the result follows from the Cebatorev density theorem and the elementary fact that for any finite transitive group there is a fixed point free element For $n = 2$, this was a question posed by Fried and Jarden.

5. Polynomials

Here are a few results about polynomials. It seems surprising that the classification of simple groups is required to prove some of these results. See [34] for the first result.

Theorem 5.1. *Let F be a field of characteristic p and $f \in F[x]$ of degree n. Assume that f is indecomposable over F but decomposes over some extension field. Then one of:*

(1) $p = 11, n = 55$*; or*

(2) $p = 7, n = 21$*; or*

(3) $n = p^a > p$.

In characteristic zero, this is classical and does not require the classification (or more generally if $\gcd(n, p) = 1$). In [39], the polynomials themselves are actually classified. This involved some interesting curve theory as well as the group theory. There are many examples of such polynomials in the final case. The fact that there are two exceptions suggests that there cannot be a simple proof of the result.

If $f \in F[x]$ is a separable polynomial of degree n with F a finite field of size q, then f is called exceptional if f is bijective over the field of size q^a for some large a (all we need is that $q^a > n^4$). There is another (geometric) description of exceptionality over any field.

Moreover, one can also extend the definition to morphisms between varieties. This idea goes back to the thesis of Dickson in the 1890's.

The following result is obtained in [33, 39] following earlier work in [14].

Theorem 5.2. *Let F be a finite field of characteristic p. Let $f \in F[x]$ be exceptional and indecomposable of degree n with n not a power of p.*

(1) *If $p > 3$, then f is has prime degree and is either a Dickson polynomial or essentially a power of x;*

(2) *if $p \leq 3$, then one of the following holds:*

   (a) *f is a Dickson polynomial of prime degree;*
   (b) *f is a power of x; or*
   (c) *$n = p^a(p^a - 1)/2$ with $a > 1$, a odd.*

Moreover, all such f are known.

Recall that the Dickson polynomials satisfy $D_{n,a}(x + a/x) = x^n + a/x^n$ and have monodromy group the dihedral group of order $2n$. They are generalizations of certain Chebyshev polynomials.

The previous theorem requires a nontrivial reduction to the monodromy group, a difficult group theory problem and then a quite interesting determination of which group theoretic solutions actually led to solutions of the original problem (and then to use that information to actually classify the polynomials). The monodromy groups occurring in the last case when $p \leq 3$ are $\mathrm{PSL}_2(p^a)$.

Here is another result which asserts that many polynomials over finite fields either are bijective or miss quite a lot of points [38].

Theorem 5.3. *Suppose that $f(x) \in \mathbb{F}_q[x]$ of degree n prime to p. Then for any a, f is either bijective on $\mathbb{F}_{q^a}$ or $|f(\mathbb{F}_{q^a})| \leq (5/6)q^a + O(q^{a/2})$.*

If the assumption that n is coprime to the characteristic is dropped, then one can construct examples where f is close to being surjective (the $5/6$ needs to be replaced by $1 - 1/n$ with n the degree of f).

6. Generation

Here is a group theoretic application (although these results do have some applications in number theory). Let $d(G)$ denote the minimal size of a generating set of G. Let $P_2(G)$ denote the probability that a random pair of elements of G generate G. We say that two normal subsets S_1, S_2 of G invariably generate G if $G = \langle s_1, s_2 \rangle$ for any pair $s_i \in S_i$.

Theorem 6.1. *Let G be a finite simple group:*

(1) *$d(G) \leq 2$;*

(2) *$P_2(G) \to 1$ as $|G| \to \infty$*

(3) *for $1 \neq y \in G$, there is $x \in G$ with $G = \langle x, y \rangle$.*

(4) *There exist conjugacy classes C_1 and C_2 of G so that G can be invariably generated by C_1, C_2.*

Remarks
(2) only implies that (1) holds with possibly finitely many exceptions.
Thompson proved (1) for G minimal simple and showed that a finite group is solvable if and only if every 2-generated subgroup is.
(1) was proved by Miller, Steinberg and finished (using the classification) by Aschbacher-Guralnick.
(2) was proved in three papers by Dixon, Kantor-Lubotzky and Liebeck-Shalev.
(4) was proved by Guralnick and Malle. The property of invariable generation is quite useful in the computation of Galois groups.

These types of generation results can give characterizations of various properties of finite groups. We mention just one. Recall that the solvable radical $R(G)$ of a finite group G is the largest normal solvable subgroup. We can characterize the elements of $R(G)$ [32].

Theorem 6.2. *Let G be a finite group. $g \in R(G)$ if and only if $\langle g, x\rangle$ is solvable for all $x \in G$.*

7. Cohomology

The computation of cohomology groups (particularly of low degree) has important consequences in many areas. The first result is obtained by reducing the problem to simple groups and then proving the result for simple groups. See [22] for the first part and [24] for the second.

Theorem 7.1. *Let G be a finite group with V an absolutely irreducible faithful G-module over a field k.*

(1) $\dim H^1(G, V) \leq (1/2)\dim V$;
(2) $\dim H^2(G, V) < 20 \dim V$.

The 20 should be replaced by $1/2$ as well, but in fact most of the time these constants can be reduced considerably. Until 2012, the largest dimension of any $H^1(G, V)$ with V absolutely irreducible and faithful was 3. There are now examples of dimension over $10,000,000$ (using Kazhdan-Lusztig polynomials and computations by Frank Lübeck as well as knowing that the Lusztig conjecture holds for p sufficiently large depending on the root system). This certainly suggests that there is no upper bound on $\dim H^1(G, V)$ with G acting absolutely irreducibly and faithfully on V.

The previous result was used in [24] to prove the following result about profinite presentations of the finite simple groups (and also gives consequences for profinite presentations of arbitrary finite groups). Recall that a profinite presentation for a group G is a short exact sequence:

$$1 \to R \to F \to G \to 1,$$

where F is a free profinite group and R is a closed normal subgroup of F. The number of relations required is the minimal number of elements of R which generate R as a closed normal subgroup of F.

Corollary 7.2. *Let G be a finite simple group. Then G has a profinite presentation with 2 generators and at most 20 relations.*

The correct answer should be 4 (and 2 if we replace the simple group by is universal central cover). For ordinary presentations, one can replace 20 by 50 with the possible exception of ${}^2G_2(3^{2a+1})$; see [23, 25].

8. Linear Groups

Even results on Lie theory sometimes require the classification.

Answering a question of Kollar-Larsen [41], it was shown in [36] that:

Theorem 8.1. *Let G be a closed subgroup of $\mathrm{GL}_n(\mathbb{C}) = \mathrm{GL}(V), n > 2$. Suppose that G acts irreducibly on $\mathrm{Sym}^d(V)$ for $d \geq 4$. Then either G contains $\mathrm{Sp}(V)$ (if $\dim V$ is even) or $\mathrm{SL}(V)$ unless $n = 6$ or 12.*

This has applications to holomony of vector bundles of smooth projective varieties. For $n = 6, 12$, sporadic groups lead to counterexamples. A similar result on subgroups of the classical groups (in characteristic 0) which leave invariant the same subspaces in small tensor powers was obtained by the same authors (answering a conjecture of Nick Katz).

The following results were obtained in [28, 30] answering two conjectures of Peter Neumann from 1966.

Theorem 8.2. *Let k be a field and G an irreducible subgroup of $GL(V)$.*

(1) *If G is finite (or compact), then the average dimension of the fixed point space of an element of G is at most $(1/2)\dim V$.*

(2) *If G is arbitrary, there exists $g \in G$ with the fixed points of g having dimension at most $(1/3)\dim V$.*

See [30] for a proof of the first result (and generalizations and applications). See [28] for the second (and generalizations). Note that both results are best possible (in the first case take G to be cyclic of order 2 – in fact this is the only example where equality holds; in the second case take G to be any irreducible subgroup of $\mathrm{SO}(3, k)$).

There is a classical result of Jordan.

Theorem 8.3. *There is a function f on the natural numbers such that if G is a finite subgroup of $\mathrm{GL}_n(\mathbb{C})$, then G contains an abelian normal subgroup of index at most $f(n)$.*

The estimates for $f(n)$ have been rather large. Using the classification, Weisfeiler, in unpublished work before his death, immensely improved the bounds. Finally, Collins [9] showed that for $n \geq 71$, one could take $f(n) = (n + 1)!$ (and of course this is best possible since S_{n+1} has an irreducible representation of dimension n).

If $\mathbb{C}$ is replaced by an algebraically closed field of characteristic p, then of course there can be arbitrarily large finite subgroups with tiny abelian normal subgroups (e.g. $\mathrm{SL}_n(p^q)$). However, one can prove an analog. This is done by Larsen and Pink [42] without the classification. Collins [10] proves essentially the best possible analog (using the classification).

9. Mashke's Theorem

Maschke's Theorem says that all finite dimensional representations of a finite group in characteristic 0 are completely reducible. The same is true for (rational) representations of Lie groups. Of course, this fails for positive characteristic (both for finite groups and for simple algebraic groups). However, we can recover some version of this. There are asymptotic versions of the following theorem which can be proved without the classification.

Theorem 9.1. *Let p be a prime and G a finite subgroup of $\mathrm{GL}(V)$ with p the characteristic of V. If $\dim V \leq p-2$, then V is completely reducible if and only if G has no nontrivial normal p-subgroup.*

See [20] for the proof. Note that the $p-2$ is sharp since A_p has indecomposable modules of dimensional $p-1$ which are not irreducible. The result depends upon essentially reducing to the case of simple groups and showing that in most cases, one only needs to consider finite groups of Lie type in the same characteristic as V. We then apply a result of Jantzen [40]. The result is also valid for algebraic groups.

10. Word Maps and Waring's Problem

Suppose that w is a nontrivial word in a free group of rank r. Then w defines a map from $G^r \to G$. Let $w(G)$ denote this image. Some particular interesting examples are powers and the commutator word. This can be viewed as an analog of Waring's problem: determine k so that every positive integer is a sum a k dth powers.

The best result along this lines is a result of Larsen, Shalev and Tiep [43]:

Theorem 10.1. *If G is a finite simple group and $|G| \geq N_w$, then $G = w(G)w(G)$.*

Of course, w may vanish on G. Even if w does not vanish, one has examples where many copies of $w(G)$ are required. Of course, power words are not surjective if the power is not relatively prime to the order of $|G|$. For some words, we do have $G = w(G)$ with no exceptions.

Theorem 10.2. *Let $w = x^{-1}y^{-1}xy$ or x^ny^n where $n = p^aq^b$ for primes p and q. If G is a finite simple group, then $G = w(G)$.*

The case of the commutator word was conjectured by Ore [52] and follows by the work in [11, 44, 52]. Special cases for the second case were proved in various papers. See [26] for the complete result.

11. Galois Groups

The question of whether every finite group is the Galois group of a Galois extension of $\mathbb{Q}$ is still very open. There is been quite a lot of progress (using methods from algebraic geometry) in showing that many groups close to being simple are Galois groups. Even in that case, there are only very partial results (there are better results if one works over cyclotomic extensions). See [50] for a survey. Rigidity has proved to be a useful tool. More recently, other methods involving more serious algebraic geometry have been used.

Serre noted the following interesting invariant of the inverse Galois problem (which perhaps seems less likely to be true but is equivalent): every finite group is the Galois group of a totally real Galois extension of $\mathbb{Q}$ (recall that a number field is totally real if every embedding into $\mathbb{C}$ is contained in $\mathbb{R}$ – for Galois extensions, it just amounts to being a subfield of $\mathbb{R}$).

12. Lattices

Quillen [54] studied the poset $\mathcal{A}_p(G)$ of elementary abelian p-subgroups of a finite group G. He proved that if if G has a nontrivial normal p-subgroup, then $\mathcal{A}_p(G)$ is contractible and conjectured that a strong converse held (involving the cohomology of the associated simplicial complex). This conjecture is still open. In [5], the best results to date have been obtained proving Quillen's conjecture for $p > 5$ as long as certain unitary groups are not involved in the group.

Pálfy and Pudlák asked whether every finite lattice embeds in the subgroup lattice of some finite group. Certainly this is false but to date no particular lattice has been ruled out. Aschbacher reduced the question to a more complicated question about simple group. There has been significant progress on this. See [2, 53] for more details on the motivation for the question.

While the knowledge of maximal subgroups of finite groups is relatively well understood (but a full classification would require knowing the dimensions of the irreducible representations of the finite quasi-simple groups and this does not seem within reach at the moment). More generally, one would like more information about the entire subgroup structure.

13. Prime Power Index

Recall that if G is a finite solvable group, then every maximal subgroup has prime power index (this is an easy exercise). Upon learning of this result as a graduate student, the author immediately made the conjecture that this characterized solvable groups (by a theorem of Philip Hall, it is true if the every maximal subgroup index a prime or the square of a prime). Bob Steinberg pointed out that the simple group $\mathrm{SL}(3,2)$ provided a counterexample (the maximal subgroups all have index either 7 or 8). Years later, the next result was obtained (and has been used many many times). See [18]. This is another example where there is one special case. This suggests that the classification really is required.

Theorem 13.1. *Let G be a finite group and suppose that every maximal subgroup of G has prime power index in G. Then either G is solvable or G has a solvable normal subgroup with $G/N \cong \mathrm{SL}(3,2)$.*

14. Beauville Surfaces

A Beauville surface, first defined by F. Catanese, is a rigid compact complex surface of the form $(C_1 \times C_2)/G$ where C_1 and C_2 are curves of genus at least 2 and G is a finite group acting freely on $C_1 \times C_2$. In [7], it was shown that all sufficiently large alternating groups admit a Beauville structure and conjectured that all finite simple groups admit Beauville

structures (with the exception of A_5 which does not).

This was proved in [16] with finitely many possible exceptions. An independent proof giving full result was obtained in [29] (and also in [13]). The methods involve showing that for many triples of conjugacy classes C_1, C_2, C_3 we can find $x_i \in C_i$ with $x_1x_2x_3 = 1$ with the x_i generating the simple group.

Higher representation theory and quantum affine Schur-Weyl duality

Seok-Jin Kang

Abstract. In this article, we explain the main philosophy of 2-representation theory and quantum affine Schur-Weyl duality. The Khovanov-Lauda-Rouquier algebras play a central role in both themes.

Mathematics Subject Classification (2010). Primary 17B37; Secondary 16E99.

Keywords. 2-representation theory, Schur-Weyl duality, Khovanov-Lauda-Rouquier algebra, quantum group.

1. Introduction

The *Khovanov-Lauda-Rouquier algebras*, introduced by Khovanov-Lauda [27, 28] and Rouquier [32, 33], are a family of $\mathbf{Z}$-graded algebras that provide a fundamental framework for *2-representation theory* and *quantum affine Schur-Weyl duality*.

Let $H_k(\zeta)$ be the finite Hecke algebra with ζ a primitive n-th root of unity and let $U_q(A^{(1)}_{n-1})$ be the quantum affine algebra of type $A^{(1)}_{n-1}$. In [29], Lascoux-Leclerc-Thibon discovered a recursive algorithm of computing Kashiwara's lower global basis(=Lusztig's canonical basis) ([25, 30]) and conjectured that the coefficient polynomials, when evaluated at $q = 1$, give the composition multiplicities of simple $H_k(\zeta)$-modules inside Specht modules.

In [2], Ariki came up with a proof of the Lascoux-Leclerc-Thibon conjecture using the idea of *categorification*. More precisely, let Λ be a dominant integral weight associated with the affine Cartan datum of type $A^{(1)}_{n-1}$ and let $H^{\Lambda}_k(\zeta)$ be the corresponding cyclotomic Hecke algebra. Let proj $(H^{\Lambda}_k(\zeta))$ denote the category of finitely generated projective $H^{\Lambda}_k(\zeta)$-modules and let $K(\text{proj}\,(H^{\Lambda}_k(\zeta)))$ be the Grothendieck group of proj $(H^{\Lambda}_k(\zeta))$. Then Ariki proved

$$\bigoplus_{k=0}^{\infty} K(\text{proj}\,(H^{\Lambda}_k(\zeta)))_{\mathbf{C}} \cong V(\Lambda),$$

where $V(\Lambda)$ is the integrable highest weight module over $A^{(1)}_{n-1}$. Moreover, he showed that the isomorphism classes of projective indecomposable modules correspond to the lower global basis of $V(\Lambda)$ at $q = 1$, from which the Lascoux-Leclerc-Thibon conjecture follows.

The idea of categorification, which was originated from [7], can be explained as follows. In the classical representation theory, we study the properties of an algebra A that are reflected on various vector spaces V. That is, we investigate various algebra homomorphisms

Proceedings of the International Congress of Mathematicians, Seoul, 2014

$\phi : A \to \mathrm{End}(V)$. We identify A with a category having a single object and its elements as morphisms. Similarly, we consider $\mathrm{End}(V)$ as a category with V as its object and linear operators on V as morphisms. Then the classical representation theory can be understood as the study of functors from a category to another, whence the *1-representation theory*.

We now *categorify* the classical representation theory. Let $A = \bigoplus_{\alpha \in Q} A_\alpha$ be a graded algebra and let $V = \bigoplus_{\lambda \in P} V_\lambda$ be a graded A-module, where Q and P are appropriate abelian groups. We construct 2-categories $\mathfrak{A}$ and $\mathfrak{B}$ whose objects are certain categories $\mathcal{A}_\alpha$ $(\alpha \in Q)$ and $\mathcal{B}_\lambda$ $(\lambda \in P)$ such that

$$\bigoplus_{\alpha \in Q} K(\mathcal{A}_\alpha) \cong A, \qquad \bigoplus_{\lambda \in P} K(\mathcal{B}_\lambda) \cong V.$$

We now investigate the properties of 2-functors $R : \mathfrak{A} \to \mathfrak{B}$. That is, by categorifying the classical representation theory, we obtain the *2-representation theory*, the study of 2-functors from a 2-category to another.

So far, one of the most interesting developments in 2-representation theory is the one via Khovanov-Lauda-Rouquier algebras. The Khovanov-Lauda-Rouquier algebras categorify the negative half of quantum groups associated with *all* symmetrizable Cartan datum [27, 28, 32, 33]. Moreover, the cyclotomic Khovanov-Lauda-Rouquier algebras give a categorification of *all* integrable highest weight modules [16]. Hence Khovanov-Lauda-Rouquier's and Kang-Kashiwara's categorification theorems provide a vast generalization of Ariki's categorification theorem. (See also [38].)

When the Cartan datum is symmetric, as was conjectured by Khovanov-Lauda [28], Varagnolo-Vasserot proved that the isomorphism classes of simple modules (respectively, projective indecomposable modules) correspond to upper global basis(=dual canonical basis) (respectively, lower global basis) [36]. However, when the Cartan datum is not symmetric, the above statements do not hold in general. It is a very interesting problem to characterize the *perfect basis* and *dual perfect basis* that correspond to simple modules and projective indecomposable modules, respectively.

On the other hand, the Khovanov-Lauda-Rouquier algebras can be viewed as a huge generalization of affine Hecke algebras in the context of *Schur-Weyl duality*. The Schur-Weyl duality, established by Schur and others (see, for example, [34, 35]), reveals a deep connection between the representation theories of symmetric groups and general linear Lie algebras. Let $V = \mathbf{C}^n$ be the vector representation of the general linear Lie algebra gl_n and consider the k-fold tensor product of V. Then gl_n acts on $V^{\otimes k}$ by comultiplication and the symmetric group Σ_k acts on $V^{\otimes k}$ (from the right) by place permutation. Clearly, these actions commute with each other. The Schur-Weyl duality states that there exists a surjective algebra homomorphism

$$\phi_k : \mathbf{C}\Sigma_k \longrightarrow \mathrm{End}_{gl_n}(V^{\otimes k}),$$

where $\mathrm{End}_{gl_n}(V^{\otimes k})$ denotes the centralizer algebra of $V^{\otimes k}$ under the gl_n-action. Moreover, ϕ_k is an isomorphism whenever $k \leq n$.

The Schur-Weyl duality can be rephrased as follows. There is a functor $\mathcal{F}$ from the category of finite dimensional Σ_k-modules to the category of finite dimensional polynomial representations of gl_n given by

$$M \longmapsto V^{\otimes k} \otimes_{\mathbf{C}\Sigma_k} M,$$

where M is a finite dimensional Σ_k-module. The functor $\mathcal{F}$ is called the *Schur-Weyl duality functor* and it defines an equivalence of categories whenever $k \leq n$.

In [14], Jimbo extended the Schur-Weyl duality to the quantum setting: Σ_k is replaced by the finite Hecke algebra H_k and gl_n is replaced by the quantum group $U_q(gl_n)$. Then he obtained the *quantum Schur-Weyl duality functor* from the category of finite dimensional H_k-modules to the category of finite dimensional polynomial representations of $U_q(gl_n)$, which also defines an equivalence of categories whenever $k \leq n$.

In [4, 5, 10], Chari-Pressley, Cherednik and Ginzburg-Reshetikhin-Vasserot constructed a *quantum affine Schur-Weyl duality functor* which relates the category of finite dimensional representations of affine Hecke algebra H_k^{aff} and the category of finite dimensional integrable $U_q'(A_{n-1}^{(1)})$-modules. The main ingredients of their constructions are (i) the fundamental representation $V(\varpi_1)$, (ii) the R-matrices on the tensor products of $V(\varpi_1)$ satisfying the Yang-Baxter equation, (iii) the intertwiners in H_k^{aff} satisfying the braid relations.

Using Khovanov-Lauda-Rouquier algebras, one can construct quantum affine Schur-Weyl duality functors in much more generality. In [17], Kang, Kashiwara and Kim constructed such a functor which relates the category of finite dimensional modules over symmetric Khovanov-Lauda-Rouquuier algebras and the category of finite dimensional integrable modules over *all* quantum affine algebras. Roughly speaking, the basic idea can be explained as follows. Using a family of *good* modules and R-matrices, we determine a quiver Γ and construct a symmetric Khovanov-Lauda-Rouquier algebra $R^{\Gamma}(\beta)$ $(\beta \in Q_+)$. We then construct a $(U_q'(\mathfrak{g}), R^{\Gamma}(\beta))$-bimodule $\widehat{V}^{\otimes\beta}$, a completed tensor power arising from good modules, and define the quantum affine Schur-Weyl duality functor $\mathcal{F}$ by

$$M \mapsto \widehat{V}^{\otimes\beta} \otimes_{R^{\Gamma}(\beta)} M,$$

where M is an $R^{\Gamma}(\beta)$-module.

Various choices of quantum affine algebras and good modules would give rise to various quantum affine Schur-Weyl duality functors. We believe that our general approach will generate a great deal of exciting developments in the forthcoming years.

2. Quantum groups

We begin with a brief recollection of representation theory of quantum groups.

Let I be a finite index set. An integral matrix $A = (a_{ij})_{i,j\in I}$ is called a *symmetrizable Cartan matrix* if (i) $a_{ii} = 2$ for all $i \in I$, (ii) $a_{ij} \leq 0$ for $i \neq j$, (iii) $a_{ij} = 0$ if and only if $a_{ji} = 0$, (iv) there exists a diagonal matrix $D = \mathrm{diag}(d_i \in \mathbf{Z}_{>0} \mid i \in I)$ such that DA is symmetric.

A *Cartan datum* consists of :

(1) a symmetrizable Cartan matrix $A = (a_{ij})_{i,j\in I}$,

(2) a free abelian group P of finite rank, the *weight latice*,

(3) $\Pi = \{\alpha_i \in P \mid i \in I\}$, the set of *simple roots*,

(4) $P^{\vee} := \mathrm{Hom}(P, \mathbf{Z})$, the *dual weight lattice*,

(5) $\Pi^{\vee} = \{h_i \in P^{\vee} \mid i \in I\}$, the set of *simple coroots*

satisfying the following properties

i) $\langle h_i, \alpha_j \rangle = a_{ij}$ for all $i, j \in I$,

ii) Π is linearly independent,

iii) for each $i \in I$, there exists an element $\Lambda_j \in P$ such that

$$\langle h_i, \Lambda_j \rangle = \delta_{ij} \text{ for all } i, j \in I.$$

The Λ_i's $(i \in I)$ are called the *fundamental weights*.

We denote by

$$P^+ := \{\Lambda \in P \mid \langle h_i, \Lambda \rangle \geq 0 \text{ for all } i \in I\}$$

the set of *dominant integral weights*. The free abelian group $Q := \bigoplus_{i \in I} \mathbf{Z}\alpha_i$ is called the *root lattice*. Set $Q_+ = \sum_{i \in I} \mathbf{Z}_{\geq 0}\alpha_i$. For $\beta = \sum k_i\alpha_i \in Q_+$, we define its *height* to be $|\beta| := \sum k_i$.

Since A is symmetrizable, there exists a symmetric bilinear form $(\ ,\ )$ on $\mathfrak{h}^* := \mathbf{Q} \otimes_{\mathbf{Z}} P^\vee$ satisfying

$$(\alpha_i, \alpha_j) = d_i a_{ij}, \quad \langle h_i, \lambda \rangle = \frac{2(\alpha_i, \lambda)}{(\alpha_i, \alpha_i)} \quad \text{for all } \lambda \in \mathfrak{h}^*,\ i, j \in I.$$

Let q be an indeterminate and set $q_i = q^{d_i}$ $(i \in I)$. For $m, n \in \mathbf{Z}_{\geq 0}$, we define

$$[n]_i := \frac{q_i^n - q_i^{-n}}{q_i - q_i^{-1}}, \qquad [n]_i! := \prod_{k=1}^{n} [k]_i.$$

We write $e_i^{(k)} := e_i^k/[k]_i!$, $f_i^{(k)} := f_i^k/[k]_i!$ $(k \in \mathbf{Z}_{\geq 0},\ i \in I)$ for the *divided powers*.

Definition 2.1. The *quantum group* $U_q(\mathfrak{g})$ corresponding to a Cartan datum $(A, P, \Pi, P^\vee, \Pi^\vee)$ is the associative algebra over $\mathbf{Q}(q)$ generated by the elements e_i, f_i $(i \in I)$, q^h $(h \in P^\vee)$ with defining relations

$$\begin{aligned}
&q^0 = 1, \quad q^h q^{h'} = q^{h+h'} \ \ (h, h' \in P^\vee),\\
&q^h e_i q^{-h} = q^{\langle h, \alpha_i \rangle} e_i, \quad q^h f_i q^{-h} = q^{-\langle h, \alpha_i \rangle} f_i \ \ (h \in P^\vee,\ i \in I),\\
&e_i f_j - f_j e_i = \delta_{ij} \frac{K_i - K_i^{-1}}{q_i - q_i^{-1}} \ \ (K_i = q^{d_i h_i},\ i \in I),\\
&\sum_{k=0}^{1-a_{ij}} (-1)^k e_i^{(1-a_{ij}-k)} e_j e_i^{(k)} = 0 \quad (i \neq j),\\
&\sum_{k=0}^{1-a_{ij}} (-1)^k f_i^{(1-a_{ij}-k)} f_j f_i^{(k)} = 0 \quad (i \neq j).
\end{aligned} \tag{2.1}$$

Let $U_q^0(\mathfrak{g})$ be the subalgebra of $U_q(\mathfrak{g})$ generated by q^h $(h \in P^\vee)$ and let $U_q^+(\mathfrak{g})$ (respectively, $U_q^-(\mathfrak{g})$) be the subalgebra of $U_q(\mathfrak{g})$ generated by e_i (respectively, f_i) for all $i \in I$. Then the algebra $U_q(\mathfrak{g})$ has the *triangular decomposition*

$$U_q(\mathfrak{g}) \cong U_q^-(\mathfrak{g}) \otimes U_q^0(\mathfrak{g}) \otimes U_q^+(\mathfrak{g}).$$

Let $\mathbf{A} = \mathbf{Z}[q, q^{-1}]$. We define the *integral form* $U_{\mathbf{A}}(\mathfrak{g})$ of $U_q(\mathfrak{g})$ to be the $\mathbf{A}$-subalgebra of $U_q(\mathfrak{g})$ generated by $e_i^{(k)}$, $f_i^{(k)}$, q^h $(i \in I,\ h \in P^\vee,\ k \in \mathbf{Z}_{\geq 0})$. Let $U_{\mathbf{A}}^0(\mathfrak{g})$ be the $\mathbf{A}$-subalgebra of $U_q(\mathfrak{g})$ generated by q^h $(h \in P^\vee)$ and let $U_{\mathbf{A}}^+(\mathfrak{g})$ (respectively, $U_{\mathbf{A}}^-(\mathfrak{g})$) be the

$\mathbf{A}$-subalgebra of $U_q(\mathfrak{g})$ generated by $e_i^{(k)}$ (respectively, $f_i^{(k)}$) ($i \in I$, $k \in \mathbf{Z}_{\geq 0}$). Then we have

$$U_{\mathbf{A}}(\mathfrak{g}) \cong U_{\mathbf{A}}^-(\mathfrak{g}) \otimes U_{\mathbf{A}}^0(\mathfrak{g}) \otimes U_{\mathbf{A}}^+(\mathfrak{g}).$$

A $U_q(\mathfrak{g})$-module V is called a *highest weight module with highest weight* $\Lambda \in P$ if there exists a nonzero vector v_Λ in V, called the *highest weight vector*, such that

(i) $e_i\, v_\Lambda = 0$ for all $i \in I$,

(ii) $q^h\, v_\Lambda = q^{\langle h, \Lambda \rangle} v_\Lambda$ for all $h \in P^\vee$,

(iii) $V = U_q(\mathfrak{g})\, v_\Lambda$.

For each $\Lambda \in P$, there exists a unique irreducible highest weight module $V(\Lambda)$ with highest weight Λ. The *integral form* of $V(\Lambda)$ is defined to be

$$V_{\mathbf{A}}(\Lambda) := U_{\mathbf{A}}(\mathfrak{g})\, v_\Lambda,$$

where v_Λ is the highest weight vector.

Consider the anti-involution $\phi : U_q(\mathfrak{g}) \to U_q(\mathfrak{g})$ defined by

$$q^h \mapsto q^h, \qquad e_i \mapsto f_i, \qquad f_i \mapsto e_i \quad (h \in P^\vee,\ i \in I).$$

Then there exists a unique non-degenerate symmetric bilinear form $(\ ,\ )$ on $V(\Lambda)$ satisfying

$$(v_\Lambda, v_\Lambda) = 1, \quad (x\, u, v) = (u, \phi(x)\, v) \quad \text{for all } x \in U_q(\mathfrak{g}),\ u, v \in V(\Lambda). \tag{2.2}$$

The *dual* of $V_{\mathbf{A}}(\Lambda)$ is defined to be

$$V_{\mathbf{A}}(\Lambda)^\vee := \{v \in V(\Lambda) \mid (u, v) \in \mathbf{A} \ \text{ for all } u \in V_{\mathbf{A}}(\Lambda)\}.$$

Note that $V_{\mathbf{A}}(\Lambda)^\vee_\lambda = \mathrm{Hom}_{\mathbf{A}}(V_{\mathbf{A}}(\Lambda)_\lambda, \mathbf{A})$ for all $\lambda \in P$.

The *Category* $\mathcal{O}_{\text{int}}$ consists of $U_q(\mathfrak{g})$-modules M such that

i) $M = \bigoplus_{\mu \in P} M_\mu$, where $M_\mu := \{m \in M \mid q^h\, m = q^{\langle h, \mu \rangle}\, m \text{ for all } h \in P^\vee\}$,

ii) e_i, f_i ($i \in I$) are locally nilpotent on M,

iii) there exist finitely many elements $\lambda_1, \ldots, \lambda_s \in P$ such that

$$\mathrm{wt}(M) := \{\mu \in P \mid M_\mu \neq 0\} \subset \bigcup_{j=1}^{s} (\lambda_j - Q_+).$$

The following properties of the category $\mathcal{O}_{\text{int}}$ are well-known. (See, for example, [11, 15, 31].)

Proposition 2.2.

(a) *The category $\mathcal{O}_{int}$ is semisimple.*

(b) *The $U_q(\mathfrak{g})$-module $V(\Lambda)$ with $\Lambda \in P^+$ belongs to $\mathcal{O}_{int}$.*

(c) *Every simple object in $\mathcal{O}_{int}$ has the form $V(\Lambda)$ for some $\Lambda \in P^+$.*

3. Khovanov-Lauda-Rouquier algebras

Let $\mathbf{k}$ be a field and let $(A, P, \Pi, P^\vee, \Pi^\vee)$ be a Cartan datum.

For each $i \neq j$, set

$$S_{ij} := \{(p,q) \in \mathbf{Z}_{\geq 0} \times \mathbf{Z}_{\geq 0} \mid (\alpha_i, \alpha_i)p + (\alpha_j, \alpha_j)q = -2(\alpha_i, \alpha_j)\}.$$

Define a family of polynomials $\mathtt{Q} = (\mathtt{Q}_{ij})_{i,j \in I}$ in $\mathbf{k}[u,v]$ by

$$\mathtt{Q}_{ij}(u,v) := \begin{cases} 0 & \text{if } i = j, \\ \sum_{(p,q) \in S_{ij}} t_{i,j;p,q} u^p v^q & \text{if } i \neq j \end{cases} \tag{3.1}$$

for some $t_{i,j;p,q} \in \mathbf{k}$ such that $t_{i,j;p,q} = t_{j,i;q,p}$ and $t_{i,j;-a_{ij},0} \in \mathbf{k}^\times$. In particular,

$$\mathtt{Q}_{ii}(u,v) = 0, \quad \mathtt{Q}_{ij}(u,v) = \mathtt{Q}_{ji}(v,u) \ \ (i \neq j).$$

The symmetric group $\mathfrak{S}_n = \langle s_1, s_2, \dots, s_{n-1} \rangle$ acts on I^n by place permutation, where s_i denotes the transposition $(i, i+1)$.

Definition 3.1. The *Khovanov-Lauda-Rouquier algebra* $R(n)$ of degree $n \geq 0$ associated with $(A, \mathtt{Q})$ is the associative algebra over $\mathbf{k}$ generated by the elements $e(\nu)$ $(\nu \in I^n)$, x_k $(1 \leq k \leq n)$, τ_l $(1 \leq l \leq n-1)$ with defining relations

$$\begin{aligned}
&e(\nu)e(\nu') = \delta_{\nu,\nu'} e(\nu), \quad \sum_{\nu \in I^n} e(\nu) = 1, \\
&x_k x_l = x_l x_k, \quad x_k e(\nu) = e(\nu) x_k, \\
&\tau_l e(\nu) = e(s_l(\nu))\tau_l, \quad \tau_k \tau_l = \tau_l \tau_k \ \text{ if } |k-l| > 1, \\
&\tau_k^2 e(\nu) = \mathtt{Q}_{\nu_k, \nu_{k+1}}(x_k, x_{k+1}) e(\nu), \\
&(\tau_k x_l - x_{s_k(l)} \tau_k) e(\nu) = \begin{cases} -e(\nu) & \text{if } l = k,\ \nu_k = \nu_{k+1}, \\ e(\nu) & \text{if } l = k+1,\ \nu_k = \nu_{k+1}, \\ 0 & \text{otherwise}, \end{cases} \\
&(\tau_{k+1}\tau_k\tau_{k+1} - \tau_k\tau_{k+1}\tau_k) e(\nu) \\
&\quad = \begin{cases} \dfrac{\mathtt{Q}_{\nu_k,\nu_{k+1}}(x_k, x_{k+1}) - \mathtt{Q}_{\nu_k,\nu_{k+1}}(x_{k+2}, x_{k+1})}{x_k - x_{k+2}} e(\nu) & \text{if } \nu_k = \nu_{k+2}, \\ 0 & \text{otherwise.} \end{cases}
\end{aligned} \tag{3.2}$$

The algebra $R(n)$ has a $\mathbf{Z}$-grading by assigning the degrees as follows:

$$\deg e(\nu) = 0, \qquad \deg x_k e(\nu) = (\alpha_{\nu_k}, \alpha_{\nu_k}), \qquad \deg \tau_l e(\nu) = -(\alpha_{\nu_l}, \alpha_{\nu_{l+1}}).$$

We denote by q the *degree-shift functor* defined by

$$(qM)_k = M_{k-1},$$

where $M = \bigoplus_{k \in \mathbf{Z}} M_k$ is a graded $R(n)$-module. Also there is an algebra involution $\psi : R(n) \to R(n)$ given by

$$\begin{aligned}
&e(\nu) \mapsto e(\nu'), \qquad x_k \mapsto x_{n-k+1}, \\
&\tau_l e(\nu) \mapsto \begin{cases} -\tau_{n-l}\, e(\nu') & \text{if } \nu_l = \nu_{l+1}, \\ \tau_{n-l}\, e(\nu') & \text{if } \nu_l \neq \nu_{l+1}, \end{cases}
\end{aligned} \tag{3.3}$$

where $\nu = (\nu_1, \nu_2, \dots, \nu_n)$ and $\nu' = (\nu_n, \dots, \nu_2, \nu_1)$.

By the embedding $R(m) \otimes R(n) \hookrightarrow R(m+n)$, we may consider $R(m) \otimes R(n)$ as a subalgebra of $R(m+n)$. For an $R(m)$-module M and an $R(n)$-module N, we define their *convolution product* $M \circ N$ by

$$M \circ N := R(m+n) \otimes_{R(m)\otimes R(n)} (M \otimes N). \tag{3.4}$$

Since $R(m+n)$ is free over $R(m) \otimes R(n)$ ([27, Proposition 2.16]), the bifunctor $(M, N) \mapsto M \circ N$ is exact in M and N.

For $n \geq 0$ and $\beta \in Q_+$ with $|\beta| = n$, set

$$I^\beta := \{\nu = (\nu_1, \dots, \nu_n) \mid \alpha_{\nu_1} + \cdots + \alpha_{\nu_n} = \beta\}, \qquad e(\beta) := \sum_{\nu \in I^\beta} e(\nu).$$

Then $e(\beta)$ is a central idempotent in $R(n)$. We also define

$$e(\beta, \alpha_i) := \sum_{\substack{\nu \in I^{\beta+\alpha_i} \\ \nu_{n+1}=i}} e(\nu), \quad e(\alpha_i, \beta) := \sum_{\substack{\nu \in I^{\beta+\alpha_i} \\ \nu_1=i}} e(\nu).$$

The algebra

$$R(\beta) := R(n)e(\beta)$$

is called the *Khovanov-Lauda-Rouquier algebra at* β.

For a $\mathbf{k}$-agebra R, we denote by $\mathrm{mod}(R)$ (respectively, $\mathrm{proj}(R)$ and $\mathrm{rep}(R)$) the category of R-modules (respectively, the category of finitely generated projective R-modules and the category of finite dimensional R-modules).

If R is a graded $\mathbf{k}$-algebra, we will use $\mathrm{Mod}(R)$ (respectively, $\mathrm{Proj}(R)$ and $\mathrm{Rep}(R)$) for the category of graded R-modules (respectively, the category of finitely generated projective graded R-modules and the category of finite dimensional graded R-modules).

For each $i \in I$, define the functors

$$\begin{aligned} E_i &: \mathrm{Mod}\,(R(\beta+\alpha_i)) \longrightarrow \mathrm{Mod}\,(R(\beta)), \\ F_i &: \mathrm{Mod}\,(R(\beta)) \longrightarrow \mathrm{Mod}\,(R(\beta+\alpha_i)) \end{aligned} \tag{3.5}$$

by

$$\begin{aligned} E_i(N) &= e(\beta, \alpha_i)\, R(\beta+\alpha_i) \otimes_{R(\beta+\alpha_i)} N, \\ F_i(M) &= R(\beta+\alpha_i)\, e(\beta, \alpha_i) \otimes_{R(\beta)} M \end{aligned} \tag{3.6}$$

for $M \in \mathrm{Mod}\,(R(\beta))$, $N \in \mathrm{Mod}\,(R(\beta+\alpha_i))$.

By [27, Proposition 2.16], the functors E_i and F_i are exact and send finitely generated projective modules to finitely generated projective modules. Hence (3.5) restricts to the functors

$$\begin{aligned} E_i &: \mathrm{Proj}\,(R(\beta+\alpha_i)) \longrightarrow \mathrm{Proj}\,(R(\beta)), \\ F_i &: \mathrm{Proj}\,(R(\beta)) \longrightarrow \mathrm{Proj}\,(R(\beta+\alpha_i)). \end{aligned} \tag{3.7}$$

For $1 \leq k < n$, set $b_k := \tau_k x_{k+1}$ and $b'_k := x_{k+1}\tau_k$. Let $w_0 = s_{i_1} \cdots s_{i_r}$ be the longest element in S_n and set

$$\mathbf{b}(n) := b_{i_1} \cdots b_{i_r}, \quad \mathbf{b}'(n) := b'_{i_r} \cdots b'_{i_1}.$$

For each $n \geq 0$, we define the *divided powers* by

$$E_i^{(n)} := \mathbf{b}'(n)E_i^n, \qquad F_i^{(n)} := F_i^n \mathbf{b}(n).$$

In [27] and [32], Khovanov-Lauda and Rouquier proved the following *categorification theorem*.

Theorem 3.2 ([27, 32]). *There exists an* $\mathbf{A}$*-algebra isomorphism*

$$U_{\mathbf{A}}^-(\mathfrak{g}) \xrightarrow{\sim} K(\text{Proj}(R)) \text{ given by } f_i^{(n)} \longmapsto [F_i^{(n)}] \ (i \in I,\ n \geq 0),$$

where $K(\text{Proj}(R)) := \bigoplus_{\beta \in Q_+} K(\text{Proj}(R(\beta)))$.

Thus we have constructed a 2-category $\mathfrak{R}$ such that the objects are the categories $\text{Proj}\,(R(\beta))$ $(\beta \in Q_+)$ and the categories $\mathcal{H}om\,(\text{Proj}\,R(\alpha), \text{Proj}\,R(\beta))$ consist of the monomials $F_{i_1} \cdots F_{i_r}$ $(i_k \in I,\ r \geq 0)$ of functors satisfying

$$\alpha_{i_1} + \cdots + \alpha_{i_r} = \begin{cases} \alpha - \beta & \text{if } \alpha \geq \beta, \\ \beta - \alpha & \text{if } \beta \geq \alpha. \end{cases}$$

The morphisms in $\mathcal{H}om\,(\text{Proj}\,R(\alpha), \text{Proj}\,R(\beta))$ are the natural transformations generated by $x_i : F_i \to F_i$, $\tau_{ij} : F_iF_j \to F_jF_i$ $(i, j \in I)$ satisfying the relations

$$\begin{aligned}
&\tau_{ij} \circ \tau_{ji} = \mathsf{Q}_{ij}(F_j\, x_i, x_j F_i), \\
&\tau_{jk}F_i \circ F_j\, \tau_{ik} \circ \tau_{ij}F_k - F_k\, \tau_{ij} \circ \tau_{ik}F_j \circ F_i\, \tau_{jk} \\
&\qquad = \begin{cases} \dfrac{\mathsf{Q}_{ij}(x_iF_j, F_j\, x_i)F_i - F_i\mathsf{Q}_{ij}(F_j\, x_i, x_jF_i)}{x_iF_jF_i - F_iF_j\, x_i} F_i & \text{if } i = k, \\ 0 & \text{otherwise}, \end{cases} \\
&\tau_{ij} \circ x_iF_j - F_j\, x_i \circ \tau_{ij} = \delta_{ij}, \\
&\tau_{ij} \circ F_i\, x_j - x_jF_i \circ \tau_{ij} = -\delta_{ij}.
\end{aligned}$$

It is straightforward to verify that $\mathfrak{R}$ satisfies all the axioms for 2-categories [32, 33].

For the later use, we define a functor $\overline{F_i} : \text{Mod}\,(R(\beta)) \longrightarrow \text{Mod}\,(R(\beta + \alpha_i))$ by

$$\overline{F_i}(M) := R(\beta + \alpha_i)\, e(\alpha_i, \beta) \otimes_{R(\beta)} M \ \text{ for } i \in I,\ M \in \text{Mod}\,(R(\beta)).$$

The properties of the functors E_i, F_i and $\overline{F_i}$ $(i \in I)$ are given in the following proposition.

Proposition 3.3 ([16]).

(a) *We have an exact sequence in Mod* $(R(\beta))$

$$0 \longrightarrow \overline{F_i}\, E_i\, M \longrightarrow E_i\overline{F_i}\, M \longrightarrow q^{-(\alpha_i,\alpha_i)}M \otimes \mathbf{k}[t_i] \longrightarrow 0$$

which is functorial in $M \in$ *Mod* $(R(\beta))$.

(b) *There exist natural isomorphisms*

$$\begin{aligned}
&E_iF_j \xrightarrow{\sim} F_jE_i, \quad E_i\overline{F_j} \xrightarrow{\sim} \overline{F_j}E_i \ \text{ if } i \neq j, \\
&E_iF_i \xrightarrow{\sim} q^{-(\alpha_i,\alpha_i)}F_iE_i \oplus \mathbf{1} \otimes \mathbf{k}[t_i] \ \text{ if } i = j,
\end{aligned}$$

where t_i *is an indeterminate of degree* (α_i, α_i) *and*

$$\mathbf{1} \otimes \mathbf{k}[t_i] : \text{Mod}\,(R(\beta)) \to \text{Mod}\,(R(\beta))$$

is the degree-shift functor sending M *to* $M \otimes \mathbf{k}[t_i]$ *for* $M \in$ *Mod* $(R(\beta))$ $(\beta \in Q_+)$.

4. Cyclotomic categorification theorem

Let $\Lambda \in P^+$ and let

$$a^\Lambda(x_1) := \sum_{\nu \in I^\beta} x_1^{\langle h_{\nu_1}, \Lambda \rangle} e(\nu) \quad \in R(\beta).$$

Then the *cyclotomic Khovanov-Lauda-Rouquier algebra* $R^\Lambda(\beta)$ ($\beta \in Q_+$) is defined to be the quotient algebra

$$R^\Lambda(\beta) := R(\beta) \big/ R(\beta) a^\Lambda(x_1) R(\beta). \tag{4.1}$$

We would like to show that the cyclotomic Khovanov-Lauda-Rouquier algebras provide a categorification of irreducible highest weight $U_q(\mathfrak{g})$-modules in the category $\mathcal{O}_{\text{int}}$.

For each $i \in I$, define the functors

$$\begin{aligned} E_i^\Lambda &: \text{Mod}(R^\Lambda(\beta + \alpha_i)) \longrightarrow \text{Mod}(R^\Lambda(\beta)), \\ F_i^\Lambda &: \text{Mod}(R^\Lambda(\beta)) \longrightarrow \text{Mod}(R^\Lambda(\beta + \alpha_i)) \end{aligned} \tag{4.2}$$

by

$$\begin{aligned} E_i^\Lambda(N) &= e(\beta, \alpha_i) R^\Lambda(\beta + \alpha_i) \otimes_{R^\Lambda(\beta+\alpha_i)} N, \\ F_i^\Lambda(M) &= R^\Lambda(\beta + \alpha_i)\, e(\beta, \alpha_i) \otimes_{R^\Lambda(\beta)} M \end{aligned} \tag{4.3}$$

for $M \in \text{Mod}(R^\Lambda(\beta))$, $N \in \text{Mod}(R^\Lambda(\beta + \alpha_i))$. However, since $R^\Lambda(\beta + \alpha_i)$ is not free over $R^\Lambda(\beta)$, there is no guarantee that E_i^Λ and F_i^Λ send finitely generated projective modules to finitely generated projective modules. To prove this, we need to show that $R^\Lambda(\beta + \alpha_i)\, e(\beta, \alpha_i)$ is a projective right $R^\Lambda(\beta)$-module.

Let

$$\begin{aligned} F^\Lambda &:= R^\Lambda(\beta + \alpha_i)\, e(\beta, \alpha_i) \\ &= \frac{R(\beta + \alpha_i)\, e(\beta, \alpha_i)}{R(\beta + \alpha_i)\, a^\Lambda(x_1) R(\beta + \alpha_i)\, e(\beta, \alpha_i)}, \\ K_0 &:= R(\beta + \alpha_i)\, e(\beta, \alpha_i) \otimes_{R(\beta)} R^\Lambda(\beta) \\ &= \frac{R(\beta + \alpha_i)\, e(\beta, \alpha_i)}{R(\beta + \alpha_i)\, a^\Lambda(x_1) R(\beta)\, e(\beta, \alpha_i)}, \\ K_1 &:= R(\beta + \alpha_i)\, e(\alpha_i, \beta) \otimes_{R(\beta)} R^\Lambda(\beta) \\ &= \frac{R(\beta + \alpha_i)\, e(\alpha_i, \beta)}{R(\beta + \alpha_i)\, a^\Lambda(x_2) R^1(\beta)\, e(\alpha_i, \beta)}, \end{aligned}$$

where $R^1(\beta)$ is the subalgebra of $R(\beta + \alpha_i)$ generated by $e(\alpha_i, \nu)$ ($\nu \in I^\beta$), x_k ($2 \le k \le n+1$), τ_l ($2 \le l \le n$). Then F^Λ, K_0 and K_1 can be regarded as $(R(\beta + \alpha_i), R^\Lambda(\beta))$-bimodules.

Let t_i be an indeterminate of degree (α_i, α_i). Then $\mathbf{k}[t_i]$ acts on $R(\beta + \alpha_i)\, e(\alpha_i, \beta)$ and K_1 from the right by $t_i = x_1 e(\alpha_i, \beta)$. On the other hand, $\mathbf{k}[t_i]$ acts on K_0 and F^Λ from the right by $t_i = x_{n+1} e(\beta, \alpha_i)$. Hence all of them have a structure of $(R(\beta + \alpha_i), R(\beta) \otimes \mathbf{k}[t_i])$-bimodules. Moreover, F^Λ, K_0 and K_1 are in fact $(R(\beta + \alpha_i), R^\Lambda(\beta) \otimes \mathbf{k}[t_i])$-bimodules.

In [27], it was shown that K_0 and K_1 are finitely generated projective right $(R^\Lambda(\beta) \otimes \mathbf{k}[t_i])$-modules. Let $\pi : K_0 \to F^\Lambda$ be the canonical projection and let $P : K_1 \to K_0$ be the right multiplication by $a^\Lambda(x_1)\, \tau_1 \cdots \tau_n$.

The following theorem is one of the main results in [16].

Theorem 4.1 ([16]). *The sequence*

$$0 \longrightarrow K_1 \xrightarrow{P} K_0 \xrightarrow{\pi} F^\Lambda \longrightarrow 0 \tag{4.4}$$

is exact as $(R(\beta+\alpha_i, R^\Lambda(\beta)\otimes \mathbf{k}[t_i])$*-bimodules.*

Hence we get a projective resolution of F^Λ of length 1 as a right $R^\Lambda(\beta)[t_i]$-module. By the following lemma, we conclude that F^Λ is a finitely generated projective right $R^\Lambda(\beta)$-module.

Lemma 4.2 ([16]). Let R be a ring and let $f(t)$ be a monic polynomial in $R[t]$ with coefficients in the center of R.

If an $R[t]$-module M is annihilated by $f(t)$ and has projective dimension ≤ 1, then M is projective as an R-module.

Thus we obtain the following important theorem.

Theorem 4.3 ([16]).

(a) $R^\Lambda(\beta+\alpha_i)\, e(\beta,\alpha_i)$ *is a projective right* $R^\Lambda(\beta)$*-module.*

(b) $e(\beta,\alpha_i)R^\Lambda(\beta+\alpha_i)$ *is a projective left* R^Λ*-module.*

(c) *The functors* E_i^Λ *and* F_i^Λ *are exact.*

(d) *The functors* E_i^Λ *and* F_i^Λ *send finitely generated projective modules to finitely generated projective modules.*

Corollary 4.4 ([16]).

For all $i \in I$ *and* $\beta \in Q_+$*, we have an exact sequence of* $R(\beta+\alpha_i)$*-modules*

$$0 \longrightarrow q^{(\alpha_i, 2\Lambda-\beta)}\overline{F_i}\, M \longrightarrow F_i\, M \longrightarrow F_i^\Lambda\, M \longrightarrow 0$$

which is functorial in $M \in$ *Mod* $R^\Lambda(\beta)$.

To complete the construction of cyclotomic categorification, it remains to show that the adjoint pair $(F_i^\Lambda, E_i^\Lambda)$ gives an sl_2*-categorification* introduced by Chuang-Rouquier [6].

Theorem 4.5 ([16]).

(a) *For* $i \neq j$*, there exists a natural isomorphism*

$$q^{-(\alpha_i,\alpha_j)} F_j^\Lambda E_i^\Lambda \xrightarrow{\sim} E_i^\Lambda F_j^\Lambda.$$

(b) *Let* $\lambda = \Lambda - \beta$ $(\beta \in Q_+)$.

(i) *If* $\langle h_i, \Lambda\rangle \geq 0$*, there exists a natural isomorphism*

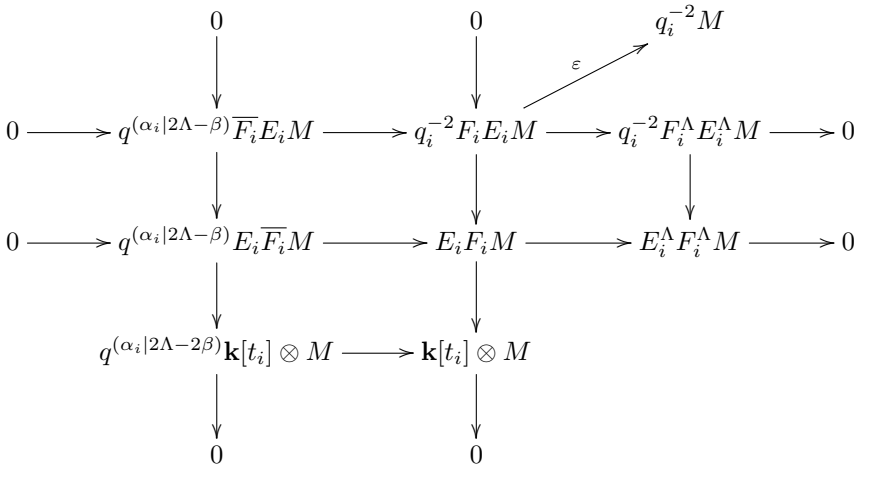
$$q_i^{-2} F_i^\Lambda E_i^\Lambda \oplus \bigoplus_{k=0}^{\langle h_i,\Lambda\rangle - 1} q_i^{2k}\mathbf{1} \xrightarrow{\sim} E_i^\Lambda F_i^\Lambda.$$

(ii) *If* $\langle h_i, \Lambda\rangle \leq 0$, *there exists a natural isomorphism*

$$q_i^{-2}F_i^{\Lambda}E_i^{\Lambda} \xrightarrow{\sim} E_i^{\Lambda}F_i^{\Lambda} \oplus \bigoplus_{k=0}^{-\langle h_i,\lambda\rangle-1} q_i^{2k-2}\mathbf{1}.$$

Proof. We will give a very rough sketch of the proof. The assertion (a) can be proved in a straightforward manner.

To prove (b), note that Theorem 4.1 and Corollary 4.4 yield the following commutative diagram.



Let $A : q^{2(\alpha_i,\Lambda-\beta)}\mathbf{k}[t_i]\otimes R^{\Lambda}(\beta) \longrightarrow \mathbf{k}[t_i]\otimes R^{\Lambda}(\beta)$ be the $R^{\Lambda}(\beta)$-bilinear map given by chasing the diagram. By a detailed analysis of the above commutative diagram at the kernel level, the Snake Lemma gives the following exact sequence of $R^{\Lambda}(\beta)$-bimodules

$$0 \longrightarrow \mathrm{Ker}\, A \longrightarrow q_i^{-2}F_i^{\Lambda}E_i^{\Lambda}R^{\Lambda}(\beta) \longrightarrow E_i^{\Lambda}F_i^{\Lambda}R^{\Lambda}(\beta) \longrightarrow \mathrm{Coker}A \longrightarrow 0.$$

If $\langle h_i, \lambda\rangle \geq 0$, we have $\mathrm{Ker}\, A = 0$, $\bigoplus_{k=0}^{a-1}\mathbf{k}\, t_i^k \otimes R^{\Lambda}(\beta) \xrightarrow{\sim} \mathrm{Coker}A$, and if $\langle h_i, \lambda\rangle \leq 0$, then $\mathrm{Coker}A = 0$, $\mathrm{Ker}(A) = q^{2(\alpha_i|\Lambda-\beta)}\bigoplus_{k=0}^{a-1}\mathbf{k}\, t_i^k \otimes R^{\Lambda}(\beta)$, from which our assertion(b) follows. □

Set

$$K(\mathrm{Proj}\,(R^{\Lambda})) := \bigoplus_{\beta\in Q_+} K(\mathrm{Proj}\, R^{\Lambda}(\beta)),$$
$$K(\mathrm{Rep}\,(R^{\Lambda})) := \bigoplus_{\beta\in Q_+} K(\mathrm{Rep}\, R^{\Lambda}(\beta)).$$

We define the endomorphisms E_i and F_i on $K(\mathrm{Proj}\,(R^{\Lambda}))$ by

$$\mathsf{E}_i = [q_i^{1-\langle h_i,\Lambda-\beta\rangle}E_i^{\Lambda}] : K(\mathrm{Proj}\, R^{\Lambda}(\beta+\alpha_i)) \longrightarrow K(\mathrm{Proj}\, R^{\Lambda}(\beta)),$$
$$\mathsf{F}_i = [F_i^{\Lambda}] : K(\mathrm{Proj}\, R^{\Lambda}(\beta)) \longrightarrow K(\mathrm{Proj}\, R^{\Lambda}(\beta+\alpha_i)).$$

On the other hand, we define E_i and F_i on $K(\text{Rep}\,(R^\Lambda))$ by

$$\mathsf{E}_i = [E_i^\Lambda] : K(\text{Rep}\, R^\Lambda(\beta+\alpha_i)) \longrightarrow K(\text{Rep}\, R^\Lambda(\beta)),$$
$$\mathsf{F}_i = [q_i^{1-\langle h_i, \Lambda-\beta\rangle} F_i^\Lambda] : K(\text{Rep}\, R^\Lambda(\beta)) \longrightarrow K(\text{Rep}\, R^\Lambda(\beta+\alpha_i)).$$

Let K_i be the endomorphism on $K(\text{Proj}\, R^\Lambda(\beta))$ and $K(\text{Rep}\, R^\Lambda(\beta))$ given by the multiplication by $q_i^{\langle h_i, \Lambda-\beta\rangle}$ for each $\beta \in Q_+$. Then we have

$$[\mathsf{E}_i, \mathsf{F}_j] = \delta_{ij} \frac{\mathsf{K}_i - \mathsf{K}_i^{-1}}{q_i - q_i^{-1}} \quad \text{for } i, j \in I.$$

Therefore, we obtain the *cyclotomic categrification theorem* for irreducible highest weight $U_q(\mathfrak{g})$-modules in the category $\mathcal{O}_{\text{int}}$.

Theorem 4.6 ([16]). *For each $\Lambda \in P^+$, there exist $U_{\mathbf{A}}(\mathfrak{g})$-module isomorphisms*

$$K(\textit{Proj}\, R^\Lambda) \xrightarrow{\sim} V_{\mathbf{A}}(\Lambda) \;\textit{ and }\; K(\textit{Rep}\, R^\Lambda) \xrightarrow{\sim} V_{\mathbf{A}}(\Lambda)^\vee.$$

Therefore, for each $\Lambda \in P^+$, we have constructed a 2-category $\mathfrak{R}^\Lambda$ consisting of Proj $(R^\Lambda(\beta))$ $(\beta \in Q_+)$, which gives an integrable 2-representation $\mathfrak{R}^\Lambda$ of $\mathfrak{R}$ in the sense of [32, 33]. (See also [38].)

Remark 4.7. There are several generalizations of Khovanov-Lauda-Rouquier algebras and categorification theorems. In [19, 22, 24], the Khovanov-Lauda-Rouquier algebras associated with Borcherds-Cartan data have been defined and their properties have been investigated including geometric realization, categorification and the connection with crystal bases. In [8, 9, 13, 20, 21, 23, 37], various versions of Khovanov-Lauda-Rouquier *super*-algebras have been introduced and the corresponding *super*-categorifications have been constructed.

5. Quantum affine algebras and R-matrices

In this section, we briefly review the finite dimensional representation theory of quantum affine algebras and the properties of R-matrices (see, for example, [1, 3, 4, 26]).

Let $(A, P, \Pi, P^\vee, \Pi^\vee)$ be a Cartan datum of affine type with $I = \{0, 1, \ldots, n\}$ the index set of simple roots. Let $0 \in I$ be the leftmost vertex in the affine Dynkin diagrams given in [15, Chapter 4]. Set $I_0 = I \setminus \{0\}$. Take relatively prime positive integers c_j's and d_j's $(j \in I)$ such that

$$\sum_{j\in I} c_j a_{ji} = 0, \quad \sum_{j\in I} a_{ij} d_j = 0 \;\text{ for all } i \in I.$$

Then the weight lattice can be written as

$$P = \bigoplus_{i\in I} \mathbf{Z}\Lambda_i \oplus \mathbf{Z}\delta,$$

where $\delta := \sum_{i\in I} d_i\alpha_i \in P$. We also define $c := \sum_{i\in I} c_i h_i \in P^\vee$.

We denote by $\mathfrak{g}$ the affine Kac-Moody algebra associated with $(A, P, P^\vee, \Pi, \Pi^\vee)$ and let $\mathfrak{g}_0$ be the finite dimensional simple Lie algebra inside $\mathfrak{g}$ generated by e_i, f_i, h_i $(i \in I_0)$. We will write W and W_0 for the Weyl group of $\mathfrak{g}$ and $\mathfrak{g}_0$, respectively.

Let $U_q(\mathfrak{g})$ be the corresponding quantum group and let $U'_q(\mathfrak{g})$ be the subalgebra of $U_q(\mathfrak{g})$ generated by e_i, f_i, $K_i^{\pm 1}$ $(i \in I)$. The algebra $U'_q(\mathfrak{g})$ will be called the *quantum affine algebra*.

Set $P_{\mathrm{cl}} := P\big/\mathbf{Z}\delta$ and let $\mathrm{cl} : P \to P_{\mathrm{cl}}$ be the canonical projection. Then we have

$$P_{\mathrm{cl}} = \bigoplus_{i\in I} \mathbf{Z}\mathrm{cl}(\Lambda_i) \ \text{ and } \ P_{\mathrm{cl}}^\vee := \mathrm{Hom}_{\mathbf{Z}}(P_{\mathrm{cl}}, \mathbf{Z}) = \bigoplus_{i\in I} \mathbf{Z}h_i.$$

A $U'_q(\mathfrak{g})$-module V is *integrable* if

(i) $V = \bigoplus_{\lambda\in P_{\mathrm{cl}}} V_\lambda$, where $V_\lambda = \{v \in V \mid K_i v = q_i^{\langle h_i,\lambda\rangle} v \text{ for all } i \in I\}$,

(ii) e_i, f_i $(i \in I)$ are locally nilpotent on V.

We denote by $\mathcal{C}_{\mathrm{int}}$ the category of finite dimensional integrable $U'_q(\mathfrak{g})$-modules.

Let M be an integrable $U'_q(\mathfrak{g})$-module. A weight vector $v \in M_\lambda$ $(\lambda \in P_{\mathrm{cl}})$ is called an *extremal weight vector* if there exists a family of nonzero vectors $\{v_{w\lambda} \mid w \in W\}$ such that

$$v_{s_i\lambda} = \begin{cases} f_i^{(\langle h_i,\lambda\rangle)} v_\lambda & \text{if } \langle h_i,\lambda\rangle \geq 0, \\ e_i^{(-\langle h_i,\lambda\rangle)} v_\lambda & \text{if } \langle h_i,\lambda\rangle \leq 0. \end{cases}$$

Let $P_{\mathrm{cl}}^0 := \{\lambda \in P_{\mathrm{cl}} \mid \langle c,\lambda\rangle = 0\}$ and set

$$\varpi_i := \Lambda_i - c_i\Lambda_0 \ \text{ for } i \in I_0.$$

Then there exists a unique finite dimensional integrable $U'_q(\mathfrak{g})$-module $V(\varpi_i)$ satisfying the following properties:

(i) all the weights of $V(\varpi_i)$ are contained in the convex hull of $W_0\,\mathrm{cl}(\varpi_i)$.

(ii) $\dim V(\varpi_i)_{\mathrm{cl}(\varpi_i)} = 1$,

(iii) for each $\mu \in W_0\,\mathrm{cl}(\varpi_i)$, there exists an extremal weight vector of weight μ,

(iv) $V(\varpi_i)$ is generated by $V(\varpi_i)_{\mathrm{cl}(\varpi_i)}$ as a $U'_q(\mathfrak{g})$-module.

The $U'_q(\mathfrak{g})$-module $V(\varpi_i)$ is called the *fundamental representation of weight* ϖ_i $(i \in I_0)$.

Let M be a $U'_q(\mathfrak{g})$-module. An involution on M is called a *bar involution* if $\overline{a\,v} = \overline{a}\,\overline{v}$ for all $a \in U'_q(\mathfrak{g})$, $v \in M$, where $\overline{e_i} = e_i$, $\overline{f_i} = f_i$, $\overline{K_i} = K_i^{-1}$ $(i \in I)$. A finite $U'_q(\mathfrak{g})$-crystal B is *simple* if (i) $\mathrm{wt}(B) \subset P_{\mathrm{cl}}^0$, (ii) there exists $\lambda \in \mathrm{wt}(B)$ such that $\#(B_\lambda) = 1$, (iii) the weight of every extremal vector of B is contained in $W_0\,\lambda$.

A finite dimensional integrable $U'_q(\mathfrak{g})$-module M is *good* if

(i) M has a bar involution,

(ii) M has a crystal basis with simple crystal,

(iii) M has a lower global basis.

For example, all the fundamental representations $V(\varpi_i)$ $(i \in I_0)$ are good. Every good module is irreducible. For any good module M, there exists an extremal weight vector v of weight λ such that $\mathrm{wt}(U'_q(\mathfrak{g})v) \subset \lambda - \sum_{i\in I_0} \mathbf{Z}_{\geq 0}\mathrm{cl}(\alpha_i)$. Such λ is called a *dominant extremal weight* and v is called a *dominant extremal weight vector*.

Take $\mathbf{k} = \overline{\mathbf{C}(q)} \subset \bigcup_{M>0} \mathbf{C}((q^{1/m}))$. Let $M_{\text{aff}} = \mathbf{k}[z, z^{-1}] \otimes_{\mathbf{k}} M$ be the *affinization* of M. For $v \in M$ and $k \in \mathbf{Z}$, the action of $U_q'(\mathfrak{g})$ on M_{aff} is given by

$$e_i(z^k \otimes v) = \begin{cases} z^{k+1} \otimes e_0 v & \text{if } i = 0, \\ z^k \otimes e_i v & \text{if } i \neq 0, \end{cases}$$

$$f_i(z^k \otimes v) = \begin{cases} z^{k-1} \otimes f_0 v & \text{if } i = 0, \\ z^k \otimes f_i v & \text{if } i \neq 0, \end{cases}$$

$$K_i^{\pm 1}(z^k \otimes v) = q_i^{\pm \langle h_i, \text{wt}(v) \rangle}(z^k \otimes v) \ \ (i \in I).$$

We define a $U_q'(\mathfrak{g})$-module automorphism $z_M : M_{\text{aff}} \to M_{\text{aff}}$ of weight δ by

$$z^k \otimes v \mapsto z^{k+1} \otimes v \ \ (v \in M,\ k \in \mathbf{Z}).$$

Let M_1, M_2 be good $U_q'(\mathfrak{g})$-modules and let u_1, u_2 be dominant extremal weight vectors of M_1 and M_2, respectively. Set $z_1 = z_{M_1}$ and $z_2 = z_{M_2}$. Then there exists a unique $U_q'(\mathfrak{g})$-module homomorphism

$$R^{\text{norm}}_{M_1,M_2}(z_1, z_2) : (M_1)_{\text{aff}} \otimes (M_2)_{\text{aff}} \longrightarrow \mathbf{k}(z_1, z_2) \otimes_{\mathbf{k}[z_1^{\pm 1}, z_2^{\pm 1}]} (M_2)_{\text{aff}} \otimes (M_1)_{\text{aff}}$$

satisfying

$$R^{\text{norm}}_{M_1,M_2}(u_1 \otimes u_2) = u_2 \otimes u_1,$$
$$R^{\text{norm}}_{M_1,M_2} \circ z_1 = z_1 \circ R^{\text{norm}}_{M_1,M_2},$$
$$R^{\text{norm}}_{M_1,M_2} \circ z_2 = z_2 \circ R^{\text{norm}}_{M_1,M_2}.$$

The homomorphism $R^{\text{norm}}_{M_1,M_2}$ is called the *normalized R-matrix of M_1 and M_2*.

Note that $\operatorname{Im} R^{\text{norm}}_{M_1,M_2} \subset \mathbf{k}(z_2/z_1) \otimes_{\mathbf{k}[(z_2/z_1)^{\pm 1}]} (M_2)_{\text{aff}} \otimes (M_1)_{\text{aff}}$. We denote by $d_{M_1,M_2}(u) \in \mathbf{k}[u]$ the monic polynomial of the smallest degree such that

$$\operatorname{Im}\left(d_{M_1,M_2}(z_2/z_1)\, R^{\text{norm}}_{M_1,M_2}\right) \subset (M_2)_{\text{aff}} \otimes (M_1)_{\text{aff}}.$$

The polynomial $d_{M_1,M_2}(u)$ is called the *denominator* of $R^{\text{norm}}_{M_1,M_2}$.

The normalized R-matrix satisfies the Yang-Baxter equation. That is, for $U_q'(\mathfrak{g})$-modules M_1, M_2, M_3, we have

$$\begin{aligned}(R^{\text{norm}}_{M_2,M_3} \otimes 1) \circ (1 \otimes R^{\text{norm}}_{M_1,M_3}) \circ (R^{\text{norm}}_{M_1,M_2} \otimes 1) \\ = (1 \otimes R^{\text{norm}}_{M_1,M_2}) \circ (R^{\text{norm}}_{M_1,M_3} \otimes 1) \circ (1 \otimes R^{\text{norm}}_{M_2,M_3}).\end{aligned}$$

6. Quantum affine Schur-Weyl duality functor

Let $\{V_s \mid s \in \mathcal{S}\}$ be a family of good modules and let v_s be a dominant extremal weight vector in V_s with weight λ_s $(s \in \mathcal{S})$. Take an index set J endowed with the maps $X : J \to \mathbf{k}^\times$ and $s : J \to \mathcal{S}$. For each $i, j \in J$, let

$$\begin{aligned}R^{\text{norm}}_{V_{s(i)},V_{s(j)}}(z_i, z_j) : (V_{s(i)})_{\text{aff}} \otimes (V_{s(j)})_{\text{aff}} \\ \longrightarrow \mathbf{k}(z_i, z_j) \otimes_{\mathbf{k}[z_i^{\pm 1}, z_j^{\pm 1}]} (V_{s(j)})_{\text{aff}} \otimes (V_{s(i)})_{\text{aff}}\end{aligned}$$

be the normalized R-matrix sending $v_{s(i)} \otimes v_{s(j)}$ to $v_{s(j)} \otimes v_{s(i)}$.

Let $d_{V_{s(i)},V_{s(j)}}(z_j/z_i)$ be the denominator of $R^{\mathrm{norm}}_{V_{s(i)},V_{s(j)}}(z_i, z_j)$. We define a quiver Γ^J as follows.

(i) We take J to be the set of vertices.

(ii) We put d_{ij} many arrows from i to j, where d_{ij} the order of zero of $d_{V_{s(i)},V_{s(j)}}(z_j/z_i)$ at $z_j/z_i = X(j)/X(i)$.

Define the Cartan matrix $A^J = (a^J_{ij})_{i,j\in J}$ by

$$a^J_{ij} = \begin{cases} 2 & \text{if } i = j, \\ -d_{ij} - d_{ji} & \text{if } i \neq j. \end{cases} \tag{6.1}$$

Thus we obtain a symmetric Cartan datum $(A^J, P, P^\vee, \Pi, \Pi^\vee)$ associated with Γ^J.

Set

$$\mathsf{Q}^J_{ij}(u, v) := \begin{cases} 0 & \text{if } i = j, \\ (u - v)^{d_{ij}}(v - u)^{d_{ji}} & \text{if } i \neq j. \end{cases} \tag{6.2}$$

We will denote by $R^J(\beta)$ $(\beta \in Q_+)$ the Khovanov-Lauda-Rouquier algebra associated with (A^J, Q^J).

For each $\nu = (\nu_1, \ldots, \nu_n) \in J^\beta$, let $\widehat{\mathcal{O}}_{\mathbf{T}^n,X(\nu)} = \mathbf{k}[[X_1 - X(\nu_1), \ldots, X_n - X(\nu_n)]]$ be the completion of $\mathcal{O}_{\mathbf{T}^n,X(\nu)}$ at $X(\nu) := (X(\nu_1), \ldots, X(\nu_n))$ and set

$$V_\nu := (V_{s(\nu_1)})_{\mathrm{aff}} \otimes \cdots \otimes (V_{s(\nu_n)})_{\mathrm{aff}},$$

where $X_k = z_{V_{s(\nu_k)}}$ $(k = 1, \ldots, n)$.

We define

$$\widehat{V}_\nu := \widehat{\mathcal{O}}_{\mathbf{T}^n,X(\nu)} \otimes_{\mathbf{k}[X_1^{\pm 1},\ldots,X_n^{\pm 1}]} V_\nu \quad \text{and} \quad \widehat{V}^{\otimes\beta} := \bigoplus_{\nu\in J^\beta} \widehat{V}_\nu\, e(\nu).$$

The following proposition is one of the main results of [17].

Proposition 6.1 ([17]). *The space $\widehat{V}^{\otimes\beta}$ is a $(U'_q(\mathfrak{g}), R^J(\beta))$-bimodule.*

Hence we obtain a functor

$$\mathcal{F}_\beta : \mathrm{mod}\,(R^J(\beta)) \longrightarrow \mathrm{mod}\, U'_q(\mathfrak{g})$$

defined by

$$M \longmapsto \widehat{V}^{\otimes\beta} \otimes_{R^J(\beta)} M \qquad \text{for } M \in \mathrm{mod}\,(R^J(\beta)).$$

Write $\mathrm{mod}\,(R^J) := \bigoplus_{\beta\in Q_+} \mathrm{mod}\,(R^J(\beta))$ and set

$$\mathcal{F} = \bigoplus_{\beta\in Q_+} \mathcal{F}_\beta : \mathrm{mod}\,(R^J) \longrightarrow \mathrm{mod}\, U'_q(\mathfrak{g}).$$

The functor $\mathcal{F}$ is called the *quantum affine Schur-Weyl duality functor*. The basic properties of $\mathcal{F}$ are summarized in the following theorem.

Theorem 6.2 ([17]).

(a) *The functor $\mathcal{F}$ restricts to*

$$\mathcal{F} : \mathit{rep}\,(R^J) \longrightarrow \mathcal{C}_{\mathit{int}},$$

where $\mathit{rep}\,(R^J) := \bigoplus_{\beta\in Q_+} \mathit{rep}\,(R^J(\beta))$ and $\mathcal{C}_{\mathit{int}}$ denotes the category of finite dimensional integrable $U_q'(\mathfrak{g})$-modules.

(b) *For each $i \in J$, let $S(\alpha_i) := \mathbf{k}\,u(i)$ be the 1-dimensional graded simple $R^J(1)$-module defined by*

$$e(j)\,u(i) = \delta_{ij}\,u(i), \quad x_1\,u(i) = 0.$$

Then we have

$$\mathcal{F}(S(\alpha_i)) \cong (V_{s(i)})_{X(i)},$$

where $(V_{s(i)})_{X(i)}$ is the evaluation module of $V_{s(i)}$ at $z_i = X(i)$.

(c) *$\mathcal{F}$ is a tensor functor; i.e., there exists a canonical $U_q'(\mathfrak{g})$-module isomorphisms*

$$\mathcal{F}(R^J(0)) \cong \mathbf{k}, \quad \mathcal{F}(M \circ N) \cong \mathcal{F}(M) \otimes \mathcal{F}(N)$$

for $M \in \mathit{rep}\,(R^J(m))$, $N \in \mathit{rep}\,(R^J(n))$.

(d) *If the quiver Γ^J is of type A_n $(n \geq 1)$, D_n $(n \geq 4)$, E_6, E_7, E_8, then $\mathcal{F}$ is exact.*

7. The Categories $\mathcal{T}_N$ and $\mathcal{C}_N$

Take $\mathbf{k} = \mathbf{C}(q)$. Let $\mathfrak{g} = A_{N-1}^{(1)}$ be the affine Kac-Moody algebra of type $A_{N-1}^{(1)}$ and let $V = V(\varpi_1)$ be the fundamental representation of $U_q'(A_{N-1}^{(1)})$ of weight ϖ_1.

Set $\mathcal{S} = \{V\}$, $J = \mathbf{Z}$ and let $X : \mathbf{Z} \to \mathbf{k}^\times$ be the map given by $j \mapsto q^{2j}$ $(j \in \mathbf{Z})$. Then the normalized R-matrix $R_{V,V}^{\mathrm{norm}} : V_{z_1} \otimes V_{z_2} \longrightarrow V_{z_2} \otimes V_{z_1}$ has the denominator $d_{V,V}(z_2/z_1) = z_2/z_1 - q^2$. Hence we have

$$d_{ij} = \begin{cases} 1 & \text{if } j = i+1, \\ 0 & \text{otehrwise,} \end{cases}$$

which yields the quiver Γ^J of type A_∞. Take $P_J = \bigoplus_{k\in\mathbf{Z}} \mathbf{Z}\,\varepsilon_k$ to be the weight lattice and let $Q^J = \bigoplus_{k\in\mathbf{Z}} \mathbf{Z}\,(\varepsilon_k - \varepsilon_{k+1})$ be the root lattice. There is a bilinear form on P_J given by $(\varepsilon_a, \varepsilon_b) = \delta_{ab}$.

For $a \leq b$, let $l = b - a + 1$ and let $L(a,b) := \mathbf{k}\,u(a,b)$ be the 1-dimensional graded simple $R^J(\varepsilon_a - \varepsilon_{b+1})$-module defined by

$$x_s\,u(a,b) = 0, \quad \tau_t\,u(a,b) = 0 \ \ (1 \leq s \leq l,\ 1 \leq t \leq l-1),$$
$$e(\nu)\,u(a,b) = \begin{cases} u(a,b) & \text{if } \nu = (a, a+1, \ldots, b), \\ 0 & \text{otherwise.} \end{cases}$$

Then we have

$$\mathcal{F}(L(a,b)) \cong \begin{cases} V(\varpi_l)_{(-q)^{a+b}} & \text{if } 0 \leq l \leq N, \\ 0 & \text{if } l > N, \end{cases}$$

where $\mathcal{F} : \mathrm{mod}\,(R^J(l)) \longrightarrow \mathrm{mod}\, U_q'(\mathfrak{g})$ is the quantum affine Schur-Weyl duality functor.

Recall that $\mathrm{Rep}\,(R^J(l))$ is the category of finite dimensional graded $R^J(l)$-modules. Set $\mathcal{R} := \bigoplus_{l\geq 0} \mathrm{Rep}\,(R^J(l))$ and let $\mathcal{S}$ be the Smallest Serre subcategory of $\mathcal{R}$ such that

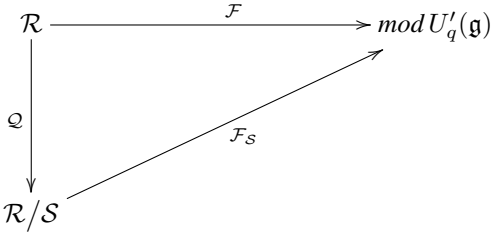
(i) $\mathcal{S}$ contains $L(a, a+N)$ for all $a \in \mathbf{Z}$,

(ii) $X \circ Y, Y \circ X \in \mathcal{S}$ for all $X \in \mathcal{R}, Y \in \mathcal{S}$.

Take the quotient category $\mathcal{R}/\mathcal{S}$ and let $\mathcal{Q} : \mathcal{R} \to \mathcal{R}/\mathcal{S}$ be the canonical projection functor. Then we have:

Proposition 7.1 ([17]).

(a) *The functor $\mathcal{F}$ factors through $\mathcal{R}/\mathcal{S}$. That is, there is a canonical functor $\mathcal{F}_{\mathcal{S}} : \mathcal{R}/\mathcal{S} \longrightarrow mod\, U_q'(\mathfrak{g})$ such that the following diagram is commutative.*



(b) *The functor $\mathcal{F}_{\mathcal{S}}$ sends a simple object in $\mathcal{R}/\mathcal{S}$ to a simple object in mod $U_q'(\mathfrak{g})$.*

Let $L_a := L(a, a+N-1)$ and $u_a := u(a, a+N-1) \in L_a$ $(a \in \mathbf{Z})$. Then $\mathcal{F}(L_a)$ is isomorphic to the trivial representation of $U_q'(\mathfrak{g})$. Let $S : P_J \to P_J$ $(\varepsilon_a \mapsto \varepsilon_{a+N-1})$ be an automorphism on P_J and let B be the bilinear form on P_J given by

$$B(x,y) := -\sum_{k>0}(S^k x, y) \ \text{ for all } x, y \in P_J.$$

We define a new tensor product $\star$ on $\mathcal{R}/\mathcal{S}$ by

$$X \star Y := q^{B(\alpha,\beta)}\, X \circ Y \quad \text{for } X \in (\mathcal{R}/\mathcal{S})_\alpha,\ Y \in (\mathcal{R}/\mathcal{S})_\beta.$$

Then there exists an isomorphism $R(a)(X) : L_a \star X \xrightarrow{\sim} X \star L_a$ which is functorial in $X \in \mathcal{R}/\mathcal{S}$. Moreover, the isomorphisms

$$R_a(L_b) : L_a \star L_b \xrightarrow{\sim} L_b \star L_a \ \text{ and } \ R_b(L_a) : L_b \star L_a \xrightarrow{\sim} L_a \star L_b$$

are inverses to each other. One can verify that $\{L_a, R_a(L_b) \mid a, b \in \mathbf{Z}\}$ forms a commuting family of central objects in $(\mathcal{R}/\mathcal{S}, \star)$ (see [17, Appendix A.6]).

Let $\mathcal{T}_N' := (\mathcal{R}/\mathcal{S})[L_a^{\star -1} \mid a \in \mathbf{Z}]$ be the localization of $\mathcal{R}/\mathcal{S}$ by this commuting family and define

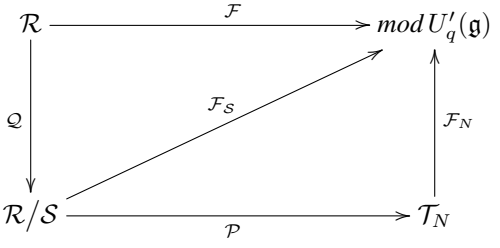
$$\mathcal{T}_N := (\mathcal{R}/\mathcal{S})[L_a \cong \mathbf{1} \mid a \in \mathbf{Z}].$$

We denote by $\mathcal{P} : \mathcal{R}/\mathcal{S} \to \mathcal{T}_N$ the canonical functor.

Theorem 7.2 ([17]).

(a) *The category $\mathcal{T}_N$ is a rigid tensor category ; i.e., every object in $\mathcal{T}_N$ has a right dual and a left dual.*

(b) *The functor $\mathcal{F}_{\mathcal{S}}$ factors through $\mathcal{T}_N$. That is, there exists a canonical functor $\mathcal{F}_N : \mathcal{T}_N \longrightarrow mod\, U_q'(\mathfrak{g})$ such that the following diagram is commutative.*



(c) *The functor $\mathcal{F}_N$ is exact and sends a simple object in $\mathcal{T}_N$ to a simple object in $mod\, U_q'(\mathfrak{g})$.*

Let $\mathcal{C}_N$ be the smallest full subcategory of $\mathcal{C}_{\text{int}}$ consisting of $U_q'(\mathfrak{g})$-modules M such that every composition factor of M appears as a composition factor of a tensor product of modules of the form $V(\varpi_1)_{q^{2j}}$ $(j \in \mathbf{Z})$. Thus $\mathcal{C}_N$ is an abelian category containing all $U_q'(\mathfrak{g})$-modules $V(\varpi_i)_{(-q)^{i+2a-1}}$ for $1 \le i \le N-1$ and $a \in \mathbf{Z}$. Moreover, $\mathcal{C}_N$ is stable under taking submodules, quotients, extensions and tensor products. Hence $\mathcal{F}_N$ restricts to an exact functor

$$\mathcal{F}_N : \mathcal{T}_N \longrightarrow \mathcal{C}_N.$$

Let $Irr\,(\mathcal{T}_N)$ (respectively, $Irr\,(\mathcal{C}_N)$) denote the set of isomorphism classes of simple objects in $\mathcal{T}_N$ (respectively, in $\mathcal{C}_N$). Define an equivalence relation on $Irr\,(\mathcal{T}_N)$ by setting $X \sim Y$ if and only if $X \xrightarrow{\sim} q^m Y$ for some $m \in \mathbf{Z}$. Set

$$Irr\,(\mathcal{T}_N)|_{q=1} := Irr\,(\mathcal{T}_N)\big/ \sim .$$

Theorem 7.3 ([17]).

(a) *The functor $\mathcal{F}_N$ induces a bijection between $Irr\,(\mathcal{T}_N)|_{q=1}$ and $Irr\,(\mathcal{C}_N)$.*

(b) *The exact functor $\mathcal{F}_N$ induces a ring isomorphism*

$$\phi_N : K(\mathcal{T}_N)|_{q=1} \xrightarrow{\sim} K(\mathcal{C}_N).$$

Therefore, the category $\mathcal{T}_N$ provides a graded lifting of $\mathcal{C}_N$ as a rigid tensor category.

8. The category $\mathcal{C}_Q$

In this section, we deal with affine Kac-Moody algebras $\mathfrak{g}$ of type $A_n^{(1)}$ $(n \ge 1)$, $D_n^{(1)}$ $(n \ge 4)$, $E_6^{(1)}$, $E_7^{(1)}$, $E_8^{(1)}$. Let $I = \{0, 1, \ldots, n\}$ be the index set for the simple roots of $\mathfrak{g}$ and set $I_0 = I \setminus \{0\}$. We denote by $\mathfrak{g}_0$ the finite dimensional simple Lie subalgebra of $\mathfrak{g}$

generated by e_i, f_i, h_i $(i \in I_0)$. Thus $\mathfrak{g}_0$ is of type A_n $(n \geq 1)$, D_n $(n \geq 4)$, E_6, E_7, E_8, respectively.

Let Q be the Dynkin quiver associated with $\mathfrak{g}_0$. A function $\xi : I_0 \to \mathbf{Z}$ is called a *height function* if $\xi_j = \xi_i - 1$ whenever we have an arrow $i \to j$.

Set

$$\widehat{I_0} := \{(i,p) \in I_0 \times \mathbf{Z} \mid p - \xi_i \in 2\mathbf{Z}\}.$$

The *repetition quiver* $\widehat{Q}$ is defined as follows.

(i) We take $\widehat{I_0}$ to be the set of vertices.

(ii) The arrows are given by

$$(i,p) \to (j,p+1), \quad (j,q) \to (i,q+1)$$

for all arrows $i \to j$ and $p, q \in Z$ such that $p - \xi_i \in \mathbf{Z}$, $q - \xi_j \in \mathbf{Z}$.

For all $i \in I_0$, let $s_i(Q)$ be the quiver obtained from Q by reversing the arrows that touch i. A reduced expression $w = s_{i_1} \cdots s_{i_l} \in W_0$ is said to be *adapted to* Q if i_k is the source of $s_{i_{k-1}} \cdots s_{i_1}(Q)$ for all $1 \leq k \leq l$. It is known that there is a unique Coxeter element $\tau \in W_0$ which is adaped to Q.

Set $\widehat{\Delta} := \Delta_+ \times \mathbf{Z}$, where Δ_+ is the set of positive roots of $\mathfrak{g}_0$. For each $i \in I_0$, let $B(i) := \{j \in I_0 \mid \text{ there is a path from } j \text{ to } i\}$ and define $\gamma_i := \sum_{j \in B(i)} \alpha_j$. We define a bijection $\phi : \widehat{I_0} \to \widehat{\Delta}$ inductively as follows.

(1) We begin with $\phi(i, \xi_i) := (\gamma_i, 0)$.

(2) If $\phi(i,p) = (\beta, j)$ is given, then we define

- $\phi(i, p-2) := (\tau(\beta), j)$ if $\tau(\beta) \in \Delta_+$,
- $\phi(i, p-2) := (-\tau(\beta), j-1)$ if $\tau(\beta) \in \Delta_-$,
- $\phi(i, p+2) := (\tau^{-1}(\beta), j)$ if $\tau^{-1}(\beta) \in \Delta_+$,
- $\phi(i, p+2) := (-\tau^{-1}(\beta), j+1)$ if $\tau^{-1}(\beta) \in \Delta_-$.

Let w_0 be the longest element of W_0 and fix a reduced expression $w_0 = s_{i_1} \cdots s_{i_l}$ which is adapted to Q. Set

$$J := \{(i,p) \in \widehat{I_0} \mid \phi(i,p) \in \Pi_0 \times \{0\}\},$$

where Π_0 denotes the set of simple roots of $\mathfrak{g}_0$. Take the maps $X : J \to \mathbf{k}^\times$ and $s : J \to \{V(\varpi_i) \mid i \in I_0\}$ defined by

$$X(i,p) = (-q)^{p+h}, \quad s(i,p) = V(\varpi_i) \quad \text{for } (i,p) \in J,$$

where h is the Coxeter number of $\mathfrak{g}_0$.

Theorem 8.1 ([18]). *For any $(i,p), (j,r) \in J$, assume that the normalized R-matrix*

$$R^{norm}_{V(\varpi_i), V(\varpi_j)}(z)$$

has a pole at $z = (-q)^{r-p}$ of order at most 1. Then the following statements hold.

(a) *The Cartan matrix A^J associated with (J, X, s) is of type $\mathfrak{g}_0$.*

(b) *There exists a quiver isomorphism*

$$Q^{rev} \xrightarrow{\sim} \Gamma^J, \quad k \mapsto \phi^{-1}(\alpha_k, 0) \ \ (k \in I_0),$$

where Q^{rev} is the reverse quiver of Q.

(c) *The functor $\mathcal{F} : \mathrm{rep}\,(R^J) \to \mathcal{C}_{int}$ is exact and*

$$\mathcal{F}(S(\alpha_k)) \cong V(\varpi_i)_{(-q)^{p+h}},$$

where $\phi(i,p) = (\alpha_k, 0)$.

Remark 8.2. When $\mathfrak{g}$ is of type $A_n^{(1)}$ $(n \geq 1)$ or $D_n^{(1)}$ $(n \geq 4)$, then the condition in Theorem 8.1 is satisfied. We conjecture that the same is true of $\mathfrak{g} = E_6^{(1)}$, $E_7^{(1)}$, $E_8^{(1)}$.

We now bring out the main subject of our interest in this section. Let $\mathcal{C}_Q$ be the smallest abelian full subcategory of $\mathcal{C}_{\text{int}}$ such that

(i) $\mathcal{C}_Q$ is stable under taking submodules, subquotients, direct sums and tensor products,

(ii) $\mathcal{C}_Q$ contains all $U_q'(\mathfrak{g})$-modules of the form $V(\beta)_z \big/ (z-1)^l\, V(\beta)_z$ $(\beta \in \Delta_+,\, l \geq 1)$. Here, $V(\beta) = V(\varpi_i)_{(-q)^{p+h}}$ such that $\phi(i,p) = (\beta, 0)$.

Let $\mathrm{Nilrep}\,(R^J(\beta))$ be the category of finite dimensional ungraded $R^J(\beta)$-modules such that all x_k's act nilpotently and set

$$\mathrm{Nilrep}\,(R^J) := \bigoplus_{\beta \in Q_+} \mathrm{Nilrep}\,(R^J(\beta)).$$

Note that every module in $\mathrm{Nilrep}\,(R^J)$ can be obtained by taking submodules, subquotients, direct sums and convolution products of $P(\alpha_k) \big/ (x_1^l)$ $(k \in I_0, l \geq 0)$, where $P(\alpha_k)$ is the projective cover of $S(\alpha_k)$. Thus we obtain a well-defined functor

$$\mathcal{F} : \mathrm{Nilrep}\,(R^J) \longrightarrow \mathcal{C}_Q,$$

which satisfies the following properties.

Theorem 8.3 ([17, 18]).

(a) *$\mathcal{F}$ is an exact tensor functor.*

(b) *$\mathcal{F}$ sends a simple object in $\mathrm{Nilrep}\,(R^J)$ to a simple object in $\mathcal{C}_Q$.*

It is straightforward to verify that $\mathcal{F}$ is a faithful functor. Since $\mathcal{C}_Q$ is the smallest abelian full subcategory of $\mathcal{C}_{\text{int}}$ satisfying the conditions (i) and (ii) given above, we conjecture that $\mathcal{F}$ is full and defines an equivalence of categories.

Remark 8.4. Note that our general approach to quantum affine Schur-Weyl duality applies to *all* quantum affine algebras and *any* choice of good modules. Thus we expect there are a lot more exciting developments to come. It is an interesting question whether our general construction can shed a new light on the hidden connection between quantum affine algebras and cluster algebras (cf. [12]).

Finitely Generated Groups with Controlled Pro-algebraic Completions

Martin Kassabov

Abstract. We construct finitely generated groups whose pro-algebraic completions are isomorphic to the product of the pro-algebraic completions of groups like $\mathrm{SL}_n(\mathbb{Z})$ and $\mathrm{SL}_n(\mathbb{Z}[x])$ for different n. This leads to examples of groups where the dimensions of the character varieties grow as any function with growth between linear and quadratic.

Mathematics Subject Classification (2010). Primary 20F69; Secondary 19C99, 20B30, 20E18, 20G05, 20G30, 20K25

Keywords. Pro-algebraic completion of groups, representation varieties, dimensions of character varieties.

1. Introduction

Let Γ be a finitely generated group, and for every positive integer d we consider the representations of Γ of dimension d over a fixed algebraically closed field $\mathbb{K}$ of characteristic 0. The set of these representations $R_\Gamma(d) = \mathrm{Hom}(\Gamma, \mathrm{GL}_d(\mathbb{K}))$ has a natural structure of an affine algebraic variety defined over $\mathbb{Q}$. There is a natural adjoint action of $\mathrm{GL}_d(\mathbb{K})$ on $R_\Gamma(d)$ and one can form the (categorical) quotient $X_\Gamma(d) = R_\Gamma(d)/\mathrm{GL}_d(\mathbb{K})$, which is also an algebraic variety defined over $\mathbb{Q}$. It is well-known that the points of this variety parameterize the isomorphism classes of completely reducible representations of Γ [14, 19].

We are mainly interested in the dimensions of these varieties $\varkappa_\Gamma(n) = \dim X_\Gamma(d)$. The group Γ is called rigid if $\varkappa_\Gamma(d) = 0$ for all d. If Γ is finitely generated and not rigid then $\varkappa_\Gamma(d)$ is bounded below by a linear function [18] and above by a quadratic function. One of our main results shows that any function satisfying a mild additional condition is the growth function of the dimension of the character varieties for some finitely generated group.

Theorem 1.1. *Let $f : \mathbb{N} \to \mathbb{N}$ be a function such that $f(d)/d$ is non-decreasing and $f(d) \leq d(d-1)/2$. Then there exists a finitely generated group Γ_f such that $\dim X_{\Gamma_f}(d) = f(d)$ for all $d \geq 3$, where $X_{\Gamma_f}(d)$ denotes the character variety of Γ_f.*

It can be shown that the groups Γ_f constructed in Theorem 1.1 are not linear. It is not known if there exists a linear group with growth of the dimensions of the character varieties strictly between linear and quadratic. The above theorem is actually an application of the following:

Proceedings of the International Congress of Mathematicians, Seoul, 2014

Theorem 1.2. *There exists a finitely generated group* Γ *inside the infinite product* $\prod_{n\geq 3} \mathrm{SL}_n(\mathbb{Z})$ *such that* Γ *contains the direct sum* $\bigoplus_{n\geq 3} \mathrm{SL}_n(\mathbb{Z})$ *and any finite dimensional representation of* Γ *factors through one of finite products* $\prod_{n\geq 3}^{d} \mathrm{SL}_n(\mathbb{Z})$ *for some* d.

The group constructed in Theorem 1.2 is rigid[1] [2], i.e., its character variety is discrete and has only finitely many isomorphism types of representations of each degree. This is almost an immediate consequence of the theorem and the rigidity of the groups $\mathrm{SL}_n(\mathbb{Z})$ for $n \geq 3$. However this group is not super-rigid.

The idea behind this result is to construct groups with controlled pro-algebraic completion. The *pro-algebraic completion*[2] $\overline{\Gamma}$ of an affine pro-algebraic group is an inverse limit of algebraic groups which captures all finite dimensional representations of the group.

The condition that all finite dimensional representations factor through finite products is equivalent to saying that the pro-algebraic completion is isomorphic to a certain infinite product, which can be captured using the language of "congruence" kernels.

The inclusion $\Gamma \hookrightarrow \prod_{n\geq 3} \mathrm{SL}_n(\mathbb{Z})$ induces a map between the pro-algebraic completions

$$\iota : \overline{\Gamma} \to \prod_{n\geq 3} \overline{\mathrm{SL}_n(\mathbb{Z})}$$

and the property that Γ surjects onto the finite products implies that ι is surjective. In general such map is not injective because Γ might have finite dimensional representations which do not extend to the infinite product (equivalently are not continuous with respect to the topology on Γ induced from the product). In general the kernel of ι is called the "congruence" kernel.[3] The condition that all finite dimensional representations factor through finite products is exactly the same as the triviality of $\ker \iota$, i.e., Theorem 1.2 gives that ι is an isomorphism.

Theorem 1.2 also provides constructions of finitely generated rigid groups such that the connected component of the pro-algebraic completion is any infinite product $\prod_i S_i$ of simple algebraic groups S_i over $\mathbb{K}$ such that the $\mathbb{Q}$-ranks of S_i are strictly increasing.

The idea behind the proofs of these theorems is first to produce rings with controlled pro-algebraic completions. It is not clear if there is an analog of Theorem 1.2 for rings, however it is relatively easy to construct a ring $\boldsymbol{R}$ with relatively small congruence kernel. Then, one can form the Steinberg groups $\mathrm{St}_n(\boldsymbol{R})$ and it can be shown that they also have relatively small completion. The final step of the construction is to use two copies of the group $\mathrm{St}_n(\boldsymbol{R})$ satisfying addition relations which can be used to kill the congruence kernels. The step significantly uses that the completion turns out to be not only a normal subgroup but also a quotient of the pro-algebraic completion of $\mathrm{St}_n(\boldsymbol{R})$ (see Lemma 3.6).

The groups in Theorem 1.1 are subgroups inside $\prod_{n\geq 3} \mathrm{SL}_n(\mathbb{Z}[x_1, \ldots, x_{f(n)}])$ which are generated by two copies of the group Γ from Theorem 1.2. The triviality of the congruence kernel is an easy consequence of the same property for the group Γ, which reduces Theorem 1.1 to computing the dimensions of the character varieties for groups like $\mathrm{SL}_n(\mathbb{Z}[x_1, \ldots, x_k])$ (see Lemma 2.15).

[1] Also called representation rigid or SS-rigid.

[2] Sometimes the pro-algebriac completion is called Hochschild-Mostow group.

[3] The terminology of congruence kernel originated in the study of finite images of arithmetic groups.

2. Pro-algebraic completions of groups and rings

2.1. Pro-algebraic completions of groups. The pro-algebraic completion is an affine pro-algebric group:

Definition 2.1. An affine pro-algebraic group $\mathcal{G}$ is an inverse limit $\varprojlim G_i$ of affine algebraic groups G_i defined over the field $\mathbb{K}$. A subgroup $\Gamma \subset \mathcal{G}$ is called Zariski dense if the image of Γ in any G_i is Zariski dense.

There is a corresponding notion of morphism between pro-algebraic groups. Since the category of pro-algebraic groups is closed under inverse limits one can define the pro-algebraic completion as an universal object:

Definition 2.2. A pro-algebraic completion for Γ relative to the field $\mathbb{K}$ is a pair $(\overline{\Gamma}, i)$ consisting of a pro-algebraic group $\overline{\Gamma}$ and a homomorphism $i : \Gamma \to \overline{\Gamma}$ such that for any pro-algebraic group $\mathcal{G}$ and any homomorphism $i' : \Gamma \to \mathcal{G}$ there is a unique morphism of pro-algebraic group $\pi : \overline{\Gamma} \to \mathcal{G}$ such that $i' = \pi \circ i$.

It is immediate from the definition that a pro-algebraic completion is unique up to a unique isomorphism. Moreover the image of Γ under i is Zariski dense in $\overline{\Gamma}$. It is also easy to see that it is enough for a pro-algebraic completion for Γ only to satisfy the definition for the case that $\mathcal{G}$ is an affine algebraic group.

A more constructive way of describing the pro-algebraic completion is as an inverse limit

$$\overline{\Gamma} = \varprojlim_{\rho} \overline{\rho(\Gamma)}^{\mathrm{Zar}},$$

taken over all finite dimensional representations $\rho : \Gamma \to \mathrm{GL}_N(\mathbb{K})$ for some N, where $\overline{H}^{\mathrm{Zar}}$ denotes the Zariski closure of the subgroup H. Equivalently $\overline{\Gamma}$ is the Zariski closure of the image of Γ in the product

$$P = \prod_{\rho} \{\mathrm{GL}_N(\mathbb{K}) \mid \rho : \Gamma \to \mathrm{GL}_N(\mathbb{K})\}$$

under the diagonal homomorphism $\Gamma \to P$ induced by the ρ's.

Since any finite quotient of Γ can be considered as a finite dimensional representation with a finite image there is a canonical surjective map $\overline{\Gamma} \to \overline{\Gamma}^{\mathrm{f}}$ from the pro-algebraic completion to the pro-finite completion. The kernel of this map is the connected component $\overline{\Gamma}^0$ of the pro-algebraic group $\overline{\Gamma}$. The following result is well known:

Lemma 2.3 ([2]). *The pro-algebraic completion splits as semi-direct product*

$$\overline{\Gamma} = \overline{\Gamma}^0 \rtimes \overline{\Gamma}^{\mathrm{f}},$$

i.e., there exists a section $\overline{\Gamma}^{\mathrm{f}} \hookrightarrow \overline{\Gamma}$ *for the projection* $\overline{\Gamma} \to \overline{\Gamma}^{\mathrm{f}}$.

Remark 2.4. The pro-algebraic completion significantly depends on the characteristic of the field $\mathbb{K}$, for example if $\mathrm{char}\,\mathbb{K} > 0$ it is known that any map from $\mathrm{SL}_n(\mathbb{Z})$ to $\mathrm{GL}_N(\mathbb{K})$ has finite image, therefore the pro-algebraic completion coincides with the pro-finite completion. However, this is not the case in characteristic 0, see Example 2.14.

2.2. Algebraic rings. In this section, we present a quick survey of some basic properties of algebraic rings. The notion of algebraic rings was introduced by M. Greenberg [6, 7][4] and was used by Kassabov-Sapir [11] and I. Rapinchuk [17] to study representations of split Chevalley groups with coefficients in finitely generated rings and the Borel-Tits conjecture about abstract homomorphism between algebraic groups [4].

Definition 2.5. Let $\mathbb{K}$ be a fixed algebraically closed field. An algebraic ring over $\mathbb{K}$ is an affine algebraic variety $\mathcal{A}$ defined over $\mathbb{K}$ with two regular maps $\boldsymbol{\alpha}, \boldsymbol{\mu} : \mathcal{A} \times \mathcal{A} \to \mathcal{A}$ called 'addition' and 'multiplication' which define a ring structure (with 1) on the set $\mathcal{A}$. These maps are required to satisfy the standard axioms for associative ring.

The following result classifies algebraic rings over algebraically closed fields of characteristic 0.

Theorem 2.6 ([6, 11, 17]). *Let $\mathcal{A}$ be an associative algebraic ring with 1 over an algebraically closed field $\mathbb{K}$ of characteristic 0. Then the connected component $\mathcal{A}^0$ containing the element 0 is an ideal of finite index in $\mathcal{A}$, which is also a subring with 1 and $\mathcal{A}$ is a split extension*

$$0 \to \mathcal{A}^0 \to \mathcal{A} \to C \to 0$$

for some finite ring C. The additive group of $\mathcal{A}$ decomposes as direct sum $\mathcal{A} \simeq \mathcal{A}^0 \oplus C$, however this need not be a direct sum of rings since the finite ring C can act nontrivially on $\mathcal{A}^0$. Moreover the subring $\mathcal{A}^0$ is isomorphic as an algebraic ring to some finite dimensional algebra over $\mathbb{K}$. In particular the subring $\mathcal{A}^0$ satisfies the identity

$$s_M(x_1, \dots x_M) := \sum_{\sigma \in \mathrm{Sym}(M)} (-1)^\sigma x_{\sigma(1)} x_{\sigma(2)} \dots x_{\sigma(M)} = 0.$$

for any integer $M > \dim \mathcal{A}$.

Outline of the proof. The connected component $\mathcal{A}^0$ is a two-sided ideal in the ring $\mathcal{A}$. Under addition $\mathcal{A}^0$ is a connected commutative algebraic group and therefore breaks up into a product of semi-simple part and unipotent part. The multiplication of $\mathcal{A}$ gives that this group has many algebraic endomorphisms, which can be used to deduce that the semi-simple part is trivial. In the case of characteristic 0 any commutative unipotent group is isomorphic to the affine space $\mathbb{K}^n$ and it can be shown that the multiplication map $\boldsymbol{\mu}$ becomes bilinear, which turns $\mathcal{A}^0$ into an algebra over $\mathbb{K}$. The expression $s_M(x_1, \dots x_M)$ is an identity in the ring $\mathcal{A}^0$ because it holds in any $\mathbb{K}$ algebra of dimension less than M.

The splitting of the exact sequence is also a consequence of the splitting of the commutative algebraic group $\mathcal{A}$ into semi-simple part C and unipotent part $\mathcal{A}^0$. As an one-sided ideal $\mathcal{A}^0$ is finitely generated,[5] which can be used to deduce that the restriction of the multiplication map $\boldsymbol{\mu} : \mathcal{A}^0 \times \mathcal{A}^0 \to \mathcal{A}^0$ is surjective. The surjectivity of this map implies that $\mathcal{A}^0$ is a subring with an identity.

For complete proofs see [6] (in the connected case), [17] (in the commutative case), and [11] (in the case $\mathbb{K} = \mathbb{C}$). □

Remark 2.7. Theorem 2.6 does not hold over fields of positive characteristic, for example the ring of truncated Witt vectors in characteristic $p > 0$ have the structure of a connected

[4] Greenberg only considered connected algebraic rings.

[5] This statement might not be true if the field $\mathbb{K}$ has positive characteristic.

algebraic ring over $\mathbb{K}$ which is not isomorphic to an algebra over $\mathbb{K}$. It seems plausible that connected algebraic rings are isomorphic to quotients of algebras over the truncated Witt vectors (this is proven in the case of connected commutative rings in [6]).

Using the notion of algebraic ring one can define pro-algebraic rings and pro-algebraic completions.

Definition 2.8. Let R be a finitely generated ring. The pro-algebraic completion $\overline{R}$ of the ring R is the inverse limit of the images of all Zariski dense homomorphisms $\rho : R \to \mathcal{A}$ where $\mathcal{A}$ is algebraic ring.

Any finite ring can be given the structure of algebraic ring, i.e, the pro-algebraic completion captures all finite quotations of the ring R, therefore there exists a canonical projection from the pro-algebraic completion $\overline{R}$ to the pro-finite completion $\overline{R}^{\mathrm{f}}$. In fact the kernel of this projection is the connected component of 0 in the ring $\overline{R}$. There is also a splitting $\overline{R} = \overline{R}^0 \oplus \overline{R}^{\mathrm{f}}$ as additive groups (in general $\overline{R}^{\mathrm{f}}$ is not an ideal in $\overline{R}$).

Example 2.9. The pro-algebraic completion of the ring $\mathrm{Mat}_n(\mathbb{Z})$ is isomorphic to

$$\overline{\mathrm{Mat}_n(\mathbb{Z})} \simeq \begin{cases} \mathrm{Mat}_n(\overline{\mathbb{Z}}^{\mathrm{f}}) \oplus \mathrm{Mat}_n(\mathbb{K}) & \text{if } \operatorname{char}\mathbb{K} = 0 \\ \mathrm{Mat}_n(\overline{\mathbb{Z}}^{\mathrm{f}}) & \text{if } \operatorname{char}\mathbb{K} > 0, \end{cases}$$

where $\overline{\mathbb{Z}}^{\mathrm{f}}$ is the pro-finite completion of the ring $\mathbb{Z}$.

Example 2.10. The pro-algebraic completion of $\mathbb{Z}[x_1, \ldots, x_k]$ is a very large ring: its connected component is product of the formal completions of the stalks $\mathcal{O}_{\hat{x}}$ over the points in the affine space $\mathbb{A}^k$ and its semi-simple part is just the product of copies of the field $\mathbb{K}$ indexed by the points of $\mathbb{A}^k$, provided that the characteristic of $\mathbb{K}$ is 0.

2.3. The Steinberg group and pro-algebraic completions. By $\mathrm{Mat}_n(R)$ we denote the ring of $n \times n$ matrices over a ring R. The elementary matrix in $\mathrm{Mat}_n(R)$ with entry $r \in R$ in position (i, j) and 0 elsewhere is $e_{i,j}(r)$, for simplicity we will write $e_{i,j} := e_{i,j}(1)$. If $i \neq j$ then the matrix $E_{i,j}(r) := \mathrm{Id} + e_{i,j}(r)$ is invertible.

Definition 2.11. The group $\mathrm{EL}_n(R)$ is defined as the subgroup of the multiplicative group $\mathrm{Mat}_n(R)^*$ generated by elementary matrices $E_{i,j}(r)$. Similarly the Steinberg group $\mathrm{St}_n(R)$ is the group generated by elements $x_{i,j}(r)$ subject to the relations:

$$\begin{aligned} x_{i,j}(r_1)x_{i,j}(r_2) &= x_{i,j}(r_1 + r_2), \\ [x_{i,j}(r_1), x_{j,k}(r_2)] &= x_{i,k}(r_1 r_2), \\ [x_{i,j}(r_1), x_{p,q}(r_2)] &= 1. \end{aligned}$$

There is a surjective homomorphism $\mathrm{St}_n(R) \to \mathrm{EL}_n(R)$ sending $x_{i,j}(r) \to E_{i,j}(r)$, because $E_{ij}(r)$ satisfy the above relations. The kernel of this homomorphism is denoted by $K_{2,n}(R)$ and often is a central subgroup of $\mathrm{St}_n(R)$ (see [9, 16]).

It is well-known and easy to show that if the ring R is finitely generated and $n \geq 3$ then the groups $\mathrm{St}_n(R)$ and $\mathrm{EL}_n(R)$ are finitely generated. Similarly, if R is finitely presented and $n \geq 4$ then the group $\mathrm{St}_n(R)$ is finitely presented, however the proof is significantly more complicated [12].

The connection between the pro-algebraic completions of these groups and the pro-algebraic completions of the ring R is given by the following result which is essentially proven in [11] (see also [17]):

Theorem 2.12. *The pro-algebraic completions of the groups* $\mathrm{St}_n(R)$ *and* $\mathrm{EL}_n(R)$ *are quotients of* $\mathrm{St}_n(\overline{R})$ *and surject onto* $\mathrm{EL}_n(\overline{R})$*, where* $\overline{R}$ *is the pro-algebraic completion of the ring* R*.*

Sketch of the proof. Let $\pi : \mathrm{St}_n(R) \to \mathrm{GL}_N(\mathbb{K})$ be a finite dimensional representation of the group $\mathrm{St}_n(R)$. The Zariski closure $\mathcal{A} = \overline{\{\pi(x_{1,2}(r)) \,|\, r \in R\}}^{\mathrm{Zar}}$ has a structure of an algebraic ring – the addition is just the multiplication in the group $\mathrm{GL}_N(\mathbb{K})$ and the multiplication can be defined using the relation

$$[x_{1,2}(r_1), x_{2,3}(r_2)] = x_{1,3}(r_1 r_2),$$

by expressing $x_{i,j}(r)$ as conjugate of $x_{1,2}(r)$. There is an induced ring homomorphism $\bar{\pi} : R \to \mathcal{A}$ with Zariski dense image. This implies that the representation π factors through the Steinberg group $\mathrm{St}_n(\mathcal{A})$ and the representation $\mathrm{St}_n(\mathcal{A}) \to \mathrm{GL}_N(\mathbb{K})$ restricted to the root subgroups $X_{i,j}(*)$ is an injective rational map.

The existence of surjections from $\overline{\mathrm{EL}_n(R)}$ and $\overline{\mathrm{St}_n(R)}$ to $\mathrm{EL}_n(\overline{R})$ relies on the observation that for any algebraic ring $\mathcal{A}$ the group $\mathrm{EL}_n(\mathcal{A})$ is linear. □

Remark 2.13. The kernel of the map $\mathrm{St}_n(\overline{R}) \to \overline{\mathrm{EL}_n(R)}$ is related to the pro-algebraic completion of the quotient $K_{2,n}(\overline{R})$ by the image of $K_{2,n}(R)$ induced from the map $R \to \overline{R}$. In many cases of rings having R sufficiently many units it can be shown that $\overline{\mathrm{EL}_n(R)}$ is the same as $\mathrm{EL}_n(\overline{R})$.

Theorem 2.12 almost immediately implies that

Example 2.14. The pro-algebraic completion of the group $\mathrm{SL}_n(\mathbb{Z})$ for $n \geq 3$ is isomorphic to

$$\overline{\mathrm{SL}_n(\mathbb{Z})} \simeq \begin{cases} \mathrm{SL}_n(\overline{\mathbb{Z}}^{\mathrm{f}}) \oplus \mathrm{SL}_n(\mathbb{K}) & \text{if } \operatorname{char} \mathbb{K} = 0 \\ \mathrm{SL}_n(\overline{\mathbb{Z}}^{\mathrm{f}}) & \text{if } \operatorname{char} \mathbb{K} > 0, \end{cases}$$

where $\overline{\mathbb{Z}}^{\mathrm{f}}$ is the pro-finite completion of the ring $\mathbb{Z}$. This result can be deduced (and is equivalent to) the congruence subgroup property [3] and Margulis' super rigidity [15].

2.4. Growth of character varieties for $\mathbf{SL}_n(\mathbb{Z}[x_1, \dots, x_k])$. The groups Γ_f of Theorem 1.1 have pro-algebriac completions, which are infinite products of groups like $\mathrm{SL}_n(\mathbb{Z}[x_1, \dots, x_k])$ and the calculation of the growth of the character variety for Γ_f uses the dimensions of the character varieties for the groups $\mathrm{SL}_n(\mathbb{Z}[x_1, \dots, x_k])$. The following lemma is relatively easy to prove, however obtaining further details, for example the number of components of the character variety is significantly more complicated and only partial answers are known [1, 13, 18].

Lemma 2.15. *The degree* d *character variety* $X_G(d)$ *for the group* $G = \mathrm{SL}_n(\mathbb{Z}[x_1, \dots, x_k])$ *is a point for* $d < n$ *and has dimension* $k\lfloor d/n \rfloor$ *for* $d \geq n$,[6] *provided that* $n \geq 3$*.*

[6] Here $\lfloor \cdot \rfloor$ is the floor function – $\lfloor \alpha \rfloor$ denotes the largest integer less or equal to the real number α.

Proof. Let π be a representation of $\mathrm{SL}_n(\mathbb{Z}[x_1,\dots,x_k])$ in $\mathrm{GL}_d(\mathbb{K})$ corresponding to a point on the character variety and let $i : \mathbb{Z}[x_1,\dots,x_k] \to \mathcal{A} = \overline{\{\pi(x_{1,2}(r)) \,|\, r \in R\}}^{\mathrm{Zar}}$ be the corresponding map into an algebraic ring constructed in Theorem 2.12. The representation π lifts to a representation of the group $\mathrm{St}_n(\mathcal{A})$ which is injective on the root subgroups.

Our first step is to limit the possibilities for the ring $\mathcal{A}$. First we limit the index of the connected component of algebraic ring using that $\mathcal{A}$ contains a finite subring C of size $|\mathcal{A}/\mathcal{A}^0|$ and that $\mathrm{St}_n(C)$ does not have any representation of degree d where the root subgroups acts faithfully if $|C|$ is large enough.

The representation π is semi-simple (since it comes from a point on the character variety) and therefore the ring $\mathcal{A}^0$ is a semi-simple connected commutative algebraic ring. By Theorem 2.6 it is isomorphic to $\mathbb{K}^\alpha$ where $\alpha = \dim \mathcal{A}$. Thus, π yields a representation of the Steinberg group $\mathrm{St}_n(\mathbb{K}^\alpha)$ which is injective on the root subgroups, which is only possible if $\alpha n \leq d$, i.e., $\alpha \leq \lfloor d/n \rfloor$.

Therefore, there are only finitely many possibilities for the ring $\mathcal{A}$ and for each ring there are finitely many representations of $\mathrm{St}_n(\mathcal{A})$ into $\mathrm{GL}_d(\mathbb{K})$, since the group $\mathrm{St}_n(\mathbb{K})$ is rigid.[7] Thus, up to finite index the points on the character variety are parameterized by ring homomorphism from $\mathbb{Z}[x_1,\dots,x_k]$ to $\mathcal{A}$, i.e.,

$$\begin{aligned}\varkappa_{\mathrm{SL}_n(\mathbb{Z}[x_1,\dots,x_k])}(d) &= \dim X_d(\mathrm{SL}_n(\mathbb{Z}[x_1,\dots,x_k]) \leq \\ &= \max_{\mathcal{A}}\{\dim \mathrm{Hom}(\mathbb{Z}[x_1,\dots,x_k],\mathcal{A}\} = \max_{\mathcal{A}}\{k \dim \mathcal{A}\} \leq k\lfloor d/n \rfloor.\end{aligned}$$

The lower bound for the dimension is even easier to explain: the space of ring homomorphisms $\mathbb{Z}[x_1,\dots,x_k] \to \mathbb{K}$ is k dimensional, which implies that

$$\dim X_n(\mathrm{SL}_n(\mathbb{Z}[x_1,\dots,x_k]) \geq k.$$

This together with the observation that $\dim X_{m+n}(\Gamma) \geq \dim X_m(\Gamma) + \dim X_n(\Gamma)$ implies $\dim X_d(\mathrm{SL}_n(\mathbb{Z}[x_1,\dots,x_k]) \geq k\lfloor d/n \rfloor$. □

3. Main construction

3.1. Frame subgroups. The main idea of the proof of Theorem 1.2 is to construct finitely generated subgroups inside infinite products of linear groups which are dense and have the additional property that all their linear representations extend to the infinite product. These are subgroups inside infinite products such that the induced map between the pro-algebraic completions is an isomorphism. However this property is not enough for one of the main technical tools in Lemma 3.2, so we need an additional condition to the definition of a frame subgroup. This definition is a slight modification of the one in [10].

Let $\{S_n\}_{n=1}^\infty$ be an infinite family of discrete linear groups, and Γ be a dense subgroup of the infinite product $\mathfrak{S} = \prod_{n=1}^{\infty} S_n$. The inclusion $\Gamma \hookrightarrow \mathfrak{S}$ induces map between the pro-algebraic completions $\iota : \overline{\Gamma} \to \overline{\mathfrak{S}}$. The pro-algebraic completion of $\mathfrak{S}$ is equal to $\overline{\mathfrak{S}} = \prod \overline{S_n}$, since we only consider continuous representations. The density of Γ implies that the map ι is

[7] Here we are only considering representations of $\mathrm{St}_n(\mathbb{K})$ restricted to the root subgroups are given by rational functions.

surjective, however often this map is not injective. The map ι is injective if and only if every finite dimensional representation π of Γ factors through some finite product $\prod_{n=1}^{N} S_n$.

The following notion of frame subgroup is slightly stronger than the triviality of the congruence kernel

Definition 3.1. A finitely generated subgroup $\Gamma < \mathfrak{S}$ is *a frame* for $\mathfrak{S}$ if the following hold:

(a) Γ contains $\bigoplus_{n=1}^{\infty} S_n$;

(b) The natural surjection $\iota : \overline{\Gamma} \to \prod \overline{S_n}$ is an isomorphism.

One can think of condition (a) as saying that Γ is a good approximation of $\mathfrak{S}$ from 'within' while condition (b) says that G approximates very well $\mathfrak{S}$ from 'above'.

More precisely, for a finite subset $V \subset \mathbb{N}$ of integers define the *V-principal congruence subgroup* Γ_V to be the kernel of the projection of Γ onto $\prod_{n\in V} S_n$. Let $\Gamma(V)$ be the projection of Γ onto $\mathfrak{S}(V) := \prod_{n\notin V} S_n$. The m-th principal congruence subgroup Γ_m is just $\Gamma_{\{1,\dots,m\}}$ and $\Gamma(m) := \Gamma(\{1,\dots,m\})$.

Part (a) of the above definition is now equivalent to

$$\Gamma = \left(\prod_{n\in V} S_n\right) \times \Gamma_V, \quad \Gamma_V = \Gamma \cap \mathfrak{S}(V).$$

Therefore the congruence subgroup Γ_V can be identified with the projection $\Gamma(V)$.

On the other hand as mentioned above, part (b) of Definition 3.1 says that any finite dimensional representation π of Γ factors through a finite product $\prod_{n=1}^{N} S_n$.

We stress that the existence of even a single example of a frame is far from obvious at this stage — it is relatively easy to construct infinitely generated frame subgroups, e.g., $\bigoplus S_i$. The following Lemma allows us to find many frame subgroups provided we already know at least one:

Lemma 3.2. *Let $A_n, B_n < C_n$, ($n \in \mathbb{N}$) be linear groups with $C_n = \langle A_n, B_n\rangle$. Suppose that X (resp. Y) is a frame subgroup of the product $\mathfrak{A} = \prod_{n=1}^{\infty} A_n$ (resp. $\mathfrak{B} = \prod_{n=1}^{\infty} B_n$). Each of X and Y can be considered as a subgroup of $\mathfrak{C} := \prod_{n=1}^{\infty} C_n$ in the natural way. Then the group*

$$Z = \langle X, Y\rangle < \mathfrak{C}$$

is a frame in $\mathfrak{C}$.

Proof. It is clear that Z contains the direct product of C_n. Suppose that N is a kernel of some finite dimensional representation of the group Z. By hypothesis N contains the m-th principal congruence subgroups X_m, Y_m for some m. Identifying them with $X(m), Y(m)$ in $\mathfrak{C}(m)$ we see that N contains $\langle X(m), Y(m)\rangle = Z(m)$, which under our identification is Z_m. □

Remark 3.3. The above lemma does not hold under the weaker assumption that the maps $\iota_X : \overline{X} \to \prod \overline{A_n}$ and $\iota_Y : \overline{Y} \to \prod \overline{B_n}$ are isomorphisms.

3.2. The ring $\boldsymbol{R}$. Our first step is to construct a finitely generated ring which is almost a "frame" in some infinite product of rings. Recall that $\mathrm{Mat}_n(R)$ denotes the ring of $n \times n$ matrices over an associative ring R and $e_{i,j}(r)$ denotes the elementary matrix in $\mathrm{Mat}_n(R)$ with entry $r \in R$ in position (i,j). The ring $\boldsymbol{R}$ described below is similar to the ring used in [10].

Let $\boldsymbol{R}$ be the subring of $\prod_{n=5}^{\infty} \mathrm{Mat}_n(\mathbb{Z})$ generated by the five elements $1 = (\mathrm{Id}_n)$, $\mathbf{a} = (a_n)$, $\mathbf{a}^{-1}$, $\mathbf{b} = (b_n)$ and $\mathbf{c} = (c_n)$, defined as follows:

$$a_n = e_{1,2} + e_{2,3} + \ldots + e_{n,1}, \quad b_n = e_{1,2}, \quad c_n = e_{2,1}.$$

Note that $\boldsymbol{R}$ contains the elements

$$\mathbf{b}_k := \mathbf{b}\mathbf{a}^{k-1} = (e_{1,k+1})_n, \quad \mathbf{c}_k := \mathbf{a}^{1-k}\mathbf{c} = (e_{k+1,1})_n.$$

It is easy to see that the elements $\mathbf{b}_i, \mathbf{c}_i$ for $i = 1, 2$ generate a subring (without unit) of $\boldsymbol{R}$ isomorphic to $\mathrm{Mat}_3(\mathbb{Z})$ sitting diagonally in the top left corner of each factor.

The main technical result is that the ring $\boldsymbol{R}$ is almost a frame:

Theorem 3.4.

(i) *The ring $\boldsymbol{R}$ contains the direct sum* $\bigoplus_{n=5}^{\infty} \mathrm{Mat}_n(\mathbb{Z})$.

(ii) *The pro-algebraic completion $\overline{\boldsymbol{R}}$ of $\boldsymbol{R}$ is*

$$\overline{\boldsymbol{R}} = \overline{\mathbb{Z}[t, t^{-1}]} \bigoplus \prod_{n=5}^{\infty} \overline{\mathrm{Mat}_n(\mathbb{Z})}.$$

Proof. Let us observe that the commutator $[b_n, a_n^{-k} b_n a_n^k]$ is non-zero iff n divides $k-1$ or $k+1$, moreover if this commutator is non-zero then it is a matrix unit of the form $e_{i,j}$ and the ideal generated by it is the whole $\mathrm{Mat}_n(\mathbb{Z})$. This, together with the observation that $\mathrm{Mat}_n(\mathbb{Z})$ is generated by a_n, b_n and c_n implies that the ring generated by $\mathbf{a}$, $\mathbf{a}^{-1}$ and $\mathbf{b}$ contains the infinite direct sum.

Let $\pi : R \to \mathcal{A}$ be a map from R into an algebraic ring $\mathcal{A}$ with kernel J. By Theorem 2.6 we have that there exists an ideal of finite index $I \lhd R$ such that I/J can be embedded into a finite dimensional algebra A. Thus, there exists $N \geq 5$ such that $\mathbf{a}^N - 1 \in I$ and $\dim A \leq N$. Let $\tilde{\boldsymbol{R}} = \boldsymbol{R}/\tilde{J}$, where

$$\tilde{J} = J + \bigoplus_{n=5}^{2N} M_n(\mathbb{Z}) \quad \text{and} \quad \tilde{I} = I + \bigoplus_{n=5}^{2N} \mathrm{Mat}_n(\mathbb{Z}).$$

Then $\mathbf{b}_2 = \mathbf{b}\mathbf{a}^{-1}\mathbf{b}\mathbf{a} \in \tilde{I}$ because

$$\mathbf{b}\mathbf{a}^{-N-1}\mathbf{b}\mathbf{a} \in \bigoplus_{n=5}^{2N} \mathrm{Mat}_n(\mathbb{Z})$$

and

$$\mathbf{b}\mathbf{a}^{-1}\mathbf{b}\mathbf{a} - \mathbf{b}\mathbf{a}^{-N-1}\mathbf{b}\mathbf{a} \in \langle \mathbf{a}^N - 1 \rangle \subset I.$$

Similar argument gives also that $\mathbf{c}_2 \in \tilde{I}$. The relations

$$\mathbf{b} = \mathbf{b}_2\mathbf{a}^{-1}, \quad \mathbf{c} = \mathbf{a}\mathbf{c}_2$$

imply that $\mathbf{b}, \mathbf{c} \in \tilde{I}$ and $\boldsymbol{R}/\tilde{I}$ is generated by $\mathbf{a}$ and $\mathbf{a}^{-1}$.

The second part of Theorem 2.6 gives that the quotient I/J can be embedded into a finite dimensional algebra A of dimension less than N. It follows that I/J and also $\tilde{I}/\tilde{J}$ satisfy the identity

$$s_N(x_1, \dots x_N) := \sum_{\sigma \in \mathrm{Sym}(N)} (-1)^\sigma x_{\sigma(1)} x_{\sigma(2)} \dots x_{\sigma(N)} = 0.$$

Thus

$$\mathbf{p}_N := s_N(\mathbf{b}, \mathbf{a}^{-1}\mathbf{b}\mathbf{a}, \mathbf{a}^{-2}\mathbf{b}\mathbf{a}^2, \dots) \in \tilde{J}.$$

For each $n > N + 2$ one has

$$s_N(b_n, a_n^{-1} b_n a_n, a_n^{-2} b_n a_n^2, \dots) = e_{1,N+1}$$

thus $\mathbf{p}_N - \mathbf{b}_N \in \bigoplus_{n=5}^{N+2} M_n(\mathbb{Z})$, i.e., $\mathbf{b}_N \in \tilde{J}$. The equality $\mathbf{b} = \mathbf{b}_N \mathbf{a}^{-1} \mathbf{c}_{N-1} \mathbf{a}$ implies that the element $\mathbf{b}$ lies in $\tilde{J}$. A similar computation also shows that $\mathbf{c} \in \tilde{J}$.

This argument implies that $\boldsymbol{R}/\tilde{J}$ is generated by $\mathbf{a}$ and $\mathbf{a}^{-1}$, i.e., is an image of $\mathbb{Z}[t, t^{-1}]$. This together with the inclusion $\bigoplus \mathrm{Mat}_n(\mathbb{Z}) \subset \boldsymbol{R}$ gives that $\boldsymbol{R}/J$ is a quotient of

$$\mathbb{Z}[t, t^{-1}] \oplus \bigoplus_{n=5}^{2N} \mathrm{Mat}_n(\mathbb{Z}).$$

The second part of the proposition follows because $\overline{\boldsymbol{R}}$ is an inverse limit of the quotients of the form $R/\ker\pi$ and

$$\overline{\boldsymbol{R}} = \varprojlim_N \overline{\mathbb{Z}[t, t^{-1}] \oplus \bigoplus_{n=5}^{N} \mathrm{Mat}_n(\mathbb{Z})} = \overline{\mathbb{Z}[t, t^{-1}]} \oplus \prod_{n=5}^{\infty} \overline{\mathrm{Mat}_n(\mathbb{Z})}.$$

□

This result gives that the "congruence" kernel $U = \ker\{\iota : \overline{\boldsymbol{R}} \to \prod \overline{\mathrm{Mat}_n(\mathbb{Z})}\}$ is isomorphic to $\overline{\mathbb{Z}[t, t^{-1}]}$ and it is not only a subgroup of the pro-algebraic completion $\overline{\boldsymbol{R}}$, but it is in fact a direct summand. This fact is crucial for the proof of Theorem 3.9.

3.3. The first approximation of a frame subgroup. The first approximation of a frame subgroup will be the group Γ_0 generated by the elementary 4×4 matrices over the ring $\boldsymbol{R}$ – since the ring $\boldsymbol{R}$ is sitting in the direct product of rings and contains their direct sum, the group $\mathrm{EL}_4(\boldsymbol{R})$ has similar properties. Unfortunately $\mathrm{EL}_4(\boldsymbol{R})$ is not a frame subgroup since it has algebraic images which can not be extended to the infinite product, because the ring $\boldsymbol{R}$ has algebraic images coming from the $\overline{\mathbb{Z}[t, t^{-1}]}$ factor in the pro-algebraic completion.

Lemma 3.5. *The group Γ_0 is generated by the following set of sixteen elements:*

$$\{e_{i,j} \mid 1 \le i \ne j \le 4\} \bigcup \{e_{1,2}(x) \mid x \in \{\mathbf{a}, \mathbf{a}^{-1}, \mathbf{b}, \mathbf{c}\}\}.$$

In fact it can be shown that Γ_0 can be generated by only 3 elements.

Since $\boldsymbol{R}$ is a subring of $\prod_{n=5}^{\infty} \mathrm{Mat}_n(\mathbb{Z})$ we can consider Γ_0 as a subgroup of

$$\prod_{n=5}^{\infty} \mathrm{EL}_4(\mathrm{Mat}_n(\mathbb{Z})) = \prod_{n=5}^{\infty} \mathrm{SL}_{4n}(\mathbb{Z}).$$

Lemma 3.6. *The group Γ_0 contains $\bigoplus_{n=5}^{\infty} \mathrm{SL}_{4n}(\mathbb{Z})$ and the pro-algebraic completion of Γ_0 is*

$$\overline{\mathrm{EL}_4(\mathbb{Z}[t,t^{-1}])} \oplus \prod_{n=5}^{\infty} \overline{\mathrm{SL}_{4n}(\mathbb{Z})}.$$

Here $U = \overline{\mathrm{EL}_4(\mathbb{Z}[t,t^{-1}])}$ is the "congruence" kernel $U = \ker \iota$. More precisely, suppose $\pi : \Gamma_0 \to \mathrm{GL}_M(\mathbb{K})$ a finite dimensional representation of the group Γ_0 with kernel $H = \ker \pi$

(i) *There exists an N such that we have the following diagram:*

$$\begin{array}{ccc} & \Gamma_0 & \\ \swarrow & & \searrow \\ \mathrm{EL}_4(\mathbb{Z}[t,t^{-1}]) & & \Gamma_0/H \\ \searrow & & \swarrow \\ & \Gamma_0/\widetilde{H} = \widetilde{\Gamma}_0 & \end{array}$$

where $\widetilde{H} = H \cdot \bigoplus_{n=5}^{N} \mathrm{SL}_{4n}(\mathbb{Z})$. The map $\Gamma_0 \to \mathrm{EL}_4(\mathbb{Z}[t,t^{-1}])$ comes from the projection $R \to \mathbb{Z}[t,t^{-1}]$, sending $\mathbf{b}$ and $\mathbf{c}$ to 0 and $\mathbf{a}$ to t;

(ii) *Let $\tilde{\pi}$ denote the map $\Gamma_0 \to \widetilde{\Gamma}_0$. Then for each pair of indices we have $\tilde{\pi}(E_{i,j}(\mathbf{b})) = \tilde{\pi}(E_{i,j}(\mathbf{c})) = 1$.*

Proof. Theorem 2.12 implies that $\overline{\Gamma_0}$ is a quotient of $\mathrm{St}_4(\overline{\boldsymbol{R}})$ therefore it is a quotient of

$$\mathrm{St}_4(\overline{\mathbb{Z}[t,t^{-1}]}) \times \prod \mathrm{St}_4(\overline{\mathrm{Mat}_n(\mathbb{Z})}).$$

One can show that K_2 of these pro-algebraic rings is trivial (although this is not essential) which allow one to replace all St_4 with EL_4. Parts (i) – (iii) easily follow using the description of the congruence kernel of the ring $\boldsymbol{R}$. □

3.4. The frame sugroup. Lemma 3.6 states that Γ_0 is close to being a frame subgroup, but it is not quite one. The way to fix that and remove this "congruence" kernel U is similar to the method in [10]. We can take two copies of Γ_0 and use elements from one copy to kill the congruence kernel of the other.

The group Γ_0 contains two interesting subgroups: Let D_1 be the subgroup generated by $E_{1,4}(\mathbf{b}_i), E_{4,1}(\mathbf{c}_i)$ for $1 \le i \le 4$. It is easy to see that D_1 is isomorphic to $\mathrm{SL}_5(\mathbb{Z})$ embedded "diagonally" in $\prod \mathrm{SL}_{4n}(\mathbb{Z})$ where each copy of $\mathrm{SL}_5(\mathbb{Z})$ is embedded in $\mathrm{SL}_{4n}(\mathbb{Z})$ at positions $1, 3n+2, 3n+3, 3n+4, 3n+5$.

The subgroup D_1 contains an element q which corresponds to the matrix

$$\begin{pmatrix} 1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 \\ 0 & 0 & 0 & 1 & 0 \end{pmatrix}.$$

As an element in $\prod \mathrm{SL}_{4n}(\mathbb{Z})$ this element is equal to $q = (q_{4n})$, where q_{4n} is a permutation matrix corresponding to the involution $(3n+2, 3n+3)(3n+4, 3n+5)$.

We remark that from Chevalley commutator relations it follows that $E_{1,4}(\mathbf{b}_i)$ and $E_{4,1}(\mathbf{c}_i)$ lie in the normal subgroup generated by $E_{12}(\mathbf{b})$ and $E_{12}(\mathbf{c})$, therefore the image of the whole group D_1 in the "congruence" kernel $\overline{\mathrm{EL}_4(\mathbb{Z}[t, t^{-1}])}$ is trivial.

Similarly, let D_2 be the subgroup generated by $E_{i,j}(\mathbf{1})$ for $1 \leq i \neq j \leq 3$. This group contains the element v corresponding to

$$\begin{pmatrix} 0 & 1 & 0 \\ 0 & 0 & 1 \\ 1 & 0 & 0 \end{pmatrix}.$$

As an element in $\prod \mathrm{SL}_{4n}(\mathbb{Z})$ this element is equal to $v = (v_{4n})$ where v_{4n} is a permutation matrix corresponding to $(1, n+1, 2n+1)(2, n+2, 2n+2)\dots(n, 2n, 3n)$. An easy computation shows that this element normally generates $\mathrm{SL}_3(\mathbb{Z})$, it even normally generates the whole group Γ_0.

Let θ_n denote the embedding of $\mathrm{SL}_n(\mathbb{Z})$ into $\mathrm{SL}_{2^n}(\mathbb{Z})$ coming from the action of $\mathrm{SL}_n(\mathbb{Z})$ on the exterior algebra $\bigwedge^* \mathbb{Z}^n$. We will need two lemmas about this embedding whose proofs are postponed until section 3.6:

Lemma 3.7.

(i) *For every $n \geq 20$ there exists an element $\varpi_n \in \mathrm{SL}_{2^n}(\mathbb{Z})$ such that $\mathrm{SL}_{2^n}(\mathbb{Z})$ is generated by the image of $\mathrm{SL}_n(\mathbb{Z})$ under θ_n and its conjugate by ϖ_n.*

(ii) *For every $n \geq 10$ there exists an element $\omega_n \in \mathrm{SL}_{2^n}(\mathbb{Z})$ such that*

$$i''_n(q_n)^{-1} i'_n(v_n) i''_n(q_n) = i'_n(v_n)^{-1}, \quad i'_n(q_n)^{-1} i''_n(v_n) i'(q_n) = i''_n(v_n)^{-1}. \quad (3.1)$$

where i'_n is the embedding θ_n and i''_n is obtained from θ_n by conjugation with ω_n. Here q_n and v_n are two commuting elements in $\mathrm{SL}_n(\mathbb{Z})$ similar to the ones described above, i.e., q_n is a permutation matrix corresponding to the product of two transpositions and v_n is a permutation matrix of order 3 corresponding to a permutation with support about $3n/4$.

Remark 3.8. It seems plausible that the elements ϖ_n and ω_n can be chosen to be the same. This will allow us to decrease the number of generators of the group constructed in Theorem 1.2 since the enlargement step in section 3.5 will not be necessary. Also, it is likely that elements with similar properties also exist for the embedding $\mathrm{SL}_n(\mathbb{Z}) \to \mathrm{SL}_{\binom{n}{n/2}}(\mathbb{Z})$ coming from the action of $\mathrm{SL}_n(\mathbb{Z})$ on $\bigwedge^{n/2} \mathbb{Z}^n$.

Let u_n denote the number 2^{4n} and let S_n be the subgroup of $\mathrm{SL}_{u_n}(\mathbb{Z})$ generated by the images of the homomorphism i'_{4n} and i''_{4n} from Lemma 3.7(ii). Consider the two homomorphisms

$$i', i'' : \prod_{n=5}^{\infty} \mathrm{SL}_{4n}(\mathbb{Z}) \to \prod_{n=5}^{\infty} S_n \subset \prod_{n=5}^{\infty} \mathrm{SL}_{u_n}(\mathbb{Z}),$$

given by $(g_n)_n \mapsto (i'_{4n}(g_n))_n$ and $(g_n)_n \mapsto (i''_{4n}(g_n))_n$.

Set $\Gamma'_0 = i'(\Gamma_0), \Gamma''_0 = i''(\Gamma_0)$ and let Γ_1 denote the subgroup of $\prod S_n$ generated by Γ'_0 and Γ''_0.

Theorem 3.9. *The group Γ_1 is a frame subgroup of $\prod S_n$.*

Proof. The group Γ_1 contains $\bigoplus_{n=5}^{\infty} S_n$, because each copy of Γ_0 contains the infinite direct sum of the images of $\mathrm{SL}_{4n}(\mathbb{Z})$ in S_n.

Suppose now that $\pi : \Gamma_1 \to \mathrm{GL}_N(\mathbb{K})$ is a finite dimensional representation of Γ_1 with kernel $H = \ker \pi$. By Proposition 3.6 (i) applied to Γ'_0 and Γ''_0, there exists an integer M such that if

$$\widetilde{H} = H.\bigoplus_{n=5}^{M} S_n \quad \widetilde{H'} = \widetilde{H} \cap \Gamma'_0, \quad \widetilde{H''} = \widetilde{H} \cap \Gamma''_0.$$

then $\widetilde{\Gamma'_0} = \Gamma'_0/\widetilde{H'}$ and $\widetilde{\Gamma''_0} = \Gamma''_0/\widetilde{H''}$ are images of $\mathrm{EL}_4(\mathbb{Z}[t, t^{-1}])$.

By Proposition 3.6 (ii) the images of $E_{i,j}(\mathbf{b})$ and $E_{i,j}(\mathbf{c})$ in $\widetilde{\Gamma'_0}$ and $\widetilde{\Gamma''_0}$ are trivial. In particular the group D_1 is in the kernel of both $\rho' = \rho \circ i'$ and $\rho'' = \rho \circ i''$, where ρ is the projection $\Gamma_1 \to \widetilde{\Gamma}$. This implies that $\rho'(q) = \rho''(q) = 1$.

By (3.1) the following relations hold in Γ_1:

$$i'(q)i''(v)i'(q) = i''(v)^{-1} \qquad i''(q)i'(v)i''(q) = i'(v)^{-1},$$

since these relations hold in every S_n. Therefore we have

$$\rho'(q)\rho''(v)\rho'(q) = \rho''(v)^{-1} \qquad \rho''(q)^{-1}\rho'(v)\rho''(q) = \rho'(v)^{-1}.$$

These, together with $\rho'(q) = \rho''(q) = 1$ and $v^3 = 1$ imply that $\rho'(v) = \rho''(v) = 1$. The elements $i'(v)$ and $i''(v)$ generate Γ'_0 and Γ''_0 as normal subgroups, which implies that ρ' and ρ'' have trivial images, i.e., $\widetilde{\Gamma_1} = \{1\}$. Therefore $\Gamma_1 = H.\bigoplus_{n=5}^{M} S_n$, hence H contains the congruence subgroup $(\Gamma_1)_M$ and Γ_1 is a frame subgroup. □

3.5. Proof of Theorem 1.2. The group Γ_1 is a frame in some 'unknown' infinite product. As mentioned before it might be possible to choose the elements ω_{4n} such that the embeddings i'_n and i''_n generate the full groups $\mathrm{SL}_{u_n}(\mathbb{Z})$, which will implies that Γ_1 is a frame in $\mathrm{SL}_{u_n}(\mathbb{Z})$. One way to bypass this problem is the following:

Lemma 3.10. *Let ϖ denote the element in $\prod \mathrm{SL}_{u_n}(\mathbb{Z})$ obtained by putting together all ϖ_{4n}. Then the group Γ_2 generated by Γ_1 and Γ_1^{ϖ} is a frame subgroup in $\prod \mathrm{SL}_{u_n}(\mathbb{Z})$.*

Proof. Part (i) of Lemma 3.7 implies that Γ_1 and Γ_1^{ϖ} satisfy the conditions of Lemma 3.2, which gives that Γ_2 is a frame subgroup. □

Before proving Theorem 1.2 we need another technical claim

Claim 3.11. *Let $\{n_i\}_{i=1}^K$ be a finite sequence of integers such that $n_i > m \geq 5$. Then the group $\prod \mathrm{SL}_{n_i}(\mathbb{Z})$ can be generated by two subgroups isomorphic to $\mathrm{SL}_m(\mathbb{Z})$.*

Proof. This relies on the well known fact that for each $n_i > m$ the alternating group Alt_{n_i} can be generated by two copies of Alt_m acting diagonally. This diagonal embedding can be extended to embedding of $\mathrm{SL}_m(\mathbb{Z})$ into $\mathrm{SL}_{n_i}(\mathbb{Z})$ which can be easily seen to generate the whole group. Combining these embeddings leads to two subgroups in $\prod \mathrm{SL}_{n_i}(\mathbb{Z})$ isomorphic to $\mathrm{SL}_m(\mathbb{Z})$ which generate the whole Cartesian product. □

Proof of Theorem 1.2. The product $\prod_{k\geq 3} \mathrm{SL}_n(\mathbb{Z})$ can be written as

$$\prod_{k\geq 3} \mathrm{SL}_n(\mathbb{Z}) = \prod_{k\geq 3}^{u_5-1} \mathrm{SL}_n(\mathbb{Z}) \times \prod_{n\geq 5} \left(\prod_{k=u_n}^{u_{n+1}-1} \mathrm{SL}_k(\mathbb{Z}) \right).$$

Let T_0 denote the product $\prod_{k\geq 3}^{u_5-1} \mathrm{SL}_n(\mathbb{Z})$ and T_n be $\prod_{k=u_n}^{u_{n+1}-1} \mathrm{SL}_k(\mathbb{Z})$. Using Claim 3.11 each of the groups T_n for $n \geq 5$ can be generated by two subgroups isomorphic to $\mathrm{SL}_{u_n}(\mathbb{Z})$, this together with Lemma 3.2 proves the existence of a frame subgroup Γ_3 in $\prod_{n\geq 5} T_n$. Since T_0 is finitely generated then $T_0 \times \Gamma_3$ is a frame subgroup in $\prod \mathrm{SL}_n(\mathbb{Z})$. □

3.6. Proof of Lemma 3.7. Consider the action of $\mathrm{SL}_n(\mathbb{Z})$ on $V_n := \bigwedge^* \mathbb{Z}^n$ which induces an embedding $\theta_n : \mathrm{SL}_n(\mathbb{Z}) \hookrightarrow \mathrm{SL}_{2^n}(\mathbb{Z})$. A key point is that θ_n sends any signed permutation matrix λ in $\mathrm{SL}_n(\mathbb{Z})$ to a signed permutation matrix in SL_{2^n} with large support, even if λ has tiny support. Let υ_n denote the embedding of $\mathrm{Sym}^{\pm}(n)$ into $\mathrm{Sym}^{\pm}(2^n)$ induced by θ_n where $\mathrm{Sym}^{\pm}(n)$ denotes the group of even signed permutations.

The image H_n of the embedding υ_n is a signed permutation group which acts on the set P of 2^n basis vectors of V_n with only $n+1$ orbits $P_{n,i}$ for $0 \leq i \leq n$ corresponding to the decomposition $V_n = \bigoplus_i \bigwedge^i \mathbb{Z}^n$. The group H contains a permutation matrix c of order 3 with very large support. Using the fact that with probability tending to 1 any two permutations of order 3 with large support generate the whole alternating group $\mathrm{Alt}(n)$, we can find a element ϖ_n such that the group generated by H and H^{ϖ_n} contains the alternating group. Part (i) of Lemma 3.7 follows immediately from the following

Claim 3.12. *The group $\mathrm{SL}_N(\mathbb{Z})$ is generated by an unipotent matrix U in Jordan normal form which has at least one Jordan block of size 1 and another one of size 2 and the alternating group $\mathrm{Alt}(N)$ acting by permutation matrices.*

Proof. The structure of U implies that there exists a 3-cycle $g \in \mathrm{Alt}(N)$ such that $[U, U^g]$ is an elementary matrix E. The orbit of E under conjugation by $\mathrm{Alt}(N)$ consists of all elementary matrices, which generate the group $\mathrm{SL}_N(\mathbb{Z})$. □

In order to prove the second part of Lemma 3.7 we need to understand the action of $\upsilon(q_n)$ and $\upsilon(\upsilon_n)$: We can split $\mathbb{Z}^n$ as a direct sum of $\mathbb{Z}^{n-4}$ and $\mathbb{Z}^4$ with υ_n acting on the first component and q_n acting on the second. This leads to decomposition of $\bigwedge^* \mathbb{Z}^n$ as tensor product

$$\bigwedge^* \mathbb{Z}^n = \left(\bigwedge^* \mathbb{Z}^{n-4} \right) \otimes \left(\bigwedge^* \mathbb{Z}^4 \right).$$

The second factor is 16 dimensional and $\upsilon(q_n)$ acts on it as a signed permutation matrix with 6 two cycles, 4 fixed points, moreover 2 of the points have positive signs and 2 have negative signs. This implies the following lemma

Lemma 3.13. *The image of the group G generated by $\upsilon(q_n)$ and $\upsilon(v_n)$ acts on the set P_n with $3M$ orbits of size 6, $2M$ orbits of size 3 fixed by q_n - on M of these orbits q_n fixes the corresponding basis vectors and on the other M orbits q_n negates the basis vectors; there are several additional orbits where v_n acts trivially, for some integer M.*

This lemma allow us to express the set P as union of G invariant sets of the following types

(a) an orbit of size 6 and an orbit of size 3 where both $\upsilon(q_n)$ and $\upsilon(v_n)$ are permutations;

(b) an orbit of size 6 and an orbit of size 3 where $\upsilon(q_n)$ is apermutation and $\upsilon(v_n)$ is a permutation times a central element;

(c) 4 orbits of size 6 and an orbit of size 3 where both $\upsilon(q_n)$ and $\upsilon(v_n)$ are permutations;

(d) an orbit of size 3 and an orbit of size 2 where both $\upsilon(q_n)$ and $\upsilon(v_n)$ are permutations;

(e) set where $\upsilon(q_n)$ acts trivially.

In order to show the existence of the required element ω_n it is enough to find a signed permutation matrix ς_n which satisfies the following relations

$$\upsilon(q_n)^{\varsigma}_n\upsilon(v_n)\upsilon(q_n)^{\varsigma}_n = \upsilon(v_n)^{-1} \quad \text{and} \quad \upsilon(q_n)\upsilon(v_n)^{\varsigma}_n\upsilon(q_n) = (\upsilon(v_n)^{\varsigma}_n)^{-1}. \tag{3.2}$$

The partition of the set P outlined above allows us to construct the element ς_n on each of the small pieces, which reduces the computation to finding suitable elements in signed permutation groups of relatively small sizes. Here is a brief construction of the elements ς_n in each of the cases:

(a) We can arrange the 9 points in a square of size 3, i.e., label the points (x, y) with $x, y \in \mathbb{F}_3$, it is possible to choose the labels such that $\upsilon(q) : (x, y) \to (x, -y)$ and $\upsilon(v) : (x, y) \to (x+1, y)$ where all computations are taken in the field with 3 elements. In this model the element $\varsigma : (x, y) \to (y, x)$ satisfies relation (3.2).

(b) This is the same as case (a) since the actions of q differ by an element in the center of groups.

(c) This is similar to case (a) however one uses 3 dimensional cube instead of a square: the points are labeled (x, y, z) with $x, y, z \in \mathbb{F}_3$ and $\upsilon(q) : (x, y, z) \to (x, -y, -z)$ and $\upsilon(v) : (x, y, z) \to (x+1, y, z)$. In this model the element $\varsigma : (x, y, z) \to (y, z, x)$ with satisfy relation (3.2).

(d) If $\upsilon(q)$ is the 3-cycle (123) and $\upsilon(v)$ is the transposition (45) we can take ς_n to be the involution $(24)(35)$.

(e) Since $\upsilon(q)$ is trivial, any element ς will satisfy the above relations.

Finally observe that the combination ς_n of the permutations described above on each piece will satisfy the relation (3.2). The element ω_n is just ς_n considered as a signed permutation matrix in $\mathrm{SL}_{u_n}(\mathbb{Z})$.

4. Application – proof of Theorem 1.1

Using Theorem 1.2 it is relatively quick to prove Theorem 1.1: a function $f(n) : \mathbb{N} \to \mathbb{N}$ will be called admissible if $f(n) \leq n(n-1)/2$ and $f(n)/n$ non-decreasing.

The next lemma follows from Theorem 1.2

Lemma 4.1. *For any admissible function f there exists a finitely generated frame subgroup inside*

$$\prod_n \mathrm{SL}_n(\mathbb{Z}[x_1, \dots, x_{f(n)}]).$$

Proof. Observe that the group $\mathrm{SL}_n(\mathbb{Z}[x_1, \dots, x_k])$ can be generated by two conjugated copies of $\mathrm{SL}_n(\mathbb{Z})$ for $k \leq n(n-1)/2$, one is the standard one and the other one is conjugated by any upper triangular matrix with entries the intermediates x_i. This allow us to apply Lemma 3.2 to the two embeddings of the frame subgroup constructed in the proof of Theorem 1.2. □

Let $I_\Gamma(n)$ denote the open subset of $X_\Gamma(n)$ which corresponds to the irreducible representations of Γ.

The dimension of $X_\Gamma(n)$ can be computed: a semi-simple representation can be written as direct sum of simple ones, i.e.,

$$\dim X_\Gamma(n) = \max\left\{\sum \dim I_\Gamma(n_i) \mid \sum n_i = n\right\}.$$

This formula reduces the computation of the dimensions of the character varieties of Γ to the dimensions of the irreducible components $\dim I_\Gamma(n)$.

Proof of Theorem 1.1. Let f be an admissible function and let Γ_f be a frame subgroup in $\prod_n \mathrm{SL}_n(\mathbb{Z}[x_1, \dots, x_{f(n)}])$. Since the group $\mathrm{SL}_n(\mathbb{Z}[x_1, \dots, x_{f(n)}])$ does not have any non-trivial representations of degree less than n, the representation and character varieties for Γ_f of degree d are the same as the ones for the finite product $G_d := \prod_{n \leq d} \mathrm{SL}_n(\mathbb{Z}[x_1, \dots, x_{f(n)}])$.

Using the above observation we need to compute the dimensions

$$\dim I_{G_d}(k), \quad \text{for } k \leq d.$$

However, the irreducible representations of product of groups are tensor products of irreducible representations of each factor therefore

$$\begin{aligned}\dim I_{G_d}(k) &= \max\left\{\sum \dim I_{\mathrm{SL}_i(\mathbb{Z}[x_1,\dots,x_{f(i)}])}(k_i) \mid \prod k_i = k,\ k_i > 2,\ k_i \neq k_j\right\} = \\ &= \max\left\{\sum f(k_i) \mid \prod k_i \leq k\right\},\end{aligned}$$

where we used that $\dim I_{\mathrm{SL}_i(\mathbb{Z}[x_1,\dots,x_{f(i)}]}(k_i)$ is 0 for $k_i < i$ and either $f(i)$ or 0 for $k_i \geq i$. If the function f is admissible the above maximum is equal to $f(k)$. Therefore for every $k \leq d$ we have

$$\dim I_{G_d}(k) = f(k).$$

This allows is to compute the dimensions of the character varieties

$$\begin{aligned}\dim X_{G_d}(k) &= \max\left\{\sum \dim I_{G_d}(k_i) \mid \sum k_i = k\right\} = \\ &= \max\left\{\sum f(k_i) \mid \sum k_i = k\right\} =\end{aligned}$$

$$= \max\left\{\sum k_i \frac{f(k_i)}{k_i} \mid \sum k_i = k\right\} \leq$$
$$\leq k \max\left\{\frac{f(k_i)}{k_i} \mid \sum k_i = k\right\} = f(k),$$

i.e., the dimensions of the character variety of degree k for G_d are bounded above by $f(k)$ for any $k \leq d$. There is a lower bound coming from

$$\dim X_{G_d}(k) \geq \dim X_{\mathrm{SL}_k(\mathbb{Z}[x_1,\ldots,x_{f(k)}])}(k) = f(k).$$

Therefore $\dim X_{\Gamma_f}(d) = f(d)$ for any d which completes the proof of Theorem 1.1. □

Remark 4.2. A modification of this construction allows us to construct a group $\tilde{\Gamma}_f$ with Kazhdan property T almost satisfying the conditions of Theorem 1.1, provided that the admissible function f satisfies the extra condition $\lim f(n)/n^2 \to 0$. The idea is to modify the construction of the ring $\boldsymbol{R}$ to obtain a finitely generated subring $\boldsymbol{R}_f$ inside

$$\prod \mathrm{Mat}_n(\mathbb{Z}[x_1 \ldots x_f(n)]).$$

The generators of the ring $\boldsymbol{R}_f$ are $\mathbf{a}^{\pm 1}$, $\mathbf{b}_f = (b_{n,f})$, $\mathbf{c}_f = (c_{n,f})$ and $\mathbf{y}_f = (y_{n,f})$, where the matrices

$$b_{n,f} = \sum_{i=0}^{n/d_n} e_{1+d_n i, 2+d_n i} \quad c_{n,f} = \sum_{i=0}^{n/d_n} e_{2+d_n i, 1+d_n i}$$

are modifications of b_n and c_n of rank about $f(n)/n$ and the new generators $y_{n,f}$ contain the variables x_i and

$$y_{n,f} = \sum_{i=0}^{n/d_n} \sum_{j=1}^{n} e_{1+d_n i, j} x_{in+j}$$

where $d_n = n^2/f(n)$.

A slight modification[8] of Theorem 3.4 shows that the pro-algebraic completion of this ring is equal to

$$\overline{\mathbb{Z}[t, t^{-1}]} \oplus \prod \overline{\mathrm{Mat}_n(\mathbb{Z}[x_1 \ldots x_f(n)])}.$$

Then, the group $\tilde{\Gamma}_f = \mathrm{EL}_3(\boldsymbol{R}_f)$ will have property T by the results of [5]. An argument similar to the one in the proof of Theorem 1.1 gives that

$$\varkappa_n(\tilde{\Gamma}_f) = f(\lfloor n/3 \rfloor).$$

Remark 4.3. Theorems 1.2 and 1.1 also hold over algebraically closed fields of positive characteristic. The construction and most of the proofs remains the same — the main difficulty is that there is no analog of Theorem 2.6 which significantly complicates the proof of Theorem 3.4.

Acknowledgements. The author was partially supported by NSF grant DMS 1303117 and Simons Foundation grant 305181. I would like to thank Nir Avni, Nikolay Nikolov, Mark Sapir and Igor Rapinchuk for the useful conversation which lead to this paper. I am grateful to everyone who reviewed the preliminary version of this paper for their suggestions which significantly improved the paper.

[8] In order to show that $\mathbf{y}$ is in the ideal J one need to use the relation $\mathbf{y} = \mathbf{bcy}$.

Model theory and algebraic geometry in groups, non-standard actions and algorithmic problems

Olga Kharlampovich and Alexei Myasnikov

Abstract. We discuss the modern theory of equations in groups, algebraic geometry and model theory in free and hyperbolic groups, as well as group actions on Λ-trees. One of our main tools is a combinatorial process that combines and generalizes a number of known results and algorithms, such as the Makanin-Razborov process for solving equations in groups, Rauzy-Veech induction in dynamical systems, classification of basic group actions in group theory and topology, and elimination and parametrization theorems in classical algebraic geometry. The development of algebraic geometry comes together with advances in the theory of fully residually free and fully residually hyperbolic groups, which are coordinate groups of irreducible algebraic varieties. We describe finitely generated groups elementarily equivalent to a free non-abelian group (another classification is given by Sela) and show that the first-order theory of a free or a torsion-free hyperbolic group is decidable (solution to Tarski's problems from 1940's). Furthermore, for such groups we give an algorithm for elimination of quantifiers to boolean combinations of $\forall\exists$-formulas. We also provide a description of definable sets in a torsion-free hyperbolic group (in particular, in a free group) and demonstrate that only cyclic subgroups and the whole group are definable in these groups (this solves Malcev's problem of 1965). In the group actions section we describe all finitely presented groups acting freely on Λ-trees (solution to Alperin's and Bass problem of 1990). At the end we outline some related open problems.

Mathematics Subject Classification (2010). Primary 20E05; Secondary 20A15, 20F67.

Keywords. Free group, model theory, group actions.

1. Fundamental questions in model-theoretic algebra

In this section we consider some fundamental model-theoretic questions that should be asked about a given algebraic structure (a group, a ring, etc.), or a class of structures, to understand its principal algebraic and logical properties. These questions include: elementary classification and decidability of the theory (Tarski's type questions), description of definable sets (Malcev's problems), quantifier elimination (to some set of formulas), elementary embeddings and model completeness (Robinson's questions), types of elements and stability, natural axioms of the theory, models of the universal theory and related algebraic geometry, Fraisse limits and existentially closed structures. Addressing these questions could be a hard task, but many interesting results appeared along this way.

The language L of group theory consists of multiplication $\cdot$, inversion $^{-1}$, and a constant symbol 1 for the identity in the group. For a given group G one may add all elements of G as constants to the language L, thus obtaining a language L_G. If G is generated by a finite set

Proceedings of the International Congress of Mathematicians, Seoul, 2014

A it suffices to include only elements of A into the language. By $\phi(p_1, \dots, p_n)$ we denote a first-order formula in the language L (or L_G) whose free variables are contained in the set $\{p_1, \dots, p_n\}$. We will also use tuple notation $\phi(P)$ where $P = (p_1, \dots, p_n)$ for variables. Each first-order formula can be represented as

$$\phi(P) = \exists x_1 \forall y_1 \dots \exists x_n \forall y_n \phi_0(P, X, Y),$$

where $\phi_0(P, X, Y)$ has no quantifiers. A formula without free variables is called a sentence. The first order theory $Th(G)$ of a group G is the set of all first-order sentences in L (or in L_G) that are true in G. $Th(G)$ is all the information about G describable in first-order logic. Groups G and H are elementarily equivalent if $Th(G) = Th(H)$. Similarly one defines the first order theory of a ring, or a field (the language in this case consists of addition, multiplication, zero and identity elements), or an arbitrary structure.

Let $\mathcal{K}$ be a class of groups (or rings). *Elementary classification* for K is a problem to describe (in algebraic terms) elementarily equivalent groups in $\mathcal{K}$, while *decidability problem* for $\mathcal{K}$ asks to describe groups G in $\mathcal{K}$ with decidable $Th(G)$. The class $\mathcal{K}$ could be the class of all groups, or all finitely generated groups, or some other interesting class of groups.

A subset $S \subseteq G^n$ is *definable* in a group (ring, structure) G if there exists a first-order formula $\phi(P)$ in L_G such that S is precisely the set of all tuples P in G^n for which $\phi(P)$ holds in G. We say that S is definable without parameters if it is defined by a formula $\phi \in L$. Malcev's type problems concern with description of all definable sets in a given group G, or some of them, say definable subgroups.

By quantifier elimination we understand *quantifier elimination* to some *set of formulas* E, called the *eliminating set*. In this case for every formula $\phi(P)$ of a language L (or L_G) there exists a formula $\phi^*(P)$, which is a boolean combination of formulas from E, such that ϕ is equivalent to ϕ^* in G. A quantifier elimination is computable (effective) if the function $\phi \to \phi^*$ is computable. If formulas from the set E are simple enough a quantifier elimination to E gives a powerful tool to study $Th(G)$. We do not discuss much of model completeness, or Fraisse limits, or existentially closed groups in a class $\mathcal{K}$, in this paper, so we refer for definitions to [28].

We discuss below several examples in algebra where the elementary theories were studied and the principle questions addressed.

Example 1.1. Tarski himself showed for the field $\mathbb{C}$ of complex numbers and its first-order theory $Th(\mathbb{C})$ that $Th(\mathbb{C}) = Th(F)$ if and only if F is an algebraically closed field of characteristic 0; $Th(\mathbb{C})$ is decidable; definable sets are precisely the constructible sets (boolean combinations of algebraic sets). The axioms of the theory state that the characteristic is 0, and every equation has a solution. Types of elements are described. This led to the development of the theory of algebraically closed fields. This theory admits elimination of quantifiers, namely, every formula is logically equivalent (in the theory of algebraically closed fields) to a boolean combination of quantifier-free formulas. $Th(\mathbb{C})$ is stable, $\aleph_1$-categorical and model complete. All fields are models of the $\forall$-theory of $\mathbb{C}$.

Example 1.2. Tarski showed, by the method of quantifier elimination, that the first-order theory of the real numbers $\mathbb{R}$ under addition and multiplication is decidable. While this result appeared only in 1948, it dates back to 1930. This is a very interesting result, because Church proved in 1936 that Peano arithmetic (the theory of natural numbers) is not decidable. The theory of real closed fields was developed by Artin and Schreier after Artin's solution to 17th Hilbert Problem. $Th(\mathbb{R})$ is decidable; $Th(\mathbb{R}) = Th(F)$ if and only if F is a real

closed field; $Th(\mathbb{R})$ is not stable (one can define an order in $\mathbb{R}$), intervals and their boolean combinations are definable sets.

A real closed field is an ordered field of characteristic 0, where every odd degree polynomial has a root and every element or its negative is a square (axioms of $\forall$-theory). There are many types (2^{ω_1}). Models of the $\forall$-theory are formal real fields. There is quantifier elimination to quantifier free formulas and formulas $\exists t(x = t^2)$.

Example 1.3. We briefly state some well-known results on elementary theories of abelian groups: elementary theory of an abelian group A has quantifier elimination to positive primitive formulas, i.e., formulas of the type $\exists x_1 \dots \exists x_n \phi$, where ϕ is a conjunction of positive atomic formulas (equations in the case of groups); this quantifier elimination is effective if and only if A has decidable index problem; the theory of A is stable; all abelian torsion-free groups are universally equivalent; definable subsets are boolean combinations of cosets; there is a precise elementary classification of all abelian groups in terms of some invariants; Fraisse limits in the class of finitely generated torsion-free abelian groups are $\mathbb{Q}$-vector spaces of countable dimension.

2. Results in free and hyperbolic groups

Around 1945 A. Tarski put forward two problems on elementary theories of free groups that served as a motivation for much of the research in group theory and logic for the last sixty years. A joint effort of mathematicians of several generations culminated in the following theorems, solving these Tarski's conjectures. Denote by F_n a free group of rank n.

Theorem 2.1 ([33]-[38], [71]-[73]). $Th(F_n) = Th(F_m)$, *for all* $m, n > 1$.

Theorem 2.2 ([33]-[39]). *The elementary theory* $Th(F)$ *of a free group* F *even with constants from* F *in the language is decidable.*

In the 60s Malcev was a leader of the very active Novosobirsk school studying similar questions. Malcev himself proved that the elementary theory of the class of all finite groups is undecidable, Ershov proved the undecidability of the theories of symmetric and finite simple groups, and also obtained axioms and the decidability of the first-order theory of the field of p-adic numbers $\mathbb{Q}_p$. The results of Ershov, Romanovskii and Noskov imply that the elementary theory of a finitely generated virtually solvable group is decidable if and only if the group is virtually abelian.

The following questions were asked by Malcev ([32], Problem 1.19) for a free non abelian group F: "Describe definable sets in F; describe definable subgroups in F; is the commutator subgroup $[F, F]$ of F definable in F?"

Before answering these questions we consider some examples.

Example 2.3. Let $W(P, A) = 1$ be an equation (with constants) in a group G. Then the algebraic set $V_G(W) = \{g \in G^n \mid W(g, A) = 1\}$ is definable in G.

Let $w(x_1, \dots, x_n) \in F(X)$ be a group word. Then the set

$$w[G] = \{g \in G \mid g = w(h_1, \dots, h_n) \text{ for some } h_1, \dots, h_n \in G\}$$

is called a *verbal set* and is defined in G by the formula

$$\phi(p) = \exists y_1 \dots \exists y_n (p = w(y_1, \dots, y_n)).$$

So $w[G] = \{g \in G \mid G \models \phi(g)\}$. In particular, the set of all commutators is definable in G.

Example 2.4. Another example of definable set is the set of all bases in $F_2 = F_2(a, b)$. This is based on Nielsen's theorem that states that elements $g, h \in F_2$ form a basis if and only if $[g, h]$ is conjugated either to $[a, b]$ or $[b, a]$. Hence the set of bases in F_2 is defined by the following formula

$$\phi(p_1, p_2) = \exists z([p_1, p_2] = z^{-1}[a, b]z \ \vee \ [p_1, p_2] = z^{-1}[b, a]z).$$

Therefore the set of primitive elements of F_2 is definable.

Example 2.5. The center and the centralizer of a finite subset are definable in any group G. In particular, maximal cyclic subgroups are definable in a free group or a torsion-free hyperbolic group (in the language with constants), and, therefore, all cyclic subgroups are definable.

For a word $w(x_1, \dots, x_n) \in F(X)$ the subgroup $w(G)$ in a group G generated by the verbal set $w[G]$ is called the *verbal subgroup* of G defined by w. The verbal subgroup $w(G)$ has *finite width* if there is a number k such that every element in $w(G)$ is a product of at most k values of the word w in G or their inverses. A verbal subgroup $w(G)$ of finite width is definable in G (without parameters).

The commutator subgroup $[G, G]$ is the verbal subgroup of G defined by the word $[x_1, x_2]$. Malcev asked about the commutator subgroup of F because if the commutator subgroup were definable the same formula in the free groups of different rank, this would imply that free groups of different ranks are not elementarily equivalent. In the case of abelian, nilpotent and solvable groups the situation is different than in a free group. Let A_m be a free abelian group of rank m. The verbal subgroup A_m^2 has width 1 in A_m, hence it is definable. A_m/A_m^2 is a vector space of dimension m over the field $\mathbb{Z}_2$ of two elements. Using definability of A_m^2 one can write a sentence D_m (without parameters) stating that the dimension of the space A_m/A_m^2 is precisely m. Therefore two free abelian groups of finite rank are elementarily equivalent if and only if they are isomorphic (therefore have the same rank).

Let G be a finitely generated free nilpotent group of rank m and class c. The commutator subgroup $[G, G]$ has finite width, hence it is definable in G. So the abelianization $G/[G, G] \simeq A_m$ is interpretable in G. Again, one can write down a sentence stating that the rank of the abelianization of G is precisely m. Two free nilpotent groups of finite rank are elementarily equivalent if and only if they are isomorphic. Similarly, two free solvable groups of finite rank are elementarily equivalent iff they are isomorphic.

Proper verbal subgroups in non-abelian free group F have infinite width [68]. The same is true for arbitrary non-elementary hyperbolic groups [59].

Theorem 2.6 ([38, 73]). *Every formula in the theory of F is equivalent to the boolean combination of $\forall\exists$-formulas.*

Every definable subset of F is defined by some boolean combination of formulas

$$\exists X \forall Y (\vee_{i=1}^{k} (U_i(P, X, Y) = 1 \wedge V_i(P, X, Y) \neq 1)), \tag{2.1}$$

where X, Y, P are tuples of variables.

Theorem 2.7 ([74]). *Every formula in the theory of a non-elementary torsion-free hyperbolic group G is equivalent to a boolean combination of $\forall\exists$-formulas. The theory is stable.*

Theorem 2.8 ([41]). *Let Γ be a torsion free hyperbolic group. There exists an algorithm, given a first-order formula ϕ to find a boolean combination of $\forall\exists$-formulas that define the same set as ϕ over Γ.*

The elementary theory of a torsion-free hyperbolic group is decidable.

Notice that in the language L_G every finite system of equations in a free group is equivalent to one equation (this is Malcev's result) and every finite disjunction of equations is equivalent to one equation (this is attributed to Gurevich). The same is true in a torsion-free hyperbolic group [40].

For a free and for a torsion-free hyperbolic group G a more precise result about quantifier elimination holds.

Theorem 2.9 ([40]). *Every definable set over G (in particular, over F) in the languige L_G is defined by some boolean combination of formulas*

$$\exists X \forall Y (U(P, X) = 1 \wedge V(P, X, Y) \neq 1), \tag{2.2}$$

where X, Y, P are tuples of variables.

The following theorem gives a solution to Malcev's problem, it describes definable subgroups in a torsion-free hyperbolic group.

Theorem 2.10 ([40]). *Proper non-cyclic subgroups of a torsion free hyperbolic group (in particular, of a free group F) are not definable.*

In the same paper [40] we prove that the set of primitive elements of F is not definable if $rank(F) > 2$.

The definition of a sub-multi pattern used in the theorem below is technical. It is Definition 6 in [40].

Theorem 2.11 ([40]). *For every definable set $P \subseteq F^m$ in a free group F, either P or its complement $\neg P$ is a sub-multipattern.*

This theorem implies Bestvina and Feighn's conjecture that every definable set in F is either negligible or co-negligible (Definition 15 in [40].)

Negligible subsets in that sense are also negligible in a sense of complexity theory. Recall that in complexity theory $T \subseteq F(X)$ is called generic if

$$\rho_n(T) = \frac{|T \cap B_n(X)|}{|B_n(X)|} \to 1, \ as \ n \to \infty,$$

where $B_n(X)$ is the ball of radius n in the Cayley graph of $F(X)$. A set is called negligible is its complement is generic.

3. Equations, algebraic geometry, and universal theory

The work of mathematicians on the Tarski conjectures was rather fruitful - several areas of group theory were developed along the way. It was clear from the beginning that one needs a precise description of solution sets of systems of equations over free groups and a robust

theory of finitely generated groups which satisfy the same universal (existential) formulas as a free non-abelian group. Basics of algebraic (or Diophantine) geometry over groups had been outlined by Baumslag, Miasnikov and Remeslennikov in [6], while the fundamentals of the elimination theory and the theory of fully residually free groups appeared in the works [33, 34]. Those two papers contain results that became fundamental for the proofs of the above theorems.

3.1. Milestones in the theory of equations in free groups. The first general results on equations in groups appeared in the 1960's [51]. Lyndon introduced an axiomatic theory of length functions and initiated the study of fully residually free groups. He proved [50] that the completion $F^{\mathbb{Z}[t]}$ of a free group F by the polynomial ring $\mathbb{Z}[t]$ is discriminated by F. This is, actually, a Fraisse model in the appropriate category. Notice, that the class of limit groups has joint embedding property and it is closed under taking subgroups, but it is not closed under amalgamation, so the standard Fraisse theorem does not apply. However, replacing arbitrary embeddings with $\exists_1$-embeddings (i.e., discriminating embeddings) one can reproduce the Fraisse construction and get similar results. If we further restrict the class of $\exists_1$-embeddings allowing only free products and centralizer extensions then the Fraisse models in this category will be all isomorphic to $F^{\mathbb{Z}[t]}$.

Malcev [56] described solutions of the equation $zxyx^{-1}y^{-1}z^{-1} = aba^{-1}b^{-1}$ in a free group. The description uses the group of automorphisms of the coordinate group of the equation, and the minimal solutions relative to these automorphisms - a very powerful idea, that nowadays is inseparable from the modern approach to equations.

Merzljakov proved [55] a remarkable theorem that any two nonabelian free groups of finite rank have the same positive theory, and also showed that positive formulas in free groups have definable Skolem functions, thus giving quantifier elimination of positive formulas in free groups to existential formulas. Recall that the positive theory of a group consists of all positive (without negations in their normal forms) sentences that are true in this group.

In the 1980's new crucial concepts were introduced. Makanin proved [52] the algorithmic decidability of the Diophantine problem over free groups, and showed that both the universal theory and the positive theory of a free group are algorithmically decidable. He created an extremely powerful technique (the Makanin elimination process) to deal with equations over free groups.

Shortly afterwards, Razborov described the solution set of an arbitrary system of equations over a free group in terms of what is known now as Makanin-Razborov diagrams [66, 67].

Solution sets of arbitrary quadratic equations over free groups were described in [15] and [23]. These equations came to group theory from topology and their role in group theory was not altogether clear then. Now they form one of the corner-stones of the theory of equations in groups, due to their relations to JSJ-decompositions of groups and NTQ systems.

3.2. Basic notions of algebraic geometry over groups. Following [6] and [35] we introduce here some basic notions of algebraic geometry over groups.

Let G be a group generated by a finite set A, $F(X)$ be a free group with basis $X = \{x_1, x_2, \dots x_n\}$, define $G[X] = G * F(X)$. If $S \subset G[X]$ then the expression $S = 1$ is called *a system of equations* over G. As an element of the free product, the left side of every equation in $S = 1$ can be written as a product of some elements from $X \cup X^{-1}$ (which are called *variables*) and some elements from A (*constants*). To emphasize this we sometimes

write $S(X, A) = 1$.

A *solution* of the system $S(X, A) = 1$ over a group G is a tuple of elements $g_1, \ldots, g_n \in G$ such that after replacement of each x_i by g_i the left hand side of every equation in $S = 1$ turns into the trivial element of G. To study equations over a given fixed group G it is convenient to consider the category of G-groups, i.e., groups which contain the group G as a distinguished subgroup. If H and K are G-groups then a homomorphism $\phi : H \to K$ is a G- homomorphism if $g^\phi = g$ for every $g \in G$, in this event we write $\phi : H \to_G K$. In this category morphisms are G-homomorphisms; subgroups are G-subgroups, etc. A solution of the system $S = 1$ over G can be described as a G-homomorphism $\phi : G[X] \longrightarrow G$ such that $\phi(S) = 1$. Denote by $ncl(S)$ the normal closure of S in $G[X]$, and by G_S the quotient group $G[X]/ncl(S)$. Then every solution of $S(X, A) = 1$ in G corresponds to a G-homomorphism $G_S \to G$, and vice versa. By $V_G(S)$ we denote the set of all solutions in G of the system $S = 1$, it is called the *algebraic set defined by* S. The algebraic set $V_G(S)$ uniquely corresponds to the normal subgroup

$$R(S) = \{T(x) \in G[X] \mid \forall A \in G^n (S(A) = 1 \to T(A) = 1\}$$

of the group $G[X]$. Notice that if $V_G(S) = \emptyset$, then $R(S) = G[X]$. The subgroup $R(S)$ contains S, and it is called the *radical of* S. The quotient group

$$G_{R(S)} = G[X]/R(S)$$

is the *coordinate group* of the system $S(X, A) = 1$. Again, every solution of $S(X) = 1$ in G can be described as a G-homomorphism $G_{R(S)} \to G$.

A group G is called a *CSA group* if every maximal abelian subgroup M of G is malnormal, i.e., $M^g \cap M = 1$ for any $g \in G - M$. The abbreviation CSA means conjugacy separability for maximal abelian subgroups. The class of CSA-groups is quite substantial. It includes all abelian groups, all torsion-free hyperbolic groups, all groups acting freely on Λ-trees and many one-relator groups (see, for example, [22].

We can define a *Zariski topology* on G^n by taking algebraic sets in G^n as a sub-basis for the closed sets of this topology.

A group G is called *equationally Noetherian* if every system $S(X) = 1$ with coefficients from G is equivalent over G to a finite subsystem $S_0 = 1$, where $S_0 \subset S$, i.e., $V_G(S) = V_G(S_0)$. It is known that linear groups (in particular, fully residually free groups) are equationally Noetherian (see [6, 9, 21]). Torsion-free hyperbolic groups are also equationally Noetherian [71]. If G is equationally Noetherian then the Zariski topology on G^n is *Noetherian* for every n, i.e., every proper descending chain of closed sets in G^n is finite. This implies that every algebraic set V in G^n is a finite union of irreducible subsets (called *irreducible components* of V), and such decomposition of V is unique. Recall that a closed subset V is *irreducible* if it is not a union of two proper closed subsets.

3.3. Fully residually free groups (limit groups) and Γ-limit groups. Finitely generated fully residually free groups (limit groups) play a crucial role in the theory of equations and first-order formulas over a free group. Recall that a group G is called *fully residually free* (or *freely discriminated*, or *ω-residually free*) if for any finite subset of non-trivial elements $g_1, \ldots, g_n \in G$ there exists a homomorphism ϕ of G into a free group F, such that $\phi(g_i) \neq 1$ for $i = 1, \ldots, n$. These groups are torsion-free, have the CSA property, each of their abelian subgroup is finitely generated, they are finitely presented [34] and linear.

Below, let Γ be a torsion-free hyperbolic group. A group G is fully residually Γ if for any finite set of non-trivial elements $g_1, \dots, g_n \in G$ there exists a Γ-homomorphism ϕ from G to Γ such that $\phi(g_i) \neq 1$ for $i = 1, \dots, n$. The following result appears for general algebras in [18]. We will formulate it for fully residually Γ groups.

Proposition 3.1. *Let G be a finitely generated Γ-group (containing a distinguished copy of Γ). Then the following conditions are equivalent:*

(1) *G is fully residually Γ;*

(2) *G is universally equivalent to Γ (in the language with constants);*

(3) *G is the coordinate group of an irreducible algebraic set over Γ;*

(4) *G is a Γ- limit group;*

(5) *G embeds into an ultrapower of Γ with Γ embeddded diagonally.*

3.4. Structure and embedding. Let Γ be a torsion-free hyperbolic group. An *iterated centralizer extension* of Γ can be obtained from Γ by a chain of HNN-extensions of a very specific type, so-called *extensions of centralizers*: $\Gamma = G_0 < G_1 < \dots < G_n$ where $G_{i+1} = \langle G_i, t_i \mid [C_{G_i}(u_i), t_i] = 1 \rangle$ (extension of the centralizer $C_{G_i}(u_i)$, where $u_i \in G_i$).

Theorem 3.2 ([34, 35]). *Given an irreducible system $S = 1$ over F one can effectively embed the coordinate group $F_{R(S)}$ into $F^{Z[t]}$ i.e., one can find $n \in \mathbb{N}$ and an embedding $F_{R(S)} \to G_n$ into an iterated centralizer extension G_n of F. The analogous result is true for a torsion-free hyperbolic group Γ in place of F [41, 42].*

Since every subgroup of a free group is free, this implies that every finitely generated fully residually free group is finitely presented (this is not true for fully residually Γ groups).

This allows one to study the coordinate groups of irreducible systems of equations via their splittings into graphs of groups. This also provides a complete description of limit groups (Γ-limit groups) and gives a lot of information about their algebraic structure. In particular, limit groups act freely on $\mathbb{Z}^n$-trees with lexicographic order, and all limit groups (strict Γ-limit groups), except for abelian and surface groups, have a non-trivial cyclic JSJ-decomposition.

Let K be an HNN-extension of a group G with associated subgroups A and B. K is called a *separated HNN-extension* if for any $g \in G$, $A^g \cap B = 1$.

Corollary 3.3 ([42]). *Let G be a Γ-limit group. There exists a group H isomorphic to G that can be obtained from a finite family $\Gamma_1, \dots, \Gamma_m$ of finitely generated subgroups of Γ and free abelian groups of finite rank by a finite sequence $\tau = (\tau_1, \dots, \tau_k)$ of operations of the following type: free products, free products with abelian amalgamated subgroups (at least one of which is a maximal abelian subgroup in its factor), free extensions of centralizers, and separated HNN-extensions with abelian associated subgroups (at least one of which is maximal).*

If G is given as the coordinate group of a finite system of equations over Γ or as a subgroup of an iterated centralizer extension of Γ (by a finite set of generators), then there is an algorithm to find a sequence τ as above, as well as the required family of subgroups $\Gamma_1, \dots, \Gamma_m$ of Γ (given by their finite generating sets), and an isomorphism between G and H.

Therefore if G is given as a subgroup of an iterated centralizer extension, we can find its representation as a coordinate group of a finite system of equations.

3.5. NTQ systems and groups. Elimination process (EP) is a symbolic rewriting process of a certain type that transforms formal systems of equations in groups or semigroups. Elimination processes proved to be crucial in solving various problems in groups: finding solutions of equations, finding non-trivial abelian splittings and JSJ decompositions, describing algebraic structure of the coordinate groups of irreducible systems of equations over a given group, classifying groups acting freely on Λ-trees, etc. They may differ a lot from one another, but they always have some common features. Most of these common features can be traced back to the original Makanin-Razborov process [66, 67], but there is a crucial one that appear first in 1996 in the paper [34], were it was used to obtain an effective description of solutions of equations in free (and fully residually free) groups in a particularly nice form. In general, this new feature can be described as an algorithm to reduce a given system of group equations over a group G (which is either free or has a free length function or is close in some sense to a free group) to a finite number of systems of equations in the *triangular quasi-quadratic* form (an analog of Gauss elimination process in the non-commutative setting). At the level of algebraic geometry this algorithm finds all irreducible components of a given algebraic set over G, in particular it embeds the coordinate group of a given system of equations in G into a finite direct product of NTQ groups (later Sela referred to NTQ groups as *ω-residually free towers* [71]). While at the level of groups the algorithm gives an embedding of a finitely generated residually G group into a finite direct product of fully residually G groups. Of course, this algorithm does not work for arbitrary groups G, but it does for quite a few of them (see, for example,[10, 11, 41, 44]).

Now we give formal definitions and describe some results.

Triangular quasi-quadratic (TQ) system is a finite system that has the following form

$$\begin{aligned} S_1\left(X_1, X_2, \ldots, X_n, A\right) &= 1, \\ S_2\left(X_2, \ldots, X_n, A\right) &= 1, \\ &\vdots \\ S_n\left(X_n, A\right) &= 1 \end{aligned}$$

where either $S_i = 1$ is quadratic in variables X_i, or $S_i = 1$ is a system $[x_j, x_k] = 1$ and, in addition, equations $[x, u] = 1$ for all $x, x_j, x_k \in X_i$ and some $u \in F_{R(S_{i+1},\ldots,S_n)}$ or S_i is empty.

A TQ system above is non-degenerate (NTQ) if for every i, $S_i(X_i, \ldots, X_n, A) = 1$ has a solution in the coordinate group $G_i = F_{R(S_{i+1},\ldots,S_n)}$, where $G_n = F$ (or $G_n = \Gamma$).

We proved in [33] (see also [35]) that *NTQ systems define irreducible algebraic sets* and, therefore, their coordinate groups, where the radical is computed in a non-abelian free group $F(A)$ (respectively, with the radical computed in a free product of $\Gamma(A)$ and a free group), that are called *NTQ groups*, are fully residually free (resp., fully residually Γ).

We represented a solution set of a system of equations canonically as a union of solutions of a finite family of NTQ groups.

Theorem 3.4 ([34, 35]). *One can effectively construct EP that starts on an arbitrary system*

$$S(X, A) = 1$$

over F and results in finitely many NTQ systems

$$U_1(Y_1, A) = 1, \ldots, U_m(Y_m, A) = 1$$

such that

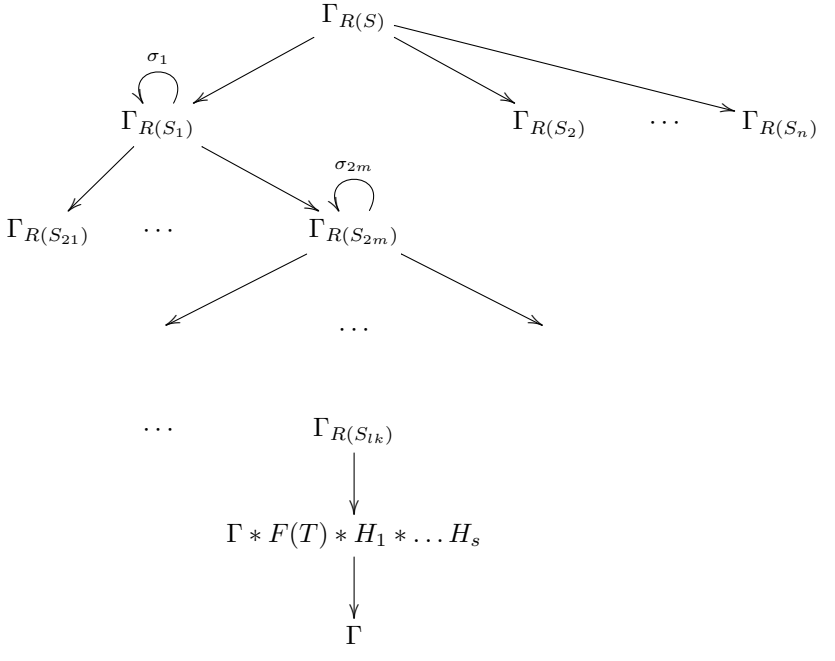
$$V_F(S) = P_1(V(U_1)) \cup \ldots \cup P_m(V(U_m))$$

for some word mappings $P_1, \ldots, P_m$. (P_i maps a tuple $\bar{Y}_i \in V(U_i)$ to a tuple $\bar{X} \in V_F(S)$. One can think about P_i as an A-homomorphism from $F_{R(S)}$ into $F_{R(U_i)}$, then any solution $\psi : F_{R(U_i)} \to F$ pre-composed with P_i gives a solution $\phi : F_{R(S)} \to F$).

Similarly one can effectively describe a solution set of a a system over a torsion-free hyperbolic group Γ [44].

Our elimination process can be viewed as a non-commutative analog of the classical elimination process in algebraic geometry.

A *Hom-diagram* is a finite rooted directed tree with groups assigned to its vertices and homomorphisms assigned to the edges. Here all groups, except, maybe, the one in the root, are fully residually Γ, (given by a finite presentation relatively to a finite number of finitely generated subgroups of Γ) arrows pointing down (except the last one) correspond to fixed epimorphisms (defined effectively in terms of generators) with non-trivial kernels, and loops correspond to automorphisms of the coordinate groups. A family of homomorphisms encoded in a path from the root to the leaf of this tree (each homomorphism in the family is a composition of a sequence of automorphisms and fixed epimorphisms assigned to edges) is called a *fundamental sequence* of homomorphisms.



where $H_1, \ldots, H_s$ are isomorphic to finitely generated subgroups of Γ, the arrows pointing to the leaf correspond to embeddings of $H_1, \ldots, H_s$ into Γ and arbitrary specializations of free variables from T.

Theorem 3.5 ([34, 35, 41]). *All solutions of the system of equations $S = 1$ in Γ can be effectively represented as homomorphisms from $\Gamma_{R(S)}$ into Γ encoded into a finite canonical Hom-diagram.*

Therefore the solution set of the system $S = 1$ consists of a finite number of fundamental sequences. And each fundamental sequence "factors through" one of the NTQ systems from Theorem 3.4 (or the analogous theorem for Γ). If $S = 1$ over Γ is irreducible, or, equivalently, $G = \Gamma_{R(S)}$ is fully residually Γ, then, obviously, one of the fundamental sequences discriminates G. This gives the following result.

Theorem 3.6 ([34, 35, 41]). *A finitely generated fully residually Γ group G is a subgroup of the coordinate group of an NTQ system. There is an algorithm to construct this embedding. There is an algorithm to construct an abelian JSJ decomposition of G.*

This corresponds to the extension theorems in the classical theory of elimination for polynomials.

Since NTQ groups are fully residually Γ, fundamental sequences corresponding to different NTQ groups discriminate fully residually Γ groups which are coordinate groups of irreducible components of system $S(X, A) = 1$. This implies

Theorem 3.7 ([34, 35, 41]). *There is an algorithm to find irreducible components for a system of equations $S(X, A) = 1$ over Γ. Equivalently, there is an algorithm to find maximal limit quotients of the coordinate group of $S(X, A) = 1$.*

3.6. Subgroups of limit groups.

Theorem 3.8. *Let G be a limit group.*

(1) *All finitely generated subgroups of G are quasi-isometrically embedded,*

(2) *Given a finite set of elements of G we can find a finite presentation of a subgroup generated by this set,*

(3) *All the classcal algorithmic problems for subgroups of G are decidable (see [38, §8]).*

4. Groups elementarily equivalent to non-abelian free groups

If an NTQ group, with the radical computed in a non-abelian free group, does not contain non-cyclic abelian groups we call it *regular NTQ group*. We have shown in [34] that regular NTQ groups are hyperbolic.

Theorem 4.1 ([38]). *Regular NTQ groups are exactly the finitely generated models of the elementary theory of a non-abelian free group.*

Sela also gave a description of finitely generated models of the elementary theory of a non-abelian free group in terms of *hyperbolic ω-residually free towers* ([73], Theorem 7). However, it was not quite correct, the definition of a hyperbolic ω-residually free tower given in [73] had to be changed. It was partially corrected in [63] and completely corrected in [64].

5. Group actions

We investigate non-Archimedean group actions, length functions and infinite words using the same elimination process that we use for solving equations in a free group. In [50] Lyndon

introduced real-valued length functions as a tool to carry over Nielsen cancelation theory from free groups to a more general setting. Some results in this direction were obtained in [3, 25–27, 65]. In [12] Chiswell described a crucial construction which shows that a group with a real-valued length function has an action on an $\mathbb{R}$-tree, and vice versa. Later, Morgan and Shalen realized that a similar construction and results hold for an arbitrary group with a Lyndon length function which takes values in an arbitrary ordered abelian group Λ (see [61]). In particular, they introduced Λ-trees as a natural generalization of $\mathbb{R}$-trees which they studied in relation with Thurston's Geometrization Program. Thus, actions on Λ-trees and Lyndon length functions with values in Λ are two equivalent languages describing the same class of groups. In the case when the action is free (the stabilizer of every point is trivial) we call groups in this class Λ-free. We refer to the book [13] for a detailed discussion on the subject.

One of the major events in combinatorial group theory in 1970's was the development of Bass-Serre theory. We refer to the book [76], where Serre laid down fundamentals of the theory of groups acting freely on simplicial trees. In particular, Bass-Serre theory makes it possible to extract information about the structure of a group from its action on a simplicial tree. Alperin and Bass [2] developed the initial framework of the theory of group actions on Λ-trees and stated the fundamental research goals: find the group theoretic information carried by an action (by isometries) on a Λ-tree; generalize Bass-Serre theory to actions on arbitrary Λ-trees.

A joint effort of several researchers culminated in a description of finitely generated groups acting freely on $\mathbb{R}$-trees [8, 20], which is now known as Rips' theorem: a finitely generated group acts freely on an $\mathbb{R}$-tree if and only if it is a free product of free abelian groups and surface groups (with an exception of non-orientable surfaces of genus $1, 2$, and 3). The key ingredient of this theory is the so-called "Rips machine", the idea of which comes from Makanin's algorithm for solving equations in free groups (see [52]). The Rips machine appears in applications as a general tool that takes a sequence of isometric actions of a group G on some "negatively curved spaces" and produces an isometric action of G on an $\mathbb{R}$-tree as the Gromov-Hausdorff limit of the sequence of spaces. Free actions on $\mathbb{R}$-trees cover all Archimedean actions, since every group acting freely on a Λ-tree for an Archimedean ordered abelian group Λ also acts freely on an $\mathbb{R}$-tree.

In the non-Archimedean case there were only partial results for particular choices of Λ. First of all, in [4] Bass studied finitely generated groups acting freely on $\Lambda_0 \oplus \mathbb{Z}$-trees with respect to the right lexicographic order on $\Lambda_0 \oplus \mathbb{Z}$, where Λ_0 is any ordered abelian group. In this case it was shown that the group acting freely on a $\Lambda_0 \oplus \mathbb{Z}$-tree splits into a graph of groups with Λ_0-free vertex groups and maximal abelian edge groups. Next, Guirardel (see [24]) obtained the structure of finitely generated groups acting freely on $\mathbb{R}^n$-trees (with the lexicographic order). In [46] the authors described the class of finitely generated groups acting freely and regularly on $\mathbb{Z}^n$-trees in terms of HNN-extensions of a very particular type. The action is *regular* if all branch points are in the same orbit. The importance of regular actions becomes clear from the results of [48], where we proved that a finitely generated group acting freely on a $\mathbb{Z}^n$-tree is a subgroup of a finitely generated group acting freely and regularly on a $\mathbb{Z}^m$-tree for $m \geqslant n$, and the paper [14], where is was shown that a group acting freely on a Λ-tree (for arbitrary Λ) can always be embedded in a length-preserving way into a group acting freely and regularly on a Λ-tree (for the same Λ).

In [45] we gave a partial solution (for finitely presented groups) of the following main problem of the Alperin-Bass program.

Problem. Describe finitely presented (finitely generated) Λ-free groups for an arbitrary ordered abelian group Λ.

We proved the following results.

Theorem 5.1. *Any finitely presented regular Λ-free group G can be represented as a union of a finite series of groups*

$$G_1 < G_2 < \cdots < G_n = G,$$

where

(1) *G_1 is a free group,*

(2) *G_{i+1} is obtained from G_i by finitely many HNN-extensions in which associated subgroups are maximal abelian, finitely generated, and the associated isomorphisms preserve the length induced from G_i.*

Theorem 5.2. *Any finitely presented Λ-free group can be isometrically embedded into a finitely presented regular Λ-free group.*

Theorem 5.3. *Any finitely presented Λ-free group G is $\mathbb{R}^n$-free for an appropriate $n \in \mathbb{N}$, where $\mathbb{R}^n$ is ordered lexicographically.*

Theorem 5.4. *Let G be a finitely presented group with a free Lyndon length function $l : G \to \Lambda$. Then the subgroup Λ_0 generated by $l(G)$ in Λ is finitely generated.*

The following result automatically follows from Theorem 5.1 and Theorem 5.2 by simple application of Bass-Serre Theory.

Theorem 5.5. *Any finitely presented Λ-free group G can be obtained from free groups by a finite sequence of amalgamated free products and HNN extensions along maximal abelian subgroups, which are free abelian groups of finite rank.*

The following result concerns abelian subgroups of Λ-free groups. For $\Lambda = \mathbb{Z}^n$ it follows from the main structural result for $\mathbb{Z}^n$-free groups and [47], for $\Lambda = \mathbb{R}^n$ it was proved in [24]. The statement 1) below answers Question 2 (page 250) from [13] in the affirmative for finitely presented Λ-free groups.

Theorem 5.6. *Let G be a finitely presented Λ-free group. Then:*

(1) *every abelian subgroup of G is a free abelian group of finite rank, which is uniformly bounded from above by the rank of the abelianization of G.*

(2) *G has only finitely many conjugacy classes of maximal non-cyclic abelian subgroups,*

(3) *G has a finite classifying space and the cohomological dimension of G is at most $\max\{2, r\}$ where r is the maximal rank of an abelian subgroup of G.*

Theorem 5.7. *Every finitely presented Λ-free group is hyperbolic relative to its non-cyclic abelian subgroups.*

This follows from the structural Theorem 5.1 and the Combination Theorem for relatively hyperbolic groups [16].

The following results answers affirmatively the strongest form of the Problem (GO3) from the Magnus list of open problems [5], in the case of finitely presented groups.

Corollary 5.8. *Every finitely presented Λ-free group is biautomatic.*

Proof. This follows from Theorem 5.7 and Rebbechi's result [70]. □

Definition 5.9. A *hierarchy* for a group G is a way to repeatedly build it starting with trivial groups by repeatedly taking amalgamated products $A *_C B$ and HNN extensions $A*_{C^t=D}$ whose vertex groups have shorter length hierarchies. The hierarchy is *quasi convex* if the amalgamated subgroup C is a finitely generated subgroups that embeds by a quasi-isometric embedding, and if C is malnormal in $A *_c B$ or $A*_{C^t=D}$.

Theorem 5.10. *Every finitely presented Λ-free group G has a quasi-convex hierarchy with abelian edge groups.*

Theorem 5.11 ([78]). *Suppose G is toral relatively hyperbolic and has a malnormal quasi convex hierarchy. Then G is virtually special (therefore has a finite index subgroup that is a subgroup of a right angled Artin group (RAAG)).*

As a corollary one gets the following result.

Corollary 5.12. *Every finitely presented Λ-free group G is locally undistorted, that is, every finitely generated subgroup of G is quasi-isometrically embedded into G.*

Corollary 5.13. *Every finitely presented Λ-free group G is virtually special, that is, some subgroup of finite index in G embeds into a right-angled Artin group.*

The following result answers in the affirmative to Question 3 (page 250) from [13] in the case of finitely presented groups.

Theorem 5.14. *Every finitely presented Λ-free group is right orderable.*

The following addresses Chiswell's question whether Λ-free groups are orderable or not.

Theorem 5.15. *Every finitely presented Λ-free group is virtually orderable, that is, it contains an orderable subgroup of finite index.*

Since right-angled Artin groups are linear and the class of linear groups is closed under finite extension we get the following

Theorem 5.16. *Every finitely presented Λ-free group is linear.*

Since every linear group is residually finite we get the following.

Corollary 5.17. *Every finitely presented Λ-free group is residually finite.*

Corollary 5.18. *Let G be a finitely presented Λ-free group. Then the following algorithmic problems are decidable in G:*

- *the Word and Conjugacy Problems;,*
- *the Diophantine Problem (decidability of arbitrary equations in G).*

Indeed, decidability of equations follows from [16]. Results of Dahmani and Groves [17] imply the following two corollaries.

Corollary 5.19. *Let G be a finitely presented Λ-free group. Then:*

- *G has a non-trivial abelian splitting and one can find such a splitting effectively,*
- *G has a non-trivial abelian JSJ-decomposition and one can find such a decomposition effectively.*

Corollary 5.20. *The isomorphism problem is decidable in the class of finitely presented groups that act freely on Λ-trees.*

Theorem 5.21. *The subgroup membership problem is decidable in every finitely presented Λ-free group.*

6. Open problems

6.1. Free, torsion-free hyperbolic, and toral relatively hyperbolic groups. The Diophantine problem in free groups is decidable, though the time complexity of the original Makanin's algorithm [52] is not primitive recursive [31]. Recent improvements on the time complexity of this problem allows one to put forward the following.

Problem 6.1. Is it true that the Diophantine problem in a free group is in NP (hence NP-complete)?

Affirmative solution to this problem would put solving equations in free groups, as well as some other rather complex algorithms in groups, into the realm of reasonable computations.

As we have mentioned in the previous sections the Tarski and Malcev's problems are now solved for torsion-free hyperbolic groups, as well as effective quantifier elimination to boolean combinations of $\forall\exists$-formulas. Elementary embeddings in the elementary theories of free and torsion-free hyperbolic groups were studied and described in [63, 64]. However, some principal model-theoretic questions (see Section 1) for free groups are still open. In particular, the following one is of crucial interest.

Problem 6.2.

1) Describe a natural system of axioms for the elementary theory of a free non-abelian group.
2) Describe a natural system of axioms for the elementary theory of a torsion-free hyperbolic group.

Problem 6.3. Describe existentially closed groups in the elementary theory of a free non-abelian (non-elementary torsion-free hyperbolic) group.

Problem 6.4. Solve principal model-theoretic questions for toral relatively hyperbolic groups.

6.2. Free products. Decidability of equations and description of algebraic sets in a free product of group $A * B$ was solved in [10].

Recently it was announced in [75] that if H_i and G_i are groups such that $Th(G_i) = Th(H_i)$, $i = 1, 2$, then $Th(H_1 * H_2) = Th(G_1 * G_2)$.

It seems it is a good time now to study elementary theories of free products.

Problem 6.5. Address the *principle model-theoretic problems* for free products of groups "modulo the factors".

In particular, the following concrete problems are of prime interest.

Problem 6.6 (Decidability of the elementary theory). Prove that if $Th(A)$ and $Th(B)$ are decidable then $Th(A * B)$ is also decidable.

Problem 6.7. Let G be a group and A a free factor of G. Prove that if $Th(G)$ is decidable then $Th(A)$ is also decidable.

To attack this problem one may use the elimination process developed in [10].

Finally, we suggest to study model theory of toral relatively hyperbolic groups. This is much more general class then torsion-free hyperbolic or limit groups, nevertheless, we believe that the methods developed for the groups above should suffice to address the larger class as well.

Problem 6.8. Solve principal model-theoretic questions for toral relatively hyperbolic groups.

Perhaps, a good start would be to address the following (easier) problem.

Problem 6.9. Solve principal model-theoretic questions for limit groups.

6.3. Right angled Artin groups. Right angled Artin groups play an increasingly important part in modern geometric and combinatorial group theory due to results of Wise [78], Agol [1] etc. Recall that a RAAG G is a group given by a presentation of the form $< a_1, \ldots, a_r | R >$, where R is a subset of the set $\{[a_i, a_j] | i, j = 1, \ldots, r\}$.

Casals-Ruiz and Kazachkov [11] obtained an algorithmic description of the solution set of a system of equations in RAAGs.

It is time now to develop algebraic geometry and model theory over RAAGS. Algebraic geometry over RAAGs is different from algebraic geometry over relatively hyperbolic groups. New types of "splittings" occur, and new "universal" splittings should be defined. Notice that it follows from [19] that the universal theory of any RAAG is decidable. We formulate here the following Tarski type questions.

Problem 6.10. Princilal model-theoretic questions for RAAGs. Let A be a right angled Artin group.

(1) Describe when two RAAGs are elementary equivalent.

(2) Is the elementary theory $Th(A)$ decidable?

(3) Describe a natural system of axioms for $Th(A)$.

(4) Which finitely generated groups are elementary equivalent to A?

It is known that two RAAGs defined by graphs Γ and Δ are isomorphic iff the graphs Γ and Δ are isomorphic [30]. This gives an easy classification of RAAGs up to isomorphism. However, according to our philosophy, to study algebraic properties of RAAGs, in particular, algebraic geometry and model theory of RAAGs, one need to look at all groups which are fully residually RAAGs. This requires a good understanding of finitely generated subgroups of RAAGs. Notice that the class $\mathcal{S}$ of all finitely generated subgroups of RAAGs is very large, as Wise's theorem reveals. For example, limit groups are virtually subgroups

of RAAG, as well as one-relator groups with torsion. We know already that RAAGs contain a lot of interesting groups as their subgroups. But we do not know yet if the class is so large that it gets out of hand. Solution to the following problem will clarify the situation.

Problem 6.11. Is the isomorphism problem for finitely generated quasi-convex subgroups of RAAGs decidable?

6.4. Pro-finite groups. Solutions to Tarsky's problems for free groups inspires us to pose the following problem.

Problem 6.12. Study the principal model-theoretic questions for free pro-p-groups of finite rank.

Notice that two finitely generated pro-p-groups are elementarily equivalent if and only if they are isomorphic [58]. The same is true for two finitely generated pro-finite groups [29], though in this case the argument is based on hard results from [62]. Observe, that the terms $\gamma_m(\hat{F}_n)$ of the lower central series of a free pro-p-groups $\hat{F}_n$ of finite rank have finite width, so they are definable in $\hat{F}_n$, hence the free nilpotent pro-p-groups which are quotients $\hat{F}_n/\gamma(\hat{F}_n)$ are interpretable in $\hat{F}_n$. That has some impact on the elementary theory of $\hat{F}_n$. Finitely generated nilpotent pro-p-groups with decidable elementary theory were described in [58], in particular, the theories of the quotients $\hat{F}_n/\gamma(\hat{F}_n)$ are decidable. Now we formulate two concrete related questions in this area.

Problem 6.13.

1) Find a set of axioms of $Th(\hat{F}_n)$.
2) Prove that the theory $Th(\hat{F}_n)$ is decidable.

To address these questions we believe one has to develop first the theory of equations and algebraic geometry over $\hat{F}_n$. To this end we formulate several questions.

Problem 6.14. Prove that the group $\hat{F}_n$ is equationally Noetherian.

Of course, equations in this case are the "pro-p-equations" (see [54] for definitions and some results).

Problem 6.15. Prove that the Diophantine problem for $\hat{F}_n$ is decidable.

6.5. Problems for free associative and Lie algebras. It is very interesting to study elementary theories of free associative and Lie algebras. It was shown in [60] that elementary theory of a finite dimensional free associative or Lie algebra with coefficients in a field with undecidable theory is also undecidable. So we may assume from the outset the we consider coefficients from a nice field, say a field of two elements or an algebraically closed field of characteristic zero.

Problem 6.16. Prove that the Diophantine problem is decidable for free associative algebras.

Problem 6.17. Are free associative finitely generated algebras equationally Noetherian?

Let $\mathcal{A}$ be such an algebra. If the answer is positive then the Zariski topology over $\mathcal{A}^n$ is Noetherian for every natural number n, so one can try to develop the algebraic geometry for

$\mathcal{A}$ along the same lines as for free groups. Otherwise, the treatment of associative algebras should be quite different.

Notice, that if $\mathcal{A}$ is equationally Noetherian, then the free Lie algebra associated with $\mathcal{A}$ is also equationally Noetherian. But whether the converse is true or not is not known. So we pose the following question independently.

Problem 6.18. Are free Lie finitely generated algebras $\mathcal{L}$ equationally Noetherian?

If free associative (Lie) algebras $\mathcal{A}$ are equationally noetherian, then by the unification theorem [18] finitely generated limits of $\mathcal{A}$ are precisely the finitely generated algebras universally equivalent to $\mathcal{A}$. In this case a lot of machinery of universal algebraic geometry is going to work. In any case the following problem is of principle interest.

Problem 6.19. Describe limits of free associative (Lie) algebras.

Unlike free groups, two free associative algebras of finite rank are elementarily equivalent if and only if they are isomorphic (these, and some other relevant facts, can be found in [60]).

The following general Tarski-type problems are of special interest.

Problem 6.20. Let $\mathcal{A}$ be a free associative (Lie) algebra of finite rank.

(1) Prove that if the ground field has decidable theory then the elementary theory $Th(\mathcal{A})$ algebra is also decidable.

(2) Describe a natural system of axioms for $Th(\mathcal{A})$.

(3) Does the elementary theory $Th(\mathcal{A})$ admit elimination of quantifiers (to boolean combinations of $\forall\exists$-sentences and the theory of the ground field)?

(4) Which finitely generated algebras are elementarily equivalent to $\mathcal{A}$?

6.6. Λ-free groups.

Conjecture 6.21. *Every finitely generated Λ-free group is finitely presented.*

This would imply that all the result mentioned in Section 5 hold also in arbitrary finitely generated Λ-free groups.

Conjecture 6.22. *Any finitely presented Λ-free group G is $\mathbb{Z}^k$-free for an appropriate $k \in \mathbb{N}$ and lexicographically ordered $\mathbb{Z}^k$.*

Towards the eigenvalue rigidity of Zariski-dense subgroups

Andrei S. Rapinchuk

Abstract. We discuss the notion of weak commensurability of Zariski-dense subgroups of semi-simple algebraic groups over fields of characteristic zero, which enables one to match in a convenient way the eigenvalues of semi-simple elements of these subgroups. The analysis of weakly commensurable arithmetic groups has led to a resolution of some long-standing problems about isospectral locally symmetric spaces. This work has also initiated a number of questions in the theory of algebraic groups dealing with the characterization of absolutely almost simple simply connected algebraic groups having the same isomorphism classes of maximal tori over the field of definition. The recent results in this direction provide evidence to support a new conjectural form of rigidity for arbitrary Zariski-dense subgroups in absolutely almost simple algebraic groups over fields of characteristic zero based on the eigenvalue information ("eigenvalue rigidity").

Mathematics Subject Classification (2010). Primary 20G15; Secondary 11E72, 53C35.

Keywords. Algebraic groups, Zariski-dense subgroups, locally symmetric spaces.

1. Introduction

The purpose of my talk is two-fold. First, I would like to report on the results obtained in a series of papers written in collaboration with G. Prasad and other co-authors. In these papers, we introduced the notion of *weak commensurability* of Zariski-dense subgroups of semi-simple algebraic groups, determined the consequences of the weak commensurability of two S-arithmetic subgroups of absolutely almost simple algebraic groups over a field of characteristic zero, and applied these results to the analysis of length-commensurable isospectral locally symmetric spaces. Second, I would like to outline a variety of problems and results in the theory of algebraic groups and related areas that this work has led to. These problems have to do with the understanding of finite-dimensional division algebras having the same maximal subfields, and more generally, with the characterization of absolutely almost simple algebraic groups having the same isomorphism classes of maximal tori over the field of definition. The results in this new direction obtained in the last several years point to a new version of the rigidity phenomenon, some aspects of which apply not only in the classical case of lattices but in fact to arbitrary Zariski-dense subgroups. Its distinctive feature is that it is formulated in terms of the eigenvalues of semi-simple elements of a given Zariski-dense subgroup, which led us to call it *eigenvalue rigidity*. Its investigation is very much a work in progress, so along with available results, we will discuss several conjectures. Overall, the possibility of having some form of rigidity for arbitrary Zariski-dense subgroups

Proceedings of the International Congress of Mathematicians, Seoul, 2014

(which may well be free) looks quite exciting, and I would like to begin with a discussion of what kinds of results one can or cannot expect in this generality.

In the theory of algebraic/Lie groups, the term "rigidity" in a very general sense is used to describe a situation where, given a semi-simple algebraic group G over a field F, the structure of a "large" subgroup Γ of $G(F)$ determines the group G as well as the "location" of Γ inside $G(F)$. More concretely, when F is a non-discrete locally compact field, then under appropriate assumptions, any abstract isomorphism $\Gamma_1 \to \Gamma_2$ between two lattices $\Gamma_1, \Gamma_2 \subset G(F)$ extends to a rational automorphism of G (strong rigidity), or even any abstract representation $\Gamma \to \mathrm{GL}_n(F)$ (virtually) extends to a rational representation $G \to \mathrm{GL}_n$ (superrigidity). This implies, for example, that the entire geometry of a compact hyperbolic manifold of dimension $\geqslant 3$ (including its volume, the Laplace spectrum, the lengths of closed geodesics, etc.) is determined by the structure of its fundamental group. Among the algebraic consequences of structural rigidity, the following is most relevant for our discussion.

Let $\Gamma = \mathrm{SL}_n(\mathbb{Z})$, where $n \geqslant 3$, and suppose we are given an absolutely almost simple simply connected algebraic group G over a number field K with ring of integers $\mathcal{O}$. If Γ is (virtually) isomorphic to $G(\mathcal{O})$ as an abstract group, then $K = \mathbb{Q}$ (and hence $\mathcal{O} = \mathbb{Z}$), and $G \simeq \mathrm{SL}_n$ as algebraic groups over $\mathbb{Q}$. Thus, the structure of a higher rank arithmetic group uniquely determines the *field of definition* and the *ambient group* as an algebraic group over this field. The results we will present suggest that one should be able to recover this data (in a somewhat weaker form) not just from a higher rank arithmetic group, but in fact from any finitely generated Zariski-dense subgroup if in place of structural information one uses information about the eigenvalues of elements, expressed in terms of *weak commensurability*. More precisely, we will see that in this set-up the field of definition can still be recovered uniquely (cf. Theorem 3.2), while the ambient algebraic group over this field is conjecturally determined up to finitely many possibilities (cf. Conjecture 6.1). The finiteness is known to hold when the field of definition is a number field, and is supported in the general case by, for example, results on division algebras having the same maximal subfields (cf. 6.5). Moreover, in many situations, S-arithmetic groups are unique (up to commensurability) in their weak commensurability class (cf. Theorem 6.3(1)), and thus are eigenvalue rigid in a strong sense. Just like structural rigidity, eigenvalue rigidity has geometric applications to isospectral locally symmetric spaces (see 2.2 and 4.4). There are other aspects of eigenvalue rigidity dealing with questions of whether various properties of Zariski-dense subgroups (such as discreteness, co-compactness, arithmeticity) can be characterized in terms of the eigenvalue information (see 4.3), but here we will focus almost exclusively on the question of to what extent the latter determines the ambient algebraic group. As we already mentioned, it is precisely shifting the focus from the structure to eigenvalues that makes results of this kind possible for arbitrary Zariski-dense subgroups.

Before discussing the results, we need to explain how we match the eigenvalues of elements of two Zariski-dense subgroups, and on the other hand, why we care about these eigenvalues.

2. Weak commensurability

The following definition, introduced in [40], provides a way of matching the eigenvalues of matrices of different sizes.

Definition 2.1. Let F be an infinite field.

(1) Let $\gamma_1 \in \mathrm{GL}_{n_1}(F)$ and $\gamma_2 \in \mathrm{GL}_{n_2}(F)$ be *semi-simple matrices*, and let

$$\lambda_1, \dots, \lambda_{n_1} \quad \text{and} \quad \mu_1, \dots, \mu_{n_2}$$

be their eigenvalues (in a fixed algebraic closure $\overline{F}$). We say that γ_1 and γ_2 are *weakly commensurable* if there exist $a_1, \dots, a_{n_1}$, $b_1, \dots, b_{n_2} \in \mathbb{Z}$ such that

$$\lambda_1^{a_1} \cdots \lambda_{n_1}^{a_{n_1}} \;=\; \mu_1^{b_1} \cdots \mu_{n_2}^{b_{n_2}} \;\neq\; 1.$$

(2) Let $G_1 \subset \mathrm{GL}_{n_1}$ and $G_2 \subset \mathrm{GL}_{n_2}$ be reductive algebraic groups defined over F. Two *Zariski-dense subgroups* $\Gamma_1 \subset G_1(F)$ and $\Gamma_2 \subset G_2(F)$ are called *weakly commensurable* if every semi-simple element $\gamma_1 \in \Gamma_1$ of infinite order is weakly commensurable to some semi-simple element $\gamma_2 \in \Gamma_2$ of infinite order, and vice versa.

It should be noted that the definition of weak commensurability can be stated in several different ways. First, in the above notations, semi-simple elements $\gamma_1 \in G_1(F)$ and $\gamma_2 \in G_2(F)$ are weakly commensurable if and only if there exist maximal F-tori T_i of G_i for $i = 1, 2$ such that $\gamma_i \in T_i(F)$ and for some characters $\chi_i \in X(T_i)$ (defined over $\overline{F}$) we have

$$\chi_1(\gamma_1) = \chi_2(\gamma_2) \neq 1.$$

This reformulation shows that the notion of weak commensurability (of γ_1 and γ_2) does not depend on the choice of matrix realizations of G_1 and G_2, and is also more convenient for technical arguments.

Second, semi-simple elements $\gamma_1 \in G_1(F)$ and $\gamma_2 \in G_2(F)$ are weakly commensurable if and only if there exist F-rational representations

$$\rho_1 \colon G_1 \longrightarrow \mathrm{GL}_{m_1} \text{ and } \rho_2 \colon G_2 \longrightarrow \mathrm{GL}_{m_2}$$

such that $\rho_1(\gamma_1)$ and $\rho_2(\gamma_2)$ have a *nontrivial common eigenvalue* (these representations can vary from one element to another).

Informally speaking, weak commensurability appears to be a rather natural way (and perhaps even the only natural way) of matching the eigenvalues of (semi-simple) elements of two algebraic groups that does not depend on the choice of their matrix realizations. On the other hand, it is easy to construct examples of very different (certainly non-conjugate) matrices that are weakly commensurable, so one needs to discuss the utility of this notion. As we will see later, while being inconsequential for individual matrices and "small" (e.g., cyclic) subgroups, weak commensurability has remarkably strong consequences for "large" subgroups (viz., Zariski-dense and particularly S-arithmetic subgroups). Now, however, we would like to point out that the main motivation for the notion of weak commensurability in our work came from the famous problem in differential geometry about isospectral Riemannian manifolds best known as M.Kac's [30] question *Can one hear the shape of a drum?*

2.2. Geometric motivation. Let M be a Riemannian manifold. In differential geometry one considers the following sets of data associated with M:

- $\mathcal{E}(M)$ - spectrum of the Beltrami-Laplace operator;

- $L(M)$ - (weak) length spectrum, i.e. the collection of lengths of all closed geodesics in M.

Then one asks whether two Riemannian manifolds M_1 and M_2 are necessarily isometric if

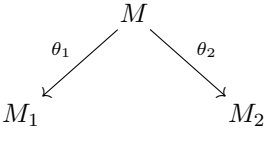
(1) $\mathcal{E}(M_1) = \mathcal{E}(M_2)$ (i.e., M_1 and M_2 are *isospectral*);

(2) $L(M_1) = L(M_2)$ (i.e., M_1 and M_2 are *iso-length spectral*)?

When asking a question of this kind, one of course needs to specialize the class of manifolds being considered, and in our work we focused on locally symmetric spaces of semi-simple groups having nonpositive curvature (recall that these are endowed with the standard Riemannian structure coming from the Killing form); this class includes such geometrically important spaces as hyperbolic manifolds and, in particular, Riemann surfaces. It is important to point out that for *compact* locally symmetric spaces, questions (1) and (2) are *related*, viz.

$$\mathcal{E}(M_1) \;=\; \mathcal{E}(M_2) \;\;\Rightarrow\;\; L(M_1) \;=\; L(M_2), \tag{S}$$

but *both* have a negative answer. Counter-examples for (arithmetically defined) Riemann surfaces were given by Vigneras [53], and then a more general group-theoretic construction was offered by Sunada [50]. Both constructions always produce pairs of *commensurable* locally symmetric spaces. We recall that Riemannian manifolds M_1 and M_2 are called *commensurable* if they admit a common finite-sheeted cover M, i.e. if there is a diagram:



in which M is a Riemannian manifold and θ_1, θ_2 are finite-sheeted locally isometric covering maps. This suggests that one should probably settle for a weaker version of the question, viz. whether M_1 and M_2 are necessarily *commensurable* given the fact that they are isospectral or iso-length-spectral. While this modified question still has a negative answer in the general case [35], our work, based on the analysis of weakly commensurable groups, shows that the answer is in the affirmative for many (arithmetically defined) locally symmetric spaces - cf. Theorem 4.5 (previously such results were available only for arithmetically defined Riemann surfaces [47] and hyperbolic 3-manifolds [12]). In fact, our results give the commensurability of pairs of locally symmetric spaces that satisfy the following condition:

(3) $\mathbb{Q} \cdot L(M_1) = \mathbb{Q} \cdot L(M_2)$.

This condition, called *length commensurability*, is conceivably much weaker than conditions (1) and (2), but surprisingly in most situations it has many of the same consequences. Its real advantage over (1) and (2) is that it is invariant under passing to commensurable manifolds.

The main point here is that the length-commensurability of finite volume locally symmetric spaces implies the weak commensurability of their fundamental groups. To give a precise statement, we need to fix some notations. Let G be an absolutely simple adjoint real algebraic group, let $\mathcal{G} = G(\mathbb{R})$ be the group of $\mathbb{R}$-points, considered as a real Lie group, and let $\mathfrak{X} = \mathcal{K}\backslash\mathcal{G}$, where $\mathcal{K}$ is a maximal compact subgroup of $\mathcal{G}$, be the associated symmetric space endowed with the Riemannian metric coming from the Killing form on the Lie algebra of $\mathcal{G}$. Furthermore, given a torsion-free discrete subgroup Γ of $\mathcal{G}$, we let $\mathfrak{X}_\Gamma = \mathfrak{X}/\Gamma$ denote

the corresponding locally symmetric space; we say that $\mathfrak{X}_\Gamma$ is *arithmetically defined* if the subgroup Γ is *arithmetic*[1]. Finally, given two simple real algebraic groups G_i $(i = 1, 2)$, we will denote the symmetric spaces of the groups $\mathcal{G}_i = G_i(\mathbb{R})$ by $\mathfrak{X}_i$, and the locally symmetric spaces obtained as quotients by torsion-free discrete subgroups Γ_i of $\mathcal{G}_i$ by $\mathfrak{X}_{\Gamma_i}$.

Theorem 2.3 ([43], Corollary 2.8). *Let $\mathfrak{X}_{\Gamma_1}$ and $\mathfrak{X}_{\Gamma_2}$ be two locally symmetric spaces having finite volume, of absolutely simple real algebraic groups G_1 and G_2. If $\mathfrak{X}_{\Gamma_1}$ and $\mathfrak{X}_{\Gamma_2}$ are length-commensurable, then Γ_1 and Γ_2 are weakly commensurable.*

While this result is straightforward for Riemann surfaces (see [43, 2.1]), its proof in the general case relies on the formula for the length of a closed geodesic c_γ in $\mathfrak{X}_\Gamma$ corresponding to a nontrivial semi-simple element $\gamma \in \Gamma$ as a function of the logarithms of eigenvalues of γ in the adjoint representation - see [40, Proposition 8.5(ii)] (note that this formula also explains why we care about the eigenvalues of semi-simple elements of discrete subgroups). So, to prove the weak commensurability of Γ_1 and Γ_2, we need to sort out the logarithms appearing in this formula, which requires transcendental number theory. More precisely, for rank one locally symmetric spaces of dimension > 2, we use the famous result of Gel'fond and Schneider that settled Hilbert's seventh problem - cf. [4]. In all other cases, our argument assumes the truth of Schanuel's conjecture (cf. [3]). This means that while all of our results on weak commensurability are, of course, unconditional, their geometric consequences are *conditional* (at least for locally symmetric spaces of rank > 1).

Since the locally symmetric spaces $\mathfrak{X}_{\Gamma_1}$ and $\mathfrak{X}_{\Gamma_2}$ are commensurable if and only if the subgroups Γ_1 and Γ_2 are commensurable as groups up to an isomorphism between G_1 and G_2 (see 3.4 below for the details of this notion), we see that in order to prove the commensurability of length-commensurable (in particular, isospectral or iso-length spectral) locally symmetric space, we need to answer the following question:

(C) *When does the weak commensurability of Γ_1 and Γ_2 imply their commensurability?*

3. First signs of eigenvalue rigidity

Before providing a rather definitive answer to Question (C) for S-arithmetic subgroups (see §4), we would like to present a few results demonstrating that weak commensurability captures some important characteristics in the case of arbitrary Zariski-dense subgroups. So, let G_1 and G_2 be absolutely almost simple algebraic groups over a field F of *characteristic zero*, and let $\Gamma_i \subset G_i(F)$ be a *finitely generated* Zariski-dense subgroup for $i = 1, 2$.

Theorem 3.1 ([40], Theorem 1). *If Γ_1 and Γ_2 are weakly commensurable, then either G_1 and G_2 are of the same Killing-Cartan type, or one of them is of type B_ℓ and the other of type C_ℓ for some $\ell \geqslant 3$.*

This result is already interesting because, in principle, Γ_1 and Γ_2 may very well be free groups, hence carry no structural information about the ambient algebraic groups. Note that what we really prove is that G_1 and G_2 have the same order of the Weyl group - it

[1]We recall that combining the celebrated results of Margulis [36] on the arithmeticity of higher rank irreducible lattices and of Corlette [15] and Gromov-Shoen [27], one obtains that a finite volume locally symmetric space $\mathfrak{X}_\Gamma$ of a simple real algebraic group is automatically arithmetically defined unless $\mathfrak{X}$ is either the real hyperbolic space $\mathbb{H}^n$ or the complex hyperbolic space $\mathbb{H}^n_{\mathbb{C}}$.

is known that this number uniquely determines the Killing-Cartan type of the group except for the ambiguity involving types B_ℓ and C_ℓ. As shown by Theorem 4.2 below, Zariski-dense, and even S-arthmetic, subgroups in groups of types B_ℓ and C_ℓ can indeed be weakly commensurable.

Now, given a Zariski-dense subgroup $\Gamma \subset G(F)$, where G is a semi-simple F-group, we let K_Γ denote the *trace field* of Γ, i.e. the subfield of F generated by the traces $\mathrm{tr}(\mathrm{Ad}\,\gamma)$ of all elements $\gamma \in \Gamma$ in the adjoint representation on the corresponding Lie algebra $\mathfrak{g} = L(G)$. By a result of Vinberg [51], the field $K = K_\Gamma$ is the minimal field of definition of $\mathrm{Ad}\ \Gamma$. This means that K is the minimal subfield of F such that all transformations in $\mathrm{Ad}\ \Gamma$ can be simultaneously represented by matrices over K in a suitable basis of $\mathfrak{g}$. If such a basis is chosen, then the Zariski closure of $\mathrm{Ad}\ \Gamma$ in $\mathrm{GL}(\mathfrak{g})$ is a semi-simple algebraic K-group $\mathcal{G}$. It is an F/K-form of the adjoint group $\overline{G}$, and we will call it the *algebraic hull* of $\mathrm{Ad}\ \Gamma$.

Theorem 3.2 ([40], Theorem 2). *Keep the notations and conventions introduced prior to Theorem 3.1. If Γ_1 and Γ_2 are weakly commensurable, then $K_{\Gamma_1} = K_{\Gamma_2}$.*

Now let K be the common trace field of two weakly commensurable Zariski-dense subgroups Γ_1 and Γ_2 as above, and let $\mathcal{G}_i$ be the algebraic hull of $\mathrm{Ad}\ \Gamma_i$ for $i = 1, 2$. We denote by L_i the minimal Galois extension of K over which $\mathcal{G}_i$ becomes an inner form of a split group.

Proposition 3.3 (cf. [44], Lemma 5.2). *In the above notations, $L_1 = L_2$.*

(We would like to mention the following useful consequence of this proposition: *Let G_1 and G_2 be absolutely almost simple groups over a field F of characteristic zero, and let E_i be the minimal Galois extension of F over which G_i becomes an inner form. If there exist finitely generated Zariski-dense subgroups $\Gamma_1 \subset G_1(F)$ and $\Gamma_2 \subset G_2(F)$ that are weakly commensurable, then $E_1 = E_2$.* Indeed, $E_i = FL_i$ in the above notations.)

3.4. *S*-arithmetic subgroups. We will now specialize to the case of S-arithmetic subgroups. We recall that if G is an absolutely almost simple algebraic group over a field F of characteristic zero, then Zariski-dense S-arithmetic subgroups of $G(F)$ can be described in terms of triples $(\mathcal{G}, K, S)$, where K is a number field contained in F, $\mathcal{G}$ is a F/K-form of the adjoint group $\overline{G}$, and S is a finite set of places of K containing all archimedean ones; the subgroups corresponding to such triples are called $(\mathcal{G}, K, S)$-*arithmetic*. We refer to [40, §1] and [43, 3.3] for the details of this description, and only indicate here that for a $(\mathcal{G}, K, S)$-arithmetic Zariski-dense subgroup Γ, the field K coincides with the trace field K_Γ, and the group $\mathcal{G}$ with the algebraic hull of $\mathrm{Ad}\ \Gamma$.

Furthermore, given two absolutely almost simple F-groups G_1 and G_2, we say that the subgroups $\Gamma_1 \subset G_1(F)$ and $\Gamma_2 \subset G_2(F)$ are *commensurable up to an F-isomorphism* between the adjoint groups $\overline{G}_1$ and $\overline{G}_2$ if there exists an F-isomorphism $\sigma\colon \overline{G}_1 \to \overline{G}_2$ such that the subgroups $\sigma(\pi_1(\Gamma_1))$ and $\pi_2(\Gamma_2)$ are commensurable as subgroups of $\overline{G}_2(F)$ in the usual sense (i.e., their intersection is of finite index in each of them), where $\pi_i\colon G_i \to \overline{G}_i$ is the canonical isogeny for $i = 1, 2$. (This notion of commensurability is precisely what we need for geometric applications, cf. §2.)

The following result shows that the description of S-arithmetic subgroups of absolutely almost simple groups in terms of triples is very convenient in the analysis of their commensurability.

Theorem 3.5. *Let G_1 and G_2 be absolutely almost simple algebraic groups defined over a field F of characteristic zero, and for $i = 1, 2$, let Γ_i be a Zariski-dense $(\mathcal{G}_i, K_i, S_i)$-arithmetic subgroup of $G_i(F)$. Then*

(1) *Γ_1 and Γ_2 are commensurable up to an F-isomorphism between $\overline{G}_1$ and $\overline{G}_2$ if and only if $K_1 = K_2$, $S_1 = S_2$, and $\mathcal{G}_1$ and $\mathcal{G}_2$ are K-isomorphic;*

(2) *if Γ_1 and Γ_2 are weakly commensurable, then $K_1 = K_2$ and $S_1 = S_2$.*

Thus, the study of the commensurability classes of weakly commensurable Zariski-dense S-arithmetic subgroups *is equivalent* to the study of K-forms $\mathcal{G}$ involved in their description. This leads to a complete resolution of question (C) for S-arithmetic subgroups that we will present in the next section.

4. Results for S-arithmetic groups and geometric consequences

The following two theorems summarize the main results dealing with the weak commensurability of S-arithmetic subgroups.

Theorem 4.1 (cf. Prasad-Rapinchuk [40, 43]). *Let G_1 and G_2 be absolutely almost simple algebraic groups over a field F of characteristic zero, and let $\Gamma_1 \subset G_1(F)$ and $\Gamma_2 \subset G_2(F)$ be Zarsiki-dense S-arithmetic subgroups.*

(1) *Assume that G_1 and G_2 are of the same Killing-Cartan type, which is different from A_n, D_{2n+1} $(n > 1)$, and E_6. If Γ_1 and Γ_2 are weakly commensurable, then they are commensurable.*

(2) *In all cases, S-arithmetic subgroups $\Gamma_2 \subset G_2(F)$ weakly commensurable to a given S-arithmetic subgroup $\Gamma_1 \subset G_1(F)$ form* finitely many *commensurability classes.*

(3) *If Γ_1 and Γ_2 as above are weakly commensurable, then Γ_1 contains unipotent elements if and only if Γ_2 does.*

(4) (arithmeticity theorem) *Let now F be a locally compact field of characteristic zero, and $\Gamma_1 \subset G_2(F)$ be an S-arithmetic lattice. If $\Gamma_2 \subset G_2(F)$ is a lattice weakly commensurable to Γ_1, then Γ_2 is also S-arithmetic.*

(In this theorem, "commensurability" means "commensurability up to an F-isomorphism between $\overline{G}_1$ and $\overline{G}_2$" as defined in 3.4.)

An interesting feature of this theorem is that for groups of type D_n, the answer to Question (C) is different depending on whether n is even or odd. Assertion (1) for type D_{2n} with $n > 2$ was originally proved in [41]. The case of type D_4 (including triality forms) was handled by Garibaldi [21] by a different method which applies to all groups of type D_{2n}. On the other hand, for each of the exceptional types A_n $(n > 1)$, D_{2n+1} $(n > 1)$, and E_6 one can construct weakly commensurable, but not commensurable, Zariski-dense S-arithmetic subgroups (see [40, §9])[2].

According to Theorem 3.1, to complete the investigation of weak commensurability for S-arithmetic subgroups, it remains to consider the case where one group is of type B_ℓ and the other of type C_ℓ for some $\ell \geqslant 3$.

[2]Note that these are precisely the types for which the multiplication by (-1) considered as an automorphism of the corresponding root system is *not* in the Weyl group.

Theorem 4.2 (Garibaldi-Rapinchuk [22]). *Let G_1 and G_2 be absolutely almost simple algebraic groups over a field F of characteristic zero having Killing-Cartan types B_ℓ and C_ℓ ($\ell \geqslant 3$), respectively, and let Γ_i be a Zariski-dense $(\mathcal{G}_i, K, S)$-arithmetic subgroup of $G_i(F)$. Then Γ_1 and Γ_2 are weakly commensurable if and only if $\mathcal{G}_1$ and $\mathcal{G}_2$ are* twins*, i.e.*

- *$\mathcal{G}_1$ and $\mathcal{G}_2$ are both split over all nonarchimedean places of K;*
- *$\mathcal{G}_1$ and $\mathcal{G}_2$ are* simultaneously *either split or anisotropic over all archimedean valuations of K.*

In §5, we will review some of the techniques involved in the proof of Theorems 4.1 and 4.2. But from a very general perspective, the essence of the argument is to obtain information about the algebraic hull $\mathcal{G}$ of an S-arithmetic group Γ that is weakly commensurable to a given S-arithmetic group – recall that according to Theorem 3.5, $\mathcal{G}$ uniquely determines Γ up to commensurability. So, to establish assertion (1) of Theorem 4.1, we prove that the algebraic hull $\mathcal{G}$ is itself unique when the type if different from A_n, D_{2n+1} $(n > 1)$, and E_6. Furthermore, for assertion (2), we prove that there are only finitely many possibilities for the $\mathcal{G}$'s. In §§6-7 we will indicate that the latter property is expected to hold not only for S-arithmetic, but in fact for arbitrary finitely generated Zariski-dense subgroups (see Conjecture 6.2). This phenomenon, if confirmed, would be a rather strong form of eigenvalue rigidity. We will now, however, briefly discuss a few other questions that one can ask in the context of weak commensurability.

4.3. Some other aspects of eigenvalue rigidity. First, it is easy to construct examples showing that a Zariski-dense subgroup weakly commensurable to a *rank-one* arithmetic subgroup need not be arithmetic (see [40, Remark 5.5]); in other words, assertion (4) of Theorem 4.1 fails if we drop the assumption that Γ_2 is a lattice. So, it would be extremely interesting to determine if a Zariski-dense subgroup weakly commensurable to a *higher rank* S-arithmetic subgroup is itself S-arithmetic (see Problem 10.1 in [43] and the subsequent discussion). This can potentially provide a new characterization of higher rank S-arithmetic subgroups involving weak commensurability (i.e., ultimately the eigenvalue information).

Second, one can ask if weak commensurability can be used to characterize the discreteness of Zariski-dense subgroups. More precisely, let G_1 and G_2 be connected absolutely almost simple algebraic groups over a nondiscrete locally compact field F, and let Γ_i be a finitely generated Zariski-dense subgroup of $G_i(F)$ for $i = 1, 2$. Assume that Γ_1 and Γ_2 are weakly commensurable. *Does the discreteness of Γ_1 imply the discreteness of Γ_2?* (Problem 10.2 in [43]). An affirmative answer to this question was given in [40, Proposition 5.6] for the case where F is a *nonarchimedean* local field, but the case $F = \mathbb{R}$ or $\mathbb{C}$ remains open.

Third, one can also ask if weak commensurability preserves cocompactness of lattices. Namely, let again G_1 and G_2 be connected absolutely almost simple algebraic groups over $F = \mathbb{R}$ or $\mathbb{C}$, and let $\Gamma_i \subset G_i(F)$ be a lattice for $i = 1, 2$. Assume that Γ_1 and Γ_2 are weakly commensurable. *Does the compactness of $G_1(F)/\Gamma_1$ imply the compactness of $G_2(F)/\Gamma_2$?* (Problem 10.3 in [43]). (We note that if G is a semi-simple algebraic group over a nonarchimedean local field F of characteristic zero, then any lattice $\Gamma \subset G(F)$ is automatically cocompact, and the problem in this case becomes vacuous.) We recall that the cocompactness of a lattice in a semi-simple real Lie group is equivalent to the absence of nontrivial unipotent elements in it, see [45, Corollary 11.13]. So, the above question is equivalent to the question of whether for two weakly commensurable *lattices*, the existence of nontrivial unipotent elements in one of them implies their existence in the other. The

combination of parts (3) and (4) of Theorem 4.1 provides an affirmative answer if one of the lattices is arithmetic. On the other hand, in this form the question itself is meaningful for arbitrary Zariski-dense subgroups (not necessarily discrete or of finite covolume), but no other cases have been considered so far.

4.4. Geometric applications. Combining Theorem 2.3, which reduced the length - commensurability of locally symmetric spaces to the weak commensurability of their fundamental groups, with the analysis of weak commensurability in Theorem 4.1, we obtain the following geometric result.

Theorem 4.5 ([40], Theorem 8.16). *Let G_1 and G_2 be connected absolutely simple real algebraic groups, and set $\mathcal{G}_i = G_i(\mathbb{R})$, for $i = 1, 2$. Then the set of arithmetically defined locally symmetric spaces $\mathfrak{X}_{\Gamma_2}$ of $\mathcal{G}_2$, which are length-commensurable to a given arithmetically defined locally symmetric space $\mathfrak{X}_{\Gamma_1}$ of $\mathcal{G}_1$, is a union of finitely many commensurability classes. It in fact consists of a single commensurability class if G_1 and G_2 have the same type different from A_n, D_{2n+1}, with $n > 1$, or E_6.*

This statement applies in various concrete geometric situations. For example, here is what it yields for hyperbolic manifolds.

Corollary 4.6. *Let M_1 and M_2 be arithmetically defined real hyperbolic d-manifolds where d is either even or is $\equiv 3 (\mathrm{mod}\, 4)$ and $d > 3$. If M_1 and M_2 are length-commensurable (in particular, compact and isospectral), then they are commensurable.*

Previously, this was known only for $d = 2$ [47] and $d = 3$ [12]. Length-commensurability implies commensurability also for all quaternionic hyperbolic manifolds. On the other hand, in the case of real hyperbolic manifolds of dimension $\equiv 1 (\mathrm{mod}\, 4)$ or of complex hyperbolic manifolds, one can construct examples of arithmetically defined length-commensurable, but not commensurable spaces. Furthermore, using Theorem 3.1 (and Proposition 3.3 to handle the isomorphism $\mathsf{A}_3 = \mathsf{D}_3$), one proves that an arithmetically defined complex hyperbolic space cannot be length-commensurable to either a real or a quaternionic arithmetically defined hyperbolic space. Employing Theorem 4.2, one also proves that arithmetically defined real and quaternionic hyperbolic spaces cannot be length-commensurable. (In fact, assuming Schanuel's conjecture in all cases, one can get rid of the arithmeticity assumption in these two statement, see [42], particularly Remark 8.5, and the discussion after Theorem 4.8 below.)

Next, parts (3) and (4) of Theorem 4.1, in conjunction with Theorem 2.3, imply the following rather surprising result which has so far defied all attempts to find a purely geometric proof.

Theorem 4.7 ([40], Theorem 8.19). *Let $\mathfrak{X}_{\Gamma_1}$ and $\mathfrak{X}_{\Gamma_2}$ be locally symmetric spaces of finite volume. Assume that one of the spaces is arithmetically defined. If the spaces are length-commensurable, then the other space is also arithmetically defined, and the compactness of one of the spaces implies the compactness of the other.*

In fact, if one of the spaces is compact and the other is not, the length spectra $L(\mathfrak{X}_{\Gamma_1})$ and $L(\mathfrak{X}_{\Gamma_2})$ are quite different - see [42, Theorem 5.9]. The question of whether the arithmeticity assumption in this theorem can be dropped boils down to one of the problems we discussed in 4.3.

Last but not least, implication (S) from 2.2 enables us to apply the above results to isospectral compact locally symmetric spaces. We then obtain the following.

Theorem 4.8 ([40], §10). *Let $\mathfrak{X}_{\Gamma_1}$ and $\mathfrak{X}_{\Gamma_2}$ be compact locally symmetric spaces, and assume that they are isospectral.*

(1) *If $\mathfrak{X}_{\Gamma_1}$ is arithmetically defined, then $\mathfrak{X}_{\Gamma_2}$ is also arithmetically defined.*

(2) *$G_1 = G_2 =: G$, hence $\mathfrak{X}_{\Gamma_1}$ and $\mathfrak{X}_{\Gamma_2}$ have the same universal cover.*

(3) *If at least one of the subgroups Γ_1 and Γ_2 is arithmetic, then unless G is of type A_n $(n > 1)$, D_{2n+1} $(n > 1)$ and E_6, the spaces $\mathfrak{X}_{\Gamma_1}$ and $\mathfrak{X}_{\Gamma_2}$ commensurable.*

We note that part (2) was proved in [40] (with the help of a result of Sai-Kee Yeung [55]) under the assumption that at least one of the groups Γ_1 or Γ_2 is arithmetic. Suppose now that both Γ_1 and Γ_2 are nonarithmetic. Then each space $\mathfrak{X}_i$ $(i = 1, 2)$ is either the real hyperbolic space $\mathbb{H}^{n_i}$ or the complex hyperbolic space $\mathbb{H}^{n_i}_{\mathbb{C}}$ for some $n_i \geqslant 2$, and the corresponding real adjoint algebraic group G_i is, respectively, either $\mathrm{PSO}(n_i, 1)$ or $\mathrm{PSU}(n_i, 1)$ in the standard notations. It follows from Theorem 3.1 that the isospectrality, hence length-commensurability, of $\mathfrak{X}_{\Gamma_1}$ and $\mathfrak{X}_{\Gamma_2}$ implies that either G_1 and G_2 must be of the same Cartan-Killing type, or one of them is of type B_ℓ and the other of type C_ℓ for some $\ell \geqslant 3$. In our situation, this can happen only if either $G_1 = G_2$ or (after a possible switch) $G_1 = \mathrm{PSO}(5, 1)$ and $G_2 = \mathrm{PSU}(3, 1)$ (of common type $\mathsf{D}_3 = \mathsf{A}_3$). In the latter case, $\mathfrak{X}_{\Gamma_1}$ is 5-dimensional, and $\mathfrak{X}_{\Gamma_2}$ is 6-dimensional. But according to Weyl's Law (see, for example, [24]) isospectral Riemannian manifolds are always of the same dimension. So, in this case $\mathfrak{X}_{\Gamma_1}$ and $\mathfrak{X}_{\Gamma_2}$ cannot be isospectral[3], leaving us with the only option $G_1 = G_2$, as required.

5. Generic elements. Isogeny Theorem

In this section, we would like to discuss two ingredients involved in the proofs of Theorems 4.1 and 4.2: the existence of generic elements in Zariski-dense subgroups and the Isogeny Theorem.

5.1. Generic elements. First, we need to recall the notion of a *generic K-torus*. Let G be a connected semi-simple algebraic group defined over an infinite field K. Fix a maximal K-torus T of G, and, as usual, let $\Phi = \Phi(G, T)$ denote the corresponding root system, and let $W(G, T)$ be its Weyl group. Furthermore, we let K_T denote the (minimal) splitting field of T in a fixed algebraic closure $\overline{K}$ of K. Then the natural action of the Galois group $\mathrm{Gal}(K_T/K)$ on the character group $X(T)$ of T induces an injective homomorphism

$$\theta_T \colon \mathrm{Gal}(K_T/K) \to \mathrm{Aut}(\Phi(G, T)).$$

We say that T is *generic* (over K) if

$$\theta_T(\mathrm{Gal}(K_T/K)) \supset W(G, T). \tag{5.1}$$

For example, any maximal K-torus of $G = \mathrm{SL}_{n,K}$ is of the form $T = \mathrm{R}^{(1)}_{E/K}(\mathbb{G}_{m,E})$ for some n-dimensional commutative étale K-algebra E. Then such a torus is generic over K if and only if E is a separable field extension of K and the Galois group of the normal closure L of E over K is isomorphic to the symmetric group S_n.

[3] In fact, it follows from the remark made after Proposition 3.3 that in this case $\mathfrak{X}_{\Gamma_1}$ and $\mathfrak{X}_{\Gamma_2}$ cannot even be length-commensurable as G_1 is an inner form of a split group over $\mathbb{R}$, and G_2 is an outer form.

Definition 5.2. Let G be a connected semi-simple algebraic group defined over a field K. A regular semi-simple element $g \in G(K)$ is called *generic* (over K) if the torus $T = Z_G(g)^\circ$ is generic (over K) as defined above (note that T is a K-torus, cf. [7, 9.1]).

Generic elements play a crucial role in our work, but they have also been used in a variety of other problems, including the study of the rigidity of actions (cf. [32, 37]) and the Auslander problem [1].

Theorem 5.3 (cf. [39], Theorem 3). *Let G be a connected absolutely almost simple algebraic group over a finitely generated field K of characteristic zero, and let $\Gamma \subset G(K)$ be a Zariski-dense subgroup. Then Γ contains a regular generic element (over K) of infinite order.*

Basically, our proof (which in fact applies to all connected semi-simple groups) shows that given a finitely generated Zariski-dense subgroup $\Gamma \subset G(K)$, one can produce a finite system of congruences (defined in terms of suitable valuations of K) such that the set of elements $\gamma \in \Gamma$ satisfying this system of congruences consists entirely of generic elements (and additionally this set is in fact a coset of a finite index subgroup in Γ, in particular, it is Zariski-dense in G). Recently, Gorodnik-Nevo [26], Jouve-Kowalski-Zywina [29], and Lubotzky-Rosenzweig [34] have developed different *quantitative* ways of showing that generic elements exist in abundance (in fact, these results demonstrate that "most" elements in Γ are generic). More precisely, the result of [26] gives the asymptotics of the number of generic elements of a given height in an arithmetic group, while the results of [34], generalizing earlier results of [29], are formulated in terms of random walks on groups and apply to arbitrary Zariski-dense subgroups in not necessarily connected semi-simple groups. These papers introduce several new ideas and techniques, but at the same time employ some elements of the argument from [39]. We also note that the proof of Theorems 4.1 and 4.2 uses not only Theorem 5.3 itself but also its different variants that provide generic elements with additional properties, e.g. having prescribed local behavior.

5.4. The Isogeny Theorem and its consequences. An important step in the proofs of Theorems 4.1 and 4.2 is the passage from the weak commensurability of two semi-simple elements to an isogeny, and in most cases even to an isomorphism, of the tori containing these elements. This is done with the help of the following technical statement which we called the *Isogeny Theorem*. After the theorem, we give a (less technical) corollary that, to a significant degree, reduces the analysis of weak commensurability to the investigation of absolutely almost simple algebraic groups having the same isomorphism/isogeny classes of maximal tori over the base field; this problem, together with some variations, will be discussed in the concluding §§6-7. We recall that a K-torus T is called (K-)*irreducible* if it does not contain any proper K-subtori; note that a maximal K-torus of an absolutely almost simple algebraic K-group which is generic over K, is automatically K-irreducible.

Theorem 5.5 ([40], Theorem 4.2). *Let G_1 and G_2 be two connected absolutely almost simple algebraic groups defined over an infinite field K, and let L_i be the minimal Galois extension of K over which G_i becomes an inner form of a split group. Suppose that for $i = 1, 2$, we are given a semi-simple element $\gamma_i \in G_i(K)$ contained in a maximal K-torus T_i of G_i. Assume that*

(i) *G_1 and G_2 are either of the same Killing-Cartan type, or one of them is of type B_n and the other is of type C_n;*

(ii) γ_1 *has infinite order;*

(iii) T_1 *is* K*-irreducible; and*

(iv) γ_1 *and* γ_2 *are weakly commensurable.*

Then:

(1) *there exists a* K*-isogeny* $\pi\colon T_2 \to T_1$ *which carries* $\gamma_2^{m_2}$ *to* $\gamma_1^{m_1}$ *for some integers* $m_1, m_2 \geqslant 1$*;*

(2) *if* $L_1 = L_2 =: L$ *and* $\theta_{T_1}(\mathrm{Gal}(L_{T_1}/L)) \supset W(G_1, T_1)$*, then*

$$\pi^*\colon X(T_1) \otimes_{\mathbb{Z}} \mathbb{Q} \to X(T_2) \otimes_{\mathbb{Z}} \mathbb{Q}$$

has the property that $\pi^*(\mathbb{Q} \cdot \Phi(G_1, T_1)) = \mathbb{Q} \cdot \Phi(G_2, T_2)$*. Moreover, if* G_1 *and* G_2 *are of the same Killing-Cartan type different from* $\mathsf{B}_2 = \mathsf{C}_2$*,* F_4 *or* G_2*, then a suitable rational multiple of* π^* *maps* $\Phi(G_1, T_1)$ *onto* $\Phi(G_2, T_2)$*, and if* G_1 *is of type* B_n *and* G_2 *is of type* C_n*, with* $n > 2$*, then a suitable rational multiple* λ *of* π^* *takes the long roots in* $\Phi(G_1, T_1)$ *to the short roots in* $\Phi(G_2, T_2)$*, while* 2λ *takes the short roots in* $\Phi(G_1, T_1)$ *to the long roots in* $\Phi(G_2, T_2)$*.*

It follows that in the situations where π^* can be, and has been, scaled so that $\pi^*(\Phi(G_1, T_1)) = \Phi(G_2, T_2)$, it induces K-isomorphisms $\tilde{\pi}\colon \widetilde{T}_2 \to \widetilde{T}_1$ and $\overline{\pi}\colon \overline{T}_2 \to \overline{T}_1$ between the corresponding tori in the simply connected and adjoint groups $\widetilde{G}_i$ and $\overline{G}_i$, respectively, that extend to $\overline{K}$-isomorphisms $\widetilde{G}_2 \to \widetilde{G}_1$ and $\overline{G}_2 \to \overline{G}_1$.

Furthermore, if G_1 and G_2 are absolutely almost simple algebraic groups over a field K of characteristic zero and $\Gamma_1 \subset G_1(K)$ and $\Gamma_2 \subset G_2(K)$ are weakly commensurable finitely generated Zariski-dense subgroups, then we already know that either G_1 and G_2 have the same type or one of them is of type B_ℓ and the other of type C_ℓ for some $\ell \geqslant 3$ (Theorem 3.1), and $L_1 = L_2$ (remark after Proposition 3.3). Thus, the important assumptions in Theorem 5.5 are satisfied automatically, and its application yields the following.

Corollary 5.6. *In the above situation, every generic maximal* K*-torus* T_1 *of* G_1 *whose intersection with* Γ_1 *contains an element of infinite order, is* K*-isogenous, and if both* G_1 *and* G_2 *are either simply connected or adjoint of the same type different from* $\mathsf{B}_2 = \mathsf{C}_2$*,* F_4 *and* G_2*, even* K*-isomorphic, to a generic maximal* K*-torus* T_2 *of* G_2 *whose intersection with* Γ_2 *contains an element of infinite order, and vice versa.*

If finitely generated Zariski-dense subgroups $\Gamma_1 \subset G_1(F)$ and $\Gamma_2 \subset G_2(F)$ are weakly commensurable, then by Theorem 3.2, they have a common trace field $K_{\Gamma_1} = K_{\Gamma_2} =: K$, which is finitely generated. Then Theorem 5.3 and its variants guarantee the existence in Γ_1 and Γ_2 of elements that are generic over K and its suitable finite extensions, and satisfy some additional conditions. Applying Theorem 5.5 and/or Corollary 5.6, we obtain that the algebraic hulls $\mathcal{G}_1$ and $\mathcal{G}_2$ of Γ_1 and Γ_2, respectively, share large families of maximal K-tori. In the case where Γ_1 and Γ_2 are S-arithmetic, this information about the common maximal tori turns out to be sufficient to prove Theorems 4.1 and 4.2. In the final two sections we will discuss the implementation of this approach for arbitrary Zariski-dense subgroups.

6. Arbitrary Zariski-dense subgroups

As we already explained, the results for arithmetic groups were obtained by analyzing the algebraic hulls of arithmetic groups which are weakly commensurable to a given one. While general Zariski-dense subgroups are not determined up to commensurability by their algebraic hull (even if they are lattices, cf. [52]), the latter remains an important invariant. At the same time, the results in the arithmetic case as well as some very recent results over general fields concerning simple algebraic groups with the same maximal tori and division algebras with the same maximal subfields, which we will discuss in the rest of this article, have led us to believe that the algebraic hull itself is *almost* determined by the presence of a Zariski-dense subgroup weakly commensurable to a given one in all situations. More precisely, we would like to propose the following *Finiteness Conjecture*.

Conjecture 6.1. *Let G_1 and G_2 be absolutely simple (adjoint) algebraic groups over a field F of characteristic zero, and let $\Gamma_1 \subset G_1(F)$ be a finitely generated Zariski-dense subgroup with trace field $K_{\Gamma_1} = K$. Then there exists a* finite *collection $\mathcal{G}_1^{(2)}, \dots, \mathcal{G}_r^{(2)}$ of F/K-forms of G_2 such that if $\Gamma_2 \subset G_2(F)$ is a finitely generated Zariski-dense subgroup that is weakly commensurable to Γ_1, then it is conjugate to a subgroup of one of the $\mathcal{G}_i^{(2)}(K)$'s ($\subset G_2(F)$).*

We already know that two weakly commensurable finitely generated Zariski-dense subgroups have the same trace field (Theorem 3.2). The above conjecture takes this result much farther by claiming that a finitely generated Zariski-dense subgroup weakly commensurable to a given one can exist only in finitely many simple algebraic groups over this field. (For example, if $G_0 = \mathrm{SO}_n(q_0)$, where q_0 is a nondegenerate quadratic form of dimension $n \geqslant 3$, $n \neq 4$, over a finitely generated field K of characteristic zero, and $\Gamma_0 \subset G_0(K)$ is a finitely generated Zariski-dense subgroup with trace field K, then according to the conjecture, there should exists a *finite* collection $q_1, \dots, q_r$ of nondegenerate n-dimensional quadratic forms over K such that if $G(K)$ for $G = \mathrm{SO}_n(q)$, with q a nondegenerate n-dimensional quadratic form over K, contains a finitely generated Zariski-dense subgroup that is weakly commensurable to Γ_0, then q *must* be similar to one of the q_i's, $i = 1, \dots, r$.)

Based on our results for S-arithmetic groups (cf., for example, Theorem 4.1(1)) and the results concerning division algebras algebras of exponent two having the same maximal subfields (see Corollary 6.8 and Theorem 7.10), one expects that in some situations one should be able to show that actually $r = 1$, which informally means that the ambient algebraic group is *uniquely* determined by the eigenvalue information of semi-simple elements in a finitely generated Zariski-dense subgroup.

Conjecture 6.1 is known to be true if K is a number field even when Γ_1 is not S-arithmetic (cf. [44, Theorem 5.1]) and also over general fields when G_1 is of type A_1. We recall that given a connected absolutely almost simple real algebraic subgroup of SL_n such that $\mathcal{G} = G(\mathbb{R})$ is noncompact and is not locally isomorphic to $\mathrm{SL}_2(\mathbb{R})$ and a lattice Γ in $\mathcal{G}$, then there exists a number field $K \subset \mathbb{R}$ such that Γ can be conjugated into $\mathrm{SL}_n(K)$, cf. [45, 7.67 and 7.68]. Combining these results, we conclude that Conjecture 6.1 is true when Γ_1 is a lattice in the group of real points of an absolutely almost simple real algebraic group. More evidence supporting this conjecture comes from the investigation of another natural problem in the theory of algebraic group — namely, characterizing absolutely almost simple algebraic K-groups having the same isomorphism/isogeny classes of maximal K-tori. The connection between the two is based on the Isogeny Theorem 5.5 and Corollary 5.6. While these two problems are not equivalent, their investigation usually involves many common

elements. To comment on these common aspects, we will temporarily shift the focus to the second problem. We will later see how the finiteness statements in the context of both problems fit into some more general conjectures about algebraic groups with reductive reduction - see Conjectures 7.5 and 7.8.

6.2. Simple algebraic groups over number fields with the same maximal tori. The tools used to prove Theorems 4.1 and 4.2 can be used to characterize absolutely almost simple algebraic groups over number fields having the same isomorphism/isogeny classes of maximal tori. We give the statements of these results below in order to demonstrate their complete similarity to the corresponding results concerning weak commensurability.

Theorem 6.3 (cf. [40], Theorem 7.5).

(1) *Let G_1 and G_2 be connected absolutely almost simple algebraic groups defined over a number field K, and let L_i be the smallest Galois extension of K over which G_i becomes an inner form of a split group. If G_1 and G_2 have the same K-isogeny classes of maximal K-tori, then either G_1 and G_2 are of the same Killing-Cartan type, or one of them is of type B_n and the other is of type C_n, and moreover, $L_1 = L_2$.*

(2) *Fix an absolutely almost simple K-group G. Then the set of isomorphism classes of all absolutely almost simple K-groups G' having the same K-isogeny classes of maximal K-tori is finite.*

(3) *Fix an absolutely almost simple simply connected K-group G whose Killing-Cartan type is different from A_n, D_{2n+1} $(n > 1)$ or E_6. Then any K-form G' of G (in other words, any absolutely almost simple simply connected K-group G' of the* same *type as G) that has the same K-isogeny classes of maximal K-tori as G, is isomorphic to G.*

The construction described in [40, §9] shows that the types excluded in (3) are honest exceptions, i.e., for each of those types one can construct non-isomorphic absolutely almost simple simply connected K-groups G_1 and G_2 of this type over a number field K that have the same isomorphism classes of maximal K-tori.

The case where G_1 and G_2 are of types B_ℓ and C_ℓ, respectively, is treated in the following theorem.

Theorem 6.4 ([22], Theorem 1.4). *Let G_1 and G_2 be absolutely almost simple algebraic groups over a number field K of types B_ℓ and C_ℓ, respectively, for some $\ell \geqslant 3$.*

(1) *The groups G_1 and G_2 have the same* isogeny *classes of maximal K-tori if and only if they are twins.*

(2) *The groups G_1 and G_2 have the same* isomorphism *classes of maximal K-tori if and only if they are twins, G_1 is adjoint, and G_2 is simply connected.*

We note that some aspects of the general problem of characterizing absolutely almost simple algebraic groups over local and global fields having the same isomorphism classes of maximal tori were considered in [20] and [31]. Another direction of research, which has already generated a number of results (cf. [5], [6] [21], [33], [41]) is the investigation of local-global principles for embedding tori into absolutely almost simple algebraic groups as maximal tori (in particular, for embedding of commutative étale algebras with involutive

automorphisms into simple algebras with involution); some number-theoretic applications of these results can be found, for example, in [17].

In order to get a better idea of what kind of results can be obtained over general fields, it is helpful to consider first the related problem of characterizing finite-dimensional division algebras having the same maximal subfields, which is somewhat reminiscent of Amitsur's famous theorem about central simple algebras having the same *generic* splitting fields (cf. [2], [25]).

6.5. Division algebras with the same maximal subfields. Let D_1 and D_2 be central division algebras of the same degree n over a field K. We say that D_1 and D_2 have the *same maximal subfields* if a degree n field extension L/K admits a K-embedding $L \hookrightarrow D_1$ if and only if it admits a K-embedding $L \hookrightarrow D_2$. We also let $\mathrm{Br}(K)$ denote the Brauer group of K, and for a (finite-dimensional) central simple K-algebra A, we let $[A] \in \mathrm{Br}(K)$ denote the corresponding Brauer class.

Definition 6.6. Let D be a central division K-algebra of degree n. The *genus* of D is defined to be

$$\mathbf{gen}(D) = \{\, [D'] \mid D' \text{is a central division} K\text{-algebra with the same maximal subfields as } D\}.$$

Two basic questions about the genus are:

(I) *When does* $\mathbf{gen}(D)$ *reduce to a single element?* (Then D is uniquely determined by its maximal subfields.)

(II) *What can one say about the size of* $\mathbf{gen}(D)$ *in the general case? In particular, when is* $\mathbf{gen}(D)$ *finite?*

We note that since the opposite algebra D^{op} has the same maximal subfields as D, the genus $\mathbf{gen}(D)$ can reduce to one element only if $D \simeq D^{\mathrm{op}}$, i.e. if $[D]$ has exponent 2 in $\mathrm{Br}(K)$. If K is a global field, then any central division algebra over K of exponent 2 is a quaternion algebra and furthermore it follows from the theorem of Albert-Hasse-Brauer-Noether (ABHN) that for any quaternion division K-algebra D we have $|\mathbf{gen}(D)| = 1$. Another consequence of (AHBN) is that $\mathbf{gen}(D)$ is finite for any central division algebra D over a global field K (see [9, 3.6]).

On the other hand, a construction proposed by M. Rost, M. Schacher, A. Wadsworth, and others (cf. [23, Example 2.1]), enables one to produce quaternion algebras over infinitely generated fields with nontrivial, and even infinite (see [38]), genus. So, both questions become nontrivial over fields more general than global fields, and the following two theorems, obtained jointly with V. Chernousov and I. Rapinchuk [8], [9], [46], contain some recent results in that direction.

The first theorem expands the variety of examples where the genus is trivial. We will say that a field F satisfies property $(*)$ if for any central division F-algebra D of exponent 2, the genus $\mathbf{gen}(D)$ reduces to a single element.

Theorem 6.7 (Stability theorem, [9, 46]). *If a field* k *of characteristic* $\neq 2$ *satisfies* $(*)$*, then so does the field of rational functions* $k(x)$.

(The stability property in characteristic 2 has not been investigated yet.)

Corollary 6.8. *Let k be either a finite field of characteristic $\neq 2$ or a number field, and let $K = k(x_1, \ldots, x_t)$ be a finitely generated purely transcendental extension of k. Then for any central division K-algebra of exponent 2, we have $|\mathbf{gen}(D)| = 1$.*

The second theorem establishes the finiteness of the genus over finitely generated fields.

Theorem 6.9. *Let D be a central division algebra of degree n over a finitely generated field K of characteristic not dividing n. Then the genus $\mathbf{gen}(D)$ is finite.*

Both theorems are based on an analysis of the ramification properties of division algebras in the genus. More precisely, given a discrete valuation v of K, we let $\mathcal{O}_{K,v}$ and $\overline{K}_v$ denote the corresponding valuation ring and residue field, respectively. Fix an integer $n > 1$ (which will later be either the degree or the exponent of D), and suppose that V is a set of discrete valuations of K that satisfy the following three conditions:

(A) *For any $a \in K^\times$, the set $V(a) := \{v \in V \mid v(a) \neq 0\}$ is finite;*

(B) *There exists a* finite *subset $V' \subset V$ such that the field of fractions of*

$$\mathcal{O} = \bigcap_{v \in V \setminus V'} \mathcal{O}_{K,v},$$

coincides with K;

(C) *For any $v \in V$, the characteristic of the residue field $\overline{K}_v$ is prime to n.*

(We note that if K is finitely generated, which will be the case in most of our applications, then (B) automatically follows from (A).) Due to (C), we can define for each $v \in V$ the corresponding *residue map*

$$\rho_v \colon {}_n\mathrm{Br}(K) \longrightarrow \mathrm{Hom}(\mathcal{G}^{(v)}, \mathbb{Z}/n\mathbb{Z}), \tag{R}$$

where ${}_n\mathrm{Br}(K)$ is the n-torsion in the Brauer group and $\mathcal{G}^{(v)}$ is the absolute Galois group of $\overline{K}_v$ (cf., for example, [48, §10] or [49, Ch.II, Appendix]). A class $[A] \in {}_n\mathrm{Br}(K)$ (or a finite-dimensional central simple K-algebra A representing this class) is said to be *unramified* at v if $\rho_v([A]) = 1$, and *ramified* otherwise. We let $\mathrm{Ram}_V(A)$ denote the set of all $v \in V$ where A is ramified; one shows that this set is always finite. We also define the unramified part of ${}_n\mathrm{Br}(K)$ with respect to V to be

$${}_n\mathrm{Br}(K)_V = \bigcap_{v \in V} \mathrm{Ker}\, \rho_v.$$

Then one shows [9, Theorem 2.2] that if ${}_n\mathrm{Br}(K)_V$ is finite, then for a central division algebra K-algebra D of degree n one has

$$|\mathbf{gen}(D)| \leqslant |{}_n\mathrm{Br}(K)_V| \cdot \varphi(n)^r, \text{ with } r = |\mathrm{Ram}_V(D)|. \tag{U}$$

Thus, to prove Theorem 6.9, one needs to show that for a finitely generated field K whose characteristic is prime to a given integer $n > 1$, there exists a set V of discrete valuations of K satisfying the above conditions (A)-(C) and such that the unramified Brauer group ${}_n\mathrm{Br}(K)_V$ is finite. This was first done by an explicit construction based on an analysis of the standard exact sequence for the Brauer group of a curve; this approach enables one to

give some explicit estimations on the size of the unramified Brauer group, hence of the genus, cf. [9, §4], [10]. Subsequently, a more general argument was pointed out to us J.-L. Colliot-Thélène (cf. [8]). More precisely, suppose our finitely generated field K is realized as the field of rational functions on a regular integral scheme X of finite type over $\mathrm{Spec}\ A$, where A is either a finite field or the ring of S-integers in a number field for some finite set S of its places, with n invertible in A, and let V be the set of discrete valuations of K associated with the divisors on X. Then the finiteness of ${}_n\mathrm{Br}(K)_V$ follows from Deligne's finiteness theorem for the étale cohomology of constructible sheaves [16] and Gabber's purity theorem [19]. The proof of Theorem 6.7 relies on the fact that if V is the set of all geometric places of the field of rational functions $k(x)$ (i.e., those that are trivial on k), where k is a field of characteristic $\neq 2$, then ${}_2\mathrm{Br}(k(x))_V$ reduces to ${}_2\mathrm{Br}(k)$ (cf. [25, Corollary 6.4.6]).

7. The genus of a simple algebraic group. Groups with reductive reduction.

In this concluding section, we will describe the ongoing project (cf. [11]) of obtaining the analogs of results from 6.5 for arbitrary absolutely almost simple algebraic groups, and connect this activity back to the Finiteness Conjecture 6.1. First, we need to extend Definition 6.6.

Definition 7.1. Let G be an absolutely almost simple simply connected algebraic group over a field K. The (K-)*genus* $\mathbf{gen}_K(G)$ (or simply $\mathbf{gen}(G)$ if this does not lead to any confusion) of G is the collection of K-isomorphism classes of K-forms G' of G that have the same K-isomorphism classes of maximal K-tori as G.

One can alternatively define the genus using "K-isogeny classes" of maximal tori in place of "K-isomorphism classes." While the exact relationship between these notions of genus has not been investigated, the Isogeny Theorem 5.5 and subsequent remarks strongly suggest that they should lead to the same qualitative results in most cases. On the other hand, A.S. Merkurjev proposed a different (in a way, more functorial) definition of the genus of an absolutely almost simple algebraic K-group G as the set of K-isomorphism classes of K-forms G' of G that have the same isomorphism/isogeny classes of maximal tori not only over K, but also over *any* field extension F/K. The results of Izboldin, Vishik and Karpenko indicate a connection between this genus for the spinor group $G = \mathrm{Spin}_n(q)$ of a quadratic form q and the motive of the projective quadric $q = 0$ in the category of Chow motives, so it makes sense to call this genus *motivic* (see [9, Remark 5.6] for more details). In this article, however, we will only use the notion of genus given in Definition 7.1.

Building on Theorem 6.9, it is natural to make the following conjecture.

Conjecture 7.2. *Let G be an absolutely almost simple simply connected algebraic group over a finitely generated field K of good characteristic*[4]*. Then $\mathbf{gen}_K(G)$ is finite.*

This conjecture is true over global fields (Theorem 6.3) and also for inner forms of type A_ℓ in the general case (see Theorem 7.6 below). While Conjecture 7.2 does not automatically imply our main Conjecture 6.1, we will now outline an approach that can potentially lead

[4]For each type, the following characteristics are defined to be *bad*: type A_ℓ - all primes dividing $(\ell+1)$, and also $p=2$ for outer forms; types B_ℓ, C_ℓ, D_ℓ - $p=2$, and also $p=3$ for ${}^{3,6}\mathsf{D}_4$; for type E_6 - $p=2,3,5$; for types E_7, E_8 - $p=2,3,5,7$; for types F_4, G_2 - $p=2,3$. All other characteristics for a given type are *good*.

to the proof of both conjectures, and also have some other implications. The considerations in 6.5 were based on an analysis of the ramification properties of central simple algebras at discrete valuations of the center. An adequate replacement of the notion of an unramified algebra for arbitrary absolutely almost simple groups is the notion of a group with *reductive reduction*. Let G be a connected absolutely almost simple simply connected algebraic group over a field K. Given a discrete valuation v of K, we let K_v denote the corresponding completion with valuation ring $\mathcal{O}_v$, valuation ideal $\mathfrak{p}_v$, and residue field $\overline{K}_v = \mathcal{O}_v/\mathfrak{p}_v$. One says that G has reductive reduction at v if there exists a reductive group scheme $\mathcal{G}$ over $\mathcal{O}_v$ with generic fiber $G \otimes_K K_v$. Then the reduction $\mathcal{G} \otimes_{\mathcal{O}_v} \overline{K}_v$ modulo $\mathfrak{p}_v$ will be denoted $\underline{G}^{(v)}$. A crucial point in the proof of the estimate (U) in 6.5, which reduces the finiteness of the genus $\mathbf{gen}(D)$ to the finiteness of the unramified Brauer group, was the fact that if $D' \in \mathbf{gen}(D)$, and $\chi = \rho_v([D])$, $\chi' = \rho_v([D'])$, where ρ_v is the residue map at v (cf. (R) in 6.5), then $\mathrm{Ker}\ \chi = \mathrm{Ker}\ \chi'$. In particular, if D is unramified at v then so is D' (thus, the property of being unramified is determined by maximal subfields). We have been able to prove the following analog of the latter fact for arbitrary absolutely almost simple groups.

Theorem 7.3 ([11]). *Assume that the residue field $\overline{K}_v$ is finitely generated and that G has reductive reduction at v. Then any $G' \in \mathbf{gen}_K(G)$ also has reductive reduction at v. Furthermore, the reduction $\underline{G'}^{(v)}$ lies in the genus $\mathbf{gen}_{\overline{K}_v}(\underline{G}^{(v)})$.*

Assume now that the field K is equipped with a set V of discrete valuations that satisfies the following two conditions

(A′) for any $a \in K^\times$, the set $V(a) := \{v \in V \mid v(a) \neq 0\}$ is finite;

(B′) for any $v \in V$, the residue field $\overline{K}^{(v)}$ is finitely generated.

Corollary 7.4. *If K and V satisfy conditions (A′) and (B′), then for any absolutely almost simple simply connected algebraic K-group G, there exists a finite subset $V_0 \subset V$ (depending on G) such that every $G' \in \mathbf{gen}_K(G)$ has reductive reduction at all $v \in V \setminus V_0$.*

The other ingredient of the proof of the finiteness of $\mathbf{gen}(D)$ in 6.5 was the finiteness of the unramified Brauer group ${}_n\,\mathrm{Br}(K)_V$ for a suitable set V of discrete valuations of K. One can expect the following general statement to be valid for the same sets V of valuations as in 6.5. Let again X be a regular integral scheme of finite type over $\mathrm{Spec}\ A$, where A is either a finite field or the ring of S-integers in a number field for some finite set S of its places, let K be the field of rational functions on X, and let V be the set of discrete valuations of K associated with the prime divisors on X (obviously, V satisfies conditions (A′) and (B′)).

Conjecture 7.5. *Let K and V be as above, and let G be an absolutely almost simple simply connected algebraic K-group such that* $\mathrm{char}\ K$ *is good for G. Then for any finite subset $V_0 \subset V$, the set of K-isomorphism classes of (inner) K-forms G' of G that have reductive reduction at all $v \in V \setminus V_0$, is finite.*

Over a number field K, the assertion of Conjecture 7.5 is an easy consequence of the finiteness results for Galois cohomology, cf. [49, Ch. III, 4.6]. (Interestingly, there are absolutely almost simple nonsplit algebraic groups over $\mathbb{Q}$ that have reductive reduction at all primes, see [28], [14], but there are no $\mathbb{Q}$-defined abelian varieties with smooth reduction at all primes [18].) At the time of this writing, our knowledge about the conjecture is limited to the following two theorems.

Theorem 7.6 (cf. [9], Theorem 5.3). *Conjectures 7.2 and 7.5 (for inner forms) are true for $G = \mathrm{SL}_{1,A}$ where A is a central simple K-algebra.*

Assume that $\mathrm{char}\, K \neq 2$ and let $\mu_2 = \{\pm 1\}$. Then for any discrete valuation v of K such that $\mathrm{char}\, \overline{K}_v \neq 2$ and any $i \geqslant 1$, one can define the residue map in Galois cohomology

$$\rho_v^i \colon H^i(K, \mu_2) \to H^{i-1}(\overline{K}_v, \mu_2)$$

extending (R) in 6.5 to all dimensions (see, for example, [13, 3.3] or [25, 6.8] for the details). Then for any set V of discrete valuations of K such that $\mathrm{char}\, \overline{K}_v \neq 2$ for all $v \in V$, one defines the unramified part $H^i(K, \mu_2)_V$ to be $\bigcap_{v \in V} \mathrm{Ker}\ \rho_v^i$ (of course, $H^2(K, \mu_2)_V = {}_2\,\mathrm{Br}(K)_V$).

Theorem 7.7 ([11]). *Let K be a finitely generated field of characteristic $\neq 2$, and let V be a set of discrete valuations of K as in Conjecture 7.5 such that $\mathrm{char}\, \overline{K}_v \neq 2$ for all $v \in V$. Assume that for any finite subset $V_0 \subset V$, the unramified cohomology groups $H^i(K, \mu_2)_{V \setminus V_0}$ are finite for all $i \geqslant 1$. Then for any $n \geqslant 5$, the set of K-isomorphism classes of the spinor groups $\mathrm{Spin}_n(q)$, where q is a nondegenerate n-dimensional quadratic form, that have reductive reduction at all $v \in V$, is finite.*

Now, our Finiteness Conjecture 6.1 would be a consequence of Conjecture 7.5 and the following.

Conjecture 7.8. *Let K and V be as in Conjecture 7.5, and assume that $\mathrm{char}\ K = 0$. Furthermore, let G_1 and G_2 be absolutely almost simple algebraic groups defined over a field $F \supset K$, and let $\Gamma_1 \subset G_1(F)$ be a Zariski-dense subgroup with trace field $K_\Gamma = K$. Then there exists a finite subset $V_0 \subset V$ (depending on Γ_1) such that if $\Gamma_2 \subset G_2(F)$ is weakly commensurable to Γ_1, then the (simply connected cover of the) algebraic hull $\mathcal{G}_2$ of Γ_2 has reductive reduction at all $v \in V \setminus V_0$.*

At this point, Conjecture 7.8 has been established for groups of type A_1 using the strong approximation theorem of Weisfeiler [54]. It seems that the same method should also be applicable in the general case.

The potential implications of Conjecture 7.5 reach beyond eigenvalue rigidity, e.g., it would also imply the finiteness of the Tate-Shafarevich set in some situations. More precisely, let K and V be as in Conjecture 7.5, and let G be an absolutely almost simple simply connected K-group. Consider the Tate-Shafarevich set

$$Ш(\overline{G}) := \mathrm{Ker}\left(H^1(K, \overline{G}) \longrightarrow \prod_{v \in V} H^1(K_v, \overline{G}) \right)$$

for the corresponding adjoint group $\overline{G}$. We can pick a finite subset $V_0 \subset V$ so that G has reductive reduction at all $v \in V \setminus V_0$. Now, let $\xi \in Ш(\overline{G})$, and let $G' = {}_\xi G$ be the corresponding twisted group. Then $G' \simeq G$ over K_v for all $v \in V$, and in particular, G' has reductive reduction at all $v \in V \setminus V_0$. Assuming Conjecture 7.5, we would have that the groups ${}_\xi G$ for $\xi \in Ш(\overline{G})$ form finitely many K-isomorphism classes; in other words, the image of $Ш(\overline{G})$ under the canonical map $H^1(K, \overline{G}) \xrightarrow{\lambda} H^1(K, \mathrm{Aut}\, G)$ is finite. But since $\overline{G} \simeq \mathrm{Int}\, G$ is of finite index in $\mathrm{Aut}\, G$, the map λ has finite fibers, so we obtain the finiteness of $Ш(\overline{G})$. In particular, Theorem 7.6 yields the following.

Corollary 7.9. *Let K and V be as in Conjecture 7.5, and let A be a central simple K-algebra of degree n not divisible by* $\mathrm{char}\ K$. *Then for $\overline{G} = \mathrm{PSL}_{1,A}$, the Tate-Shafarevich set $Ш(\overline{G})$ is finite.*

Finally, we would to point out that the techniques involved in Theorem 7.3 are instrumental not only for proving the finiteness of $\mathbf{gen}_K(G)$, but also for its quantitative analysis. For example, they give yet another instance where a K-form is *uniquely* determined by its maximal K-tori.

Theorem 7.10. *Let $K = k(x)$, where k is a global field of characteristic $\neq 2$. For any K-group G of type G_2, the genus $\mathbf{gen}_K(G)$ reduces to a single element.*

One expects a similar statement to hold over such a field K also for groups of types B_ℓ, C_ℓ ($\ell \geqslant 2$) and F_4 (maybe under some additional assumptions).

Acknowledgements. The author was partially supported by NSF grant DMS-1301800. The author is grateful to Vladimir Chernousov, Gopal Prasad and Igor Rapinchuk for comments and suggestions that helped to improve the exposition.

Local and global Frobenius splitting

Karen E. Smith

Abstract. We survey recent progress in local and global Frobenius splitting, explaining the ideas that unify them, including a new way to look at test ideals.

Mathematics Subject Classification (2010). Primary 13A35; Secondary 14B15, 14B05, 14J45, 14E30.

Keywords. Frobenius splitting, F-purity, F-regularity, F-singularities, tight closure, test ideals, multiplier ideals, compatibly split ideals, log canonical, log terminal, rational singularity, Cohen-Macaulay.

1. Introduction

Frobenius splitting has inspired a vast arsenal of techniques in commutative algebra, algebraic geometry, and representation theory. A great many papers and books exist on the topic, with related techniques developed by different camps of researchers, often in language impenetrable to others. Only in the most recent years have many of the most elegant ideas coalesced into a simple and coherent story. I assume that my duty is to summarize some of the state of the art.

The story of Frobenius splitting begins in the 1970's with Hochster and Roberts' celebrated proof of the Cohen-Macaulayness of rings of invariants [41]. The term "Frobenius splitting" was coined a decade later in the exceptionally beautiful paper of Mehta and Ramanathan [65], which jump-started an entire industry devoted to better understanding (e.g., singularities and vanishing of cohomology for) naturally occurring varieties (such as Schubert varieties) in the representation theory of algebraic groups. On the commutative algebra side, Hochster and Roberts' legacy eventually spawned the theory of tight closure [44]. By the nineties, tight closure was being used to define "characteristic p analogs" of important notions in the minimal model program, a process still evolving today.

The last few years have witnessed the continued expansion of Frobenius splitting techniques into further reaches of mathematics; new applications have been found, for example, to Fomin and Zelevinsky's cluster algebras, and there is hope that some of these tools might be used to make progress towards the minimal model program in prime characteristic. Our understanding of *test ideals*—originally defined by Hochster and Huneke as a technical component of the theory of tight closure—has crystalized: now test ideals can be viewed as an instance of *compatible splitting* in the language of Mehta and Ramanathan, as a prime characteristic analog of multiplier ideals or within the broader context of Kawamata's centers of log canonicity, or as annihilators of certain important Artinian modules with Frobenius action. This triumvirate of perspectives on test ideals as major components of three quite

Proceedings of the International Congress of Mathematicians, Seoul, 2014

different areas—algebro-geometric representation theory, birational geometry, and commutative algebra, respectively—bespeaks the depth and importance of Frobenius splitting.

In this talk, I begin in the local setting, reviewing the definition of Frobenius splitting and the closely related but slightly stronger notion of F-regularity due to Hochster and Huneke. This notion ultimately to "characteristic p analogs" of rational, log canonical, log terminal, and DuBois singularities. In a recent application, a large class of cluster algebras (*locally acyclic cluster algebras*) are shown to have canonical singularities [6].

In the global setting, I'll summarize the recent progress on unraveling the geometry of Frobenius split and globally F-regular varieties. These varieties (which are also defined in characteristic zero by "reduction to characteristic p") are important because of the wealth of vanishing theorems about them and because they are characteristic p analogs of some central players in the birational classification of algebraic varieties.

We now understand that global splittings of Frobenius for projective varieties are the same as local splittings "at the vertex of the cone" with respect to any polarization of the variety. This means that the local commutative algebraic theory of Hochster-Roberts-Huneke is equivalent to the global projective theory of Mehta-Ramanathan, despite the fact that the theories developed almost independently during the end of the twentieth century (witness the remarkable disjointness of the monographs [48] and [20]).

A culminating idea is Karl Schwede's recent insight that the test ideal can be viewed as one ideal in a lattice of ideals (which he calls uniformly F-compatible) that are special with respect to the Frobenius map. Such a lattice of ideals had already been intensely studied in commutative algebra as annihilators of "modules with Frobenius action," but Schwede's dual insight gave rise to a simpler and more elegant definition of test ideals which immediately tied them to Mehta and Ramanathan's compatibly split ideals, as well as to Kawamata's theory of log canonical centers. In the last part of my talk, I will explain this new development, as well as an asymptotic theory of test ideals which leads to a simple proof of a theorem on the behavior of symbolic powers of ideals in any polynomial ring.

This paper should be viewed as an extended abstract for my ICM lecture; it is grossly inadequate as a serious survey of this ever expanding field. Having recently written a comprehensive exposition on this topic for MSRI based on a mini-course for the opening workshop for last year's Program in Commutative Algebra, I refer readers who prefer a more leisurely development of the ideas in the main cases there. There are also many other excellent surveys on recent developments, including [83] or [14], both of which contain a more technical and extensive survey of test ideals. Older surveys such as [91] explain more about reduction to characteristic p and the connections between singularities in the minimal model program and characteristic p techniques. Other possible surveys of interest include Huneke's lectures on Tight Closure [48] and Brion-Kumar's text on Mehta-Ramanathan's Frobenius splitting [20]. There are also many topics that I simply won't have time to touch, including connections with Hilbert-Kunz multiplicities (see [49]) or the difficult arithmetic issues arising in the work on F-pure thresholds (see [5] or [70]).

2. The Frobenius map for rings

Let R be any commutative ring of prime characteristic p. The Frobenius map (or p-th power map) is a ring homomorphism:

$$F : R \to R; \qquad r \mapsto r^p.$$

Viewing the second copy of R as an R-module via Frobenius, the Frobenius map is also an R-module map. A nice notation for this map is $F : R \to F_*R$, which is consistent with the notation for sheaves.

The ring R is said to be **F-finite** if the Frobenius map is finite. This is a mild assumption; for example, the class of F-finite rings is closed under localization, surjective image, completion at a maximal ideal, and finite extensions. In particular, finitely generated algebras over a perfect field are F-finite.

A basic fact due to Kunz [57] is that *an F-finite ring R is regular if and only if F_*R is a locally free R-module.*[1] Frobenius splitting can be viewed as a weakened version of this freeness:

Definition 2.1. A reduced ring R of characteristic p is **Frobenius split** (or **F-split**) if the Frobenius map $F : R \to F_*R$ splits (in the category of R-modules).

An F-finite regular ring is Frobenius split by Kunz's theorem. Any direct summand of a Frobenius split ring is Frobenius split itself. So Veronese subrings of polynomial rings are Frobenius split but not regular. So is the ring of invariants of a finite group acting on a polynomial ring over a field whose characteristic does not divide the order of the group.

The first systematic use of Frobenius splitting is in [41, 42], although Hochster and Roberts defined a different notion called F-purity which they proved equivalent to Frobenius splitting in the F-finite case (and possibly always).

2.1. Notation. For a reduced ring R, the Frobenius map $F : R \to F_*R$ is equivalent to the the inclusion of R^p-modules $R^p \hookrightarrow R$. This in turn is equivalent to the inclusion of R-modules $R \hookrightarrow R^{1/p}$, where $R^{1/p}$ is the subring of p-th roots of elements of R in an algebraic closure of the total field of fractions of R.

2.2. F-regularity. A refinement of Frobenius splitting is the notion of F-regularity, which is defined via iterates of Frobenius:

$$F^e : R \to R \qquad r \mapsto r^{p^e}.$$

Again, we denote this map by $R \to F^e_*R$ to emphasize that we view the second copy of R as an R-module via iterates of Frobenius.

Definition 2.2 ([43]). An F-finite ring R is **strongly F-regular**[2] if for every element $f \in R$ not in any minimal prime of R, there exists $e \in \mathbb{N}$ such that the R-module map $R \to F^e_*R$ sending 1 to $f \in F^e_*R$ splits. Put differently, this means that R is reduced, and for all f not in any minimal prime, there exists $e \in \mathbb{N}$ and $\phi \in \mathrm{Hom}_R(R^{1/p^e}, R)$ such that $\phi(f^{1/p^e}) = 1$.

An F-regular ring is not free over R^{p^e} (unless it is regular), but it will have *many* summands isomorphic to R^{p^e}. Indeed, every non-zero element of R will generate an R^{p^e}-module direct summand of R for sufficiently large e. It is easy to see that regular rings are F-regular, and that F-regular rings are Frobenius split. Furthermore, direct summands of F-regular rings are F-regular. F-regular rings have many nice properties:

[1] More generally, even if R is not F-finite, Kunz shows that an excellent ring of characteristic $p > 0$ is regular if and only if its Frobenius map is flat. F-finite rings are always excellent [58].

[2] Hochster and Huneke introduced three flavors of F-regularity, all conjectured to be equivalent. The equivalence is known, for example, for graded rings [61] and for rings with isolated non-$\mathbb{Q}$-Gorenstein points [63]. In recent years, the adjective "strongly" is sometimes dropped from this term, at least in some corners of the literature.

Theorem 2.3.

(1) *F-regular rings are Cohen-Macaulay and normal* [43]*;*

(2) *F-regular rings are pseudo-rational*[3] [90].

Corollary 2.4 (The Hochster-Roberts Theorem [41]). *Fix any ground field k. Let G be a linearly reductive algebraic group over k acting on a regular Noetherian k-algebra S. Then the ring of invariants*

$$S^G := \{f \in S \mid f \circ g = f \quad \text{for all } \ g \in G\}$$

is Cohen-Macaulay.

The proof in characteristic p is immediate: the linear reductivity implies that S^G is a *direct summand* of the regular ring S, hence it is F-regular, and therefore Cohen-Macaulay, by the theorem above. The characteristic zero statement is proved by reduction to characteristic p. Later, Boutot gave a different proof in the characteristic zero case, which does not use reduction to characteristic p, although it still exploits the philosophy of "splitting" [18].

2.3. Recent application to cluster algebras. Fomin and Zelevinsky introduced *cluster algebras* as a way to understand total positivity in a variety of contexts [26]. Fix a purely transcendental field $\mathcal{F} = k(x_1, \ldots, x_n)$ of dimension n over some ground field k. A cluster algebra is a k-subalgebra $\mathcal{A}$ of $\mathcal{F}$ generated by a distinguished collection of rational functions which come together in overlapping groups of algebraically independent generators for $\mathcal{F}$ over k called *clusters*. The clusters are not arbitrary, but are related to one another by a sequence of *mutations* (defined via specific combinatorial rules). Each cluster is indexed by a skew-symmetrizable matrix (or a quiver in a simplified setting) which are related to one another by a corresponding sequence of mutations. See [26, 27] and especially [7] for details.

Many of the motivating examples of cluster algebras are famously well-behaved rings, including for example, (localizations of) the Plucker homogeneous coordinate rings for Grassmannians and other rings from combinatorial representation theory. However, a number of pathological examples also satisfy the definition and there is a sense that the "right class" of cluster algebras is yet to be identified.

The acyclic cluster algebras form one well-understood and well-behaved class, but this class is far too restrictive to be of major importance in its own right [7]. Greg Muller recently introduced the **locally acyclic** cluster algebras, a *much wider* class which simultaneously rules out all of the pathological examples while being flexible enough to include nearly all of the interesting ones [68]. By definition, a cluster algebra is *locally acyclic* if its spectrum admits a "cluster cover" by acyclic cluster algebras—that is, a cover by affine open sets Spec $\mathcal{A}_y$, where y is a product of cluster variables such that $\mathcal{A}_y$ has a naturally induced cluster algebra structure which is acyclic. See [68].

Theorem 2.5 ([6]). *Every locally acyclic cluster algebra over a field of prime characteristic is strongly F-regular.*

It follows that every locally acyclic cluster algebra over a field of characteristic zero has rational singularities [90], and hence canonical singularities (since they are always Gorenstein) [23]. The theorem applies to a wide range of cluster algebras, including for example,

[3]Pseudorationality is a characteristic-free notion introduced in [60] which agrees with rational singularities in characteristic zero.

cluster algebras of Grassmannians, cluster algebras of *marked surfaces* with at least two marked points on the boundary [68, Theorem 10.6], as well as cluster algebras of double Bruhat cells and more generally, *positroid cells* [69].

2.3.1. The Laurent Phenomenon and upper cluster algebras. By the *Laurent Phenomenon*, each cluster variable is a Laurent polynomial in every other cluster [7]. This implies that a cluster algebra $\mathcal{A}$ is contained in its upper cluster algebra

$$\mathcal{U} := \bigcap_{\text{clusters } \mathbf{x} \subset \mathbb{A}} k[x_1^{\pm 1}, x_2^{\pm 1}, ..., x_n^{\pm 1}] \subset \mathcal{F}.$$

For locally acyclic cluster algebras, $\mathcal{A} = \mathcal{U}$, but the inclusion is strict in general [7, 68].

If $k[x_1^{\pm 1}, x_2^{\pm 1}, ..., x_n^{\pm 1}]$ is the Laurent ring in some cluster, there is a Frobenius splitting defined by

$$\phi\left(\lambda x_1^{a_1} x_2^{a_2} \cdots x_n^{a_n}\right) = \begin{cases} \phi(\lambda) x_1^{a_1/p} x_2^{a_2/p} \cdots x_n^{a_n/p} & \text{if } a_1, a_2, ..., a_n \in p\mathbb{Z} \\ 0 & \text{otherwise} \end{cases}$$

(where $\phi : F_* k \to k$ is any fixed splitting of the ground field). This induces a Frobenius splitting of the function field $\mathcal{F}$. It is shown in [6] that *all clusters induces the same splitting of* $\mathcal{F}$. Thus there is a canonical cluster splitting on any upper cluster algebra. This is closely related to the fact that the cluster log forms

$$\frac{dx_1 \wedge dx_2 \wedge \cdots \wedge dx_n}{x_1 \cdots x_n}$$

do not depend on the choice of cluster (up to sign),[4] since a Frobenius splitting is a section of the sheaf $\mathcal{O}_X((1-p)K_X)$. See Section 4.2.

2.4. F-signature. A numerical refinement of F-regularity called the *F-signature* sharpens the classification of F-singularities by measuring the *growth rate* of the rank of a maximal free summand of the R-module $F_*^e R$ as e goes to infinity. This was first studied in [96].

Fix a local F-finite domain R. For each natural number e, we can decompose the R module $F_*^e R$ as a direct sum of indecomposable modules, and count the number of summands that are isomorphic to R. Let a_e denote the rank of a maximal free summand of the R-module $F_*^e R$. [Note that if R is Frobenius split then $a_e \geq 1$, and if R is regular then $a_e = p^{de}$ where d is the rank of the free module $F_* R$ over R.] For an F-regular ring, we expect many summands of $F_*^e R$ isomorphic to R, so we expect a_e to grow with e.

Definition 2.6. The **F-signature** of R is

$$s(R) = \lim_{e \to \infty} \frac{a_e}{p^{de}},$$

where $d = [K : K^p]$ for K the fraction field of R. This limit was recently shown to exist [101].

The F-signature is one if and only if R is regular, as proved by Huneke and Leuschke, who also coined the term "F-signature" [50]. The F-signature is positive if and only if R

[4] This observation also appears in the unpublished work of Allen Knutson and David Speyer.

is F-regular [3]. Thus each F-regular ring has an F-signature strictly between zero and one; we can think of F-signature as a measurement of how close an F-regular ring is to being regular. For example, the rational double points $xy = z^{n+1}$ have F-signature $1/(n+1)$ [50], reflecting the fact that the singularity is "worse" for larger n. Formulas for the F-signature of toric varieties are worked out in Von Korff's PhD thesis [102].

Tucker vastly generalizes and simplifies much of the literature on F-signature in [101], to which we refer for a nice exposition. The state of the art on F-signature can be found in the recent papers of Blickle, Schwede and Tucker [16] and [17], which include generalizations of F-signature to pairs (and triples). The F-signature is closely related to the Hilbert-Kunz multiplicity, a subject pioneered by Paul Monsky [67]; see Huneke's survey [49] or Brenner's paper [19]. No known examples of non-rational F-signatures are known (though some expect that they exist).

2.5. Characteristic zero definitions. Let k denote any field of characteristic 0, and let R be a finitely generated k-algebra. Fix a presentation

$$R \cong k[x_1, \ldots, x_n]/(f_1, \ldots, f_r).$$

Let A be the $\mathbb{Z}$-subalgebra of k generated by all coefficients of the polynomials $f_1, \ldots, f_r$, and set

$$R_A = A[x_1, \ldots, x_n]/(f_1, \ldots, f_r).$$

Since A is a finitely generated $\mathbb{Z}$-algebra, the residue field of A at each of its maximal ideals is finite. The map Spec $R_A \to$ Spec A can be viewed as a "family of models" for R. The closed fibers of this map are characteristic p schemes (of varying p) whereas the $k-$valued points reproduce R.

Definition 2.7. The ring R is said to have **dense Frobenius split type** (or **dense F-regular type**) if there is a dense set of maximal ideals μ in Spec A such that $A/\mu \otimes_A R_A$ is Frobenius split (or F-regular).[5]

Definition 2.7 does not depend on the presentation of R, nor on the choice of A. See [47].

Example 2.8.

(1) The ring $\mathbb{C}[x, y, z]/(y^2 - xz)$ has dense F-regular type. As a matter of fact, taking $A = \mathbb{Z}$, the closed fibers of the family are the rings $\mathbb{F}_p[x, y, z]/(y^2 - xz)$, which are F-regular for *every* prime number p.

(2) The ring $\mathbb{C}[x, y, z]/(x^3 + y^3 + z^3)$ has dense Frobenius split type, but *not* dense F-regular type, nor open Frobenius split type. Indeed, $\mathbb{F}_p[x, y, z]/(x^3 + y^3 + z^3)$ is Frobenius split if and only if $p \equiv 1 (\text{mod } 3)$, so that there is an infinite set of prime numbers p for which the "reduction mod p" is Frobenius split. On the other hand, for every $p \geq 5$ and every e, one can show that there is **no map** sending x^{1/p^e} to 1. So this ring is not dense F-regular type.

[5] We can also define **open** Frobenius split (F-regular) type to be when $A/\mu \otimes_A R_A$ is F-split (F-regular) for an *open* set of maximal ideals μ in Spec A. It is expected that dense and open F-regular type are equivalent; this is known in Gorenstein rings and related settings; see [90] and [36].

2.6. Connections with the singularities in the minimal model program. Frobenius splitting and F-regularity in characteristic zero are closely related to a number of important issues arising independently in algebraic geometry, including log canonical and log terminal singularities, positivity, and multiplier ideals.

Theorem 2.9. *Let R be a finitely generated domain over a field of characteristic zero. Then*

(1) *If R is Gorenstein, then R has dense F-regular type if and only if R has rational singularities [32, 66, 90].*

(2) *If R is $\mathbb{Q}$-Gorenstein, then R has dense F-regular type if and only if R has log terminal singularities [36].*

(3) *If R is $\mathbb{Q}$-Gorenstein and has dense Frobenius split type, then R has log canonical singularities [36].*

All three statements can also be made for "pairs;" see Section 3.2.

There are related notions which can be defined in terms of local cohomology modules: F-injectivity means that Frobenius acts injectively on the local cohomology modules of a local ring with support in the maximal ideal, while F-rationality means that these local cohomology modules have no nontrivial proper submodules stable under Frobenius. F-rational type is equivalent to rational singularities [90], [32], [66]. F-injective type implies DuBois singularities [76].

The converse of Theorem 2.6 (3) is conjectured to hold in general as well. This long-standing open question related to an important conjecture linking the *F-pure threshold* and the *log canonical threshold;* see Section 5.4.

3. The global theory

Let X denote a scheme of prime characteristic p. The Frobenius map $F : X \to X$ is the identity map on the underlying topological space of X, while the corresponding map of sheaves $\mathcal{O}_X \to F_*\mathcal{O}_X$ is the p-th power map locally on sections.

Consistent with the terminology for rings, we say that a scheme X is *F-finite* if the quasi-coherent sheaf $F_*\mathcal{O}_X$ is *coherent.* Our main interest is when X is a variety over a perfect field k of characteristic p; such a variety is always F-finite. Note that the Frobenius map is rarely a map of varieties, since it is not linear over the ground field k (unless $k = \mathbb{F}_p$).

Kunz's Theorem implies that an F-finite scheme X is regular if and only if the coherent $\mathcal{O}_X$-module $F_*\mathcal{O}_X$ is locally free. A scheme X is *locally Frobenius split* if the map $\mathcal{O}_X \to F_*\mathcal{O}_X$ splits locally in a neighborhood of each point, or equivalently, if all stalks $\mathcal{O}_{X,p}$ are Frobenius split. Likewise, we say X is *locally F-regular* if all stalks are F-regular. A locally F-regular scheme is normal, Cohen-Macaulay and pseudo-rational by Theorem 2.3.

It is much stronger, of course, to require a *global* splitting of the Frobenius map:

Definition 3.1. Let X be an F-finite scheme of prime characteristic.

(1) X is *Frobenius split* if the Frobenius map $\mathcal{O}_X \to F_*\mathcal{O}_X$ splits as a map of $\mathcal{O}_X$-modules [65];

(2) X is globally F-regular if for all effective Cartier divisors D, there is an e such that the composition

$$\mathcal{O}_X \to F_*^e\mathcal{O}_X \hookrightarrow F_*^e\mathcal{O}_X(D)$$

splits as a map of $\mathcal{O}_X$-modules [93].

Globally F-regular varieties are Frobenius split in a strong sense: there are typically *many* splittings of Frobenius. Indeed, consider any effective divisor D on a globally F-regular variety X. A splitting of (2) above is a map $F^e_*\mathcal{O}_X(D) \xrightarrow{\phi} \mathcal{O}_X$, which can be restricted to $F^e_*\mathcal{O}_X$ to induce a splitting of $\mathcal{O}_X \to F^e_*\mathcal{O}_X$ as well. So we have a splitting of the (iterated) Frobenius $\mathcal{O}_X \to F^e_*\mathcal{O}_X$ which factors through $F^e_*\mathcal{O}_X(D)$—that is, a *Frobenius splitting along D* [73, 74]. A strongly F-regular variety is Frobenius split (for some iterate) along every effective divisor.

Frobenius split varieties satisfy strong vanishing theorems:

Theorem 3.2. *Let X be a Frobenius split projective scheme over an F-finite field, and let $\mathcal{L}$ be an invertible sheaf.*

(1) *If $H^i(X, \mathcal{L}^n) = 0$ for $n \gg 0$, then $H^i(X, \mathcal{L}) = 0$ [65].*

(2) *In particular, if $\mathcal{L}$ is ample, then $H^i(X, \mathcal{L})$ vanishes for all $i > 0$.*

(3) *In particular, if X is Cohen-Macaulay and $\mathcal{L}$ is ample, then $H^i(X, \omega \otimes \mathcal{L}) = 0$ for all $i > 0$ by Serre duality.*

(4) *If X is globally F-regular and $\mathcal{L}$ is nef, then $H^i(X, \mathcal{L})$ vanishes for all $\mathcal{L}$ and all $i > 0$ [93].*

Thus it is worthwhile to have criteria for Frobenius splitting and globally F-regularity. One useful criterion is essentially due to Hochster and Roberts, although the interpretation here is from [91, 4.10.2]:

Proposition 3.3. *A projective variety X is Frobenius split if and only if the induced map $H^{\dim X}(X, \omega_X) \to H^{\dim X}(X, F^*\omega_X)$ is injective.*

Example 3.4. It follows that a variety with trivial canonical bundle (such as an elliptic curve, or in higher dimension, an abelian variety or a Calabi-Yau) is Frobenius split if and only if it is ordinary. The study of ordinarity for Abelian varieties is a difficult problem in number theory; see e.g. [64].

The only smooth projective curve that is globally F-regular is $\mathbb{P}^1$; this follows by applying Theorem 3.2 (4) to the canonical bundle. In higher dimension as well, global F-regularity is a type of positivity. Indeed, Mehta and Ramanathan pointed out that a Frobenius splitting can be viewed as a special kind of pluri-anticanonical form:

Lemma 3.5. *Let X be a normal projective variety over a perfect field. Then we have*

$$\mathcal{H}om_{\mathcal{O}_X}(F^e_*\mathcal{O}_X, \mathcal{O}_X) \cong F^e_*\omega_X^{1-p^e}.$$

So we expect that globally F-regular schemes will admit many effective divisors in the linear systems $|(1 - p^e)K_X|$. Indeed, this property essentially characterizes globally F-regular varieties:

Theorem 3.6 ([82, 93]). *If X is a globally F-regular projective variety of characteristic p, then X is log Fano.*

By log Fano we mean a normal projective variety which admits an effective $\mathbb{Q}$-divisor Δ such that $-K_X - \Delta$ is ample, and the pair (X, Δ) has (at worst) Kawamata log terminal singularities.[6]

The proof of Theorem 3.6 constructs the $\mathbb{Q}$-divisor Δ as follows: Fix an ample divisor D. A splitting of Frobenius along D is a map $F^e_*\mathcal{O}_X(D) \to \mathcal{O}_X$, which in turn can be viewed as a global section of $\mathrm{Hom}_{\mathcal{O}_X}(F^e_*\mathcal{O}_X(D), \mathcal{O}_X) \cong \omega_X^{1-p^e}(-D)$. This gives rise to an effective divisor D' in the linear system $|(1-p^e)K_X - D|$, and we set $\Delta = \frac{1}{p^e-1}D'$. Note that the construction very much depends on the characteristic, p.

The converse of Theorem 3.6 fails because of irregularities in small characteristic. For example, the cubic hypersurface defined by $x^3 + y^3 + z^3 + w^3$ in $\mathbb{P}^3$ is Fano in every characteristic $p \neq 3$, but not globally F-regular nor even Frobenius split in characteristic two. However, it *is* globally F-regular for all characteristics $p \geq 5$.

Theorem 3.7 ([82, 93]). *If X is a log Fano variety of characteristic zero, then X has globally F-regular type.*

The converse to Theorem 3.7 is open. If X has globally F-regular type, then in each characteristic p model, the proof of Theorem 3.6 constructs a "witness" divisor Δ_p establishing that the pair (X_p, Δ_p) is log Fano. But Δ_p depends on p and there is no *a priori* reason that there must be some divisor Δ on the characteristic zero variety which reduces mod p to Δ_p.

Conjecture 3.8. *A projective globally F-regular type variety (of characteristic zero) is log Fano.*

Conjecture 3.8 has been proved for surfaces [30] as well as for $\mathbb{Q}$-factorial Mori Dream spaces [29]. This raises the question: are globally F-regular type varieties (of characteristic zero) Mori Dream Spaces? Moreover, since log Fano spaces (of characteristic zero) are Mori Dream spaces by [9, Cor 1.3.2], the answer is necessarily *yes* if Conjecture 3.8 is true. What about in characteristic p?

Question 3.9. *Assume that X is globally F-regular. Is it true that the Picard group of X is finitely generated? Is it true that the Cox ring of X is always finitely generated?*

Similar issues arise regarding the geometry of Frobenius split varieties:

Theorem 3.10 ([82]). *If X is a normal Frobenius split projective variety of characteristic p, then X is log Calabi-Yau.*

By log Calabi-Yau we mean that X admits an effective $\mathbb{Q}$-divisor such that (X, Δ) is log canonical[7] and $K_X + \Delta$ is $\mathbb{Q}$-linearly equivalent to the trivial divisor.

Again, the converse fails because of irregularities in small characteristic. However, we do expect an analog of Theorem 3.7 to hold.

Conjecture 3.11 ([82]). *If X is a log Calabi-Yau variety of characteristic zero, then X has Frobenius split type.*

Conjecture 3.11 is known in dimension two [30] and for Mori Dream spaces [29].

[6] Kawamata log terminal singularity is usually defined in characteristic 0 using a resolution of singularities, but it can be defined in any characteristic as follows. A pair (X, Δ) consisting of a normal variety with an effective $\mathbb{Q}$-divisor is *Kawamata log terminal* if $K_X + \Delta$ is $\mathbb{Q}$-Cartier, and for *all* birational proper maps $\pi : Y \to X$ with Y normal, choosing K_Y so that $\pi_* K_Y = K_X$, each coefficient of $\pi^*(K_X + \Delta) - K_Y$ is strictly less than 1.

[7] We define log canonical in characteristic p similarly to how we defined klt singularities.

3.1. Local versus global splitting. Despite developing separately, the local and global theories are completely equivalent. Indeed, a projective variety is Frobenius split or globally F-regular if and only if "its affine cone" has that property:

Theorem 3.12 ([82, 93]). *Let X be any projective scheme over a perfect field. The following are equivalent:*

(1) *X is Frobenius split;*
(2) *the ring $S_{\mathcal{L}} = \bigoplus_{n\in\mathbb{N}} H^0(X, \mathcal{L}^n)$ is Frobenius split for all invertible $\mathcal{L}$;*
(3) *the section ring $S_{\mathcal{L}} = \bigoplus_{n\in\mathbb{N}} H^0(X, \mathcal{L}^n)$ is Frobenius split for some ample invertible $\mathcal{L}$.*

Likewise, a projective variety X is globally F-regular if and only if some (equivalently, every) section ring $S_{\mathcal{L}}$ with respect to an ample invertible sheaf $\mathcal{L}$ is F-regular.

Example 3.13. Grassmannians of any dimension and characteristic are globally F-regular. Indeed, the homogeneous coordinate ring for the Plücker embedding of any Grassmannian is F-regular [45]. More generally, all Schubert varieties are globally F-regular [59]. A normal projective toric variety (of any characteristic) is globally F-regular, since a section ring given by a torus invariant ample divisor will be generated by monomials, hence F-regular [95].

3.2. Pairs. During the last decade, a theory of "F-singularities of pairs" has flourished, inspired by the rich theory of pairs developed in birational geometry [54]. The idea to create tight closure theory for pairs was a major breakthrough, pioneered by Nobuo Hara and Keiichi Watanabe in [36]. Once defined, the theory of tight closure theory for pairs—including F-regularity, F-splitting and test ideals— rapidly developed in a long series of technical papers by the Japanese school of tight closure, including Hara, Watanabe, Takagi, Yoshida and others.

By *pair* in this context, we have in mind a normal irreducible scheme X of finite type over a perfect field, together with either a $\mathbb{Q}$-divisor Δ (or an ideal sheaf $\mathfrak{a}$ raised to some fractional exponent.[8]) In the geometric setting, an additional assumption—namely that $K_X + \Delta$ is $\mathbb{Q}$-Cartier—is usually imposed, because a standard technique involves pulling back to different birational models. One possible advantage to the algebra set-up is that it is not necessary to assume that $K_X + \Delta$ is $\mathbb{Q}$-Cartier for the definitions, although alternatives have also been proposed directly in the world of birational geometry as well; see [25]. See also [80].

Definition 3.14. Let X be a normal F-finite variety, and Δ an effective $\mathbb{Q}$-divisor on X.

(1) The pair (X, Δ) is sharply Frobenius split (respectively locally sharply Frobenius split) if there exists an $e \in \mathbb{N}$ such that the natural map

$$\mathcal{O}_X \to F^{p^e}_* \mathcal{O}_X(\lceil (p^e - 1)\Delta \rceil)$$

splits as an map of sheaves of $\mathcal{O}_X$-modules (respectively, splits locally at each stalk).

(2) The pair (X, Δ) is globally (respectively, locally) F-regular if for all effective divisors D, there exists an $e \in \mathbb{N}$ such that the natural map

$$\mathcal{O}_X \to F^{p^e}_* \mathcal{O}_X(\lceil (p^e - 1)\Delta \rceil + D)$$

[8] There are even triples $(X, \Delta, \mathfrak{a}^t)$ incorporating aspects of both variants.

splits as an map of sheaves of $\mathcal{O}_X$-modules (respectively, splits locally at each stalk).

Remark 3.15. A slightly different definition of Frobenius splitting for a pair (X, Δ) was first given by Hara and Watanabe [36]. The variant here, which fits better into our context, was introduced by Karl Schwede [77].

Theorem 3.16 ([36]). *Let (X, Δ) be a pair where X is a normal variety of prime characteristic and Δ is a $\mathbb{Q}$-divisor such that $K_X + \Delta$ is $\mathbb{Q}$-Cartier.*

(1) *If (X, Δ) is a locally F-regular pair, then (X, Δ) is Kawamata log terminal.*

(2) *If (X, Δ) is a locally sharply Frobenius split pair, then (X, Δ) is log canonical.*

Similarly, there are global versions: Theorem 3.7 and 3.10 also hold for "pairs." See [82]. In characteristic zero, the converse of (1) holds, as does its global analog. The local and global converses of (2) are conjectured; this appears to be a difficult problem with deep connections to arithmetic.

We can think of F-regularity as a "characteristic p analog" of Kawamata log terminal singularities, and (at least conjecturally) Frobenius splitting as a "characteristic p analog" of log canonical singularities. The analogy runs deep: F-pure thresholds become "characteristic p analogs" of log canonical thresholds [99], test ideals become "characteristic p analogs" of multiplier ideals [33, 94], centers of sharp F-purity become "characteristic p analogs" of log canonicity [78], F-injectivity becomes a "characteristic p analog" of Dubois singularities [76].

3.2.1. Possible applications to the minimal model program in characteristic p. Recently, attention has turned to solving the minimal model program in prime characteristic, where a big obstruction is the failure of vanishing theorems. There is hope that the Frobenius splitting and tight-closure inspired definitions will help overcome this difficulty. For example, it is not even known in characteristic p whether klt singularities are Cohen-Macaulay, even when resolution of singularities is assumed [55]. Perhaps F-regularity is the "right" class of singularities to consider in prime characteristic instead? As another example, the test ideal is better than the multiplier ideal at capturing some of the subtleties in prime characteristic, for example, under pull back under wildly ramified mappings [84]. The world of F-singularities is beginning to get implemented in the minimal model program (see e.g. [31]), but the final outcome of this endeavor is not yet clear. Another place where Frobenius techniques have been helpful is in effective generation of adjoint bundles; this goes back to [92] which is reproved in dual format in [81], and generalized recently in [72]. See also [53].

4. The test ideal

The *test ideal* is a distinguished ideal reflecting the Frobenius properties of a prime characteristic ring. Test ideals can be defined very generally for pairs on more or less arbitrary Noetherian schemes of characteristic p. However, the theory becomes most transparent in two special cases, the "classical commutative algebra case" and the "classical algebraic geometry case."

The test ideal is a "characteristic p analog" of the multiplier ideal in characteristic zero. This was first proved in the absolute case in [94] and (independently) [33]; the proofs were later adapted to the relative case when test ideals of pairs were introduced [35, 37].

In the classical commutative algebra case, the scheme is the spectrum of a local ring R and we are interested in the "absolute" test ideal. In this case, the test ideal $\tau(R)$ is essentially Hochster and Huneke's test ideal for tight closure.[9] The test ideal can be viewed as just one (the smallest) ideal in a lattice of ideals special with respect to the Frobenius map.

The idea of viewing the test ideal as one ideal in a special lattice given by Frobenius has been around for some time. For example, the test ideal of a Gorenstein ring (R, m) is the annihilator of the maximal proper submodule of the injective hull of the residue field of R stable under any action of Frobenius [62, 89, 90]. But Karl Schwede recently dualized this point of view, leading to a more accessible and elegant theory which ties the test ideal in with Mehta and Ramanathan's theory of compatibly split ideals.

4.1. Schwede's definition of the test ideal. Let R be an F-finite reduced ring of characteristic p.

Definition 4.1. Fix any R-linear map $\varphi : R^{1/p^e} \to R$. An ideal J of R is called φ-*compatible* if $\varphi(J^{1/p^e}) \subseteq J$. That is, J is φ-compatible if there is a commutative diagram

$$\begin{array}{ccc} R^{1/p^e} & \xrightarrow{\varphi} & R \\ \downarrow & & \downarrow \\ (R/J)^{1/p^e} & \dashrightarrow & R/J, \end{array}$$

where the vertical arrows are the natural surjections, showing that φ descends to a map $(R/J)^{1/p^e} \to R/J$.

Definition 4.2 ([78]). An ideal J in an F-finite ring is **uniformly F-compatible** if it is compatible with respect to *every* R-linear map $R^{1/p^e} \to R$, for all e. The **test ideal** is the smallest uniformly compatible ideal not contained in any minimal prime.

It is a non-obvious fact that there exists a smallest such ideal. This is essentially due to Hochster and Huneke in their proof the existence of "completely stable test elements" [43]. For a summary of the proof in this context, see [83].

The test ideal behaves well under localization. In addition, it is easy to see that a ring R is F-regular if and only if its test ideal is trivial. Thus the test ideal defines the locus of non-F-regular points of Spec R.

The set of uniformly F compatibly ideals forms a lattice closed under sum and intersection. If R is Frobenius split, all these ideals are radical as well. This lattice has been studied before: it is the precisely the lattice of F-ideals discussed in [89] and [90], as well as the lattice of annihilators of $\mathcal{F}(E)$-modules of [62], in their respective contexts. If we restrict to just one φ which happens to be a Frobenius splitting of R, this is the lattice of compatibly split ideals of Mehta and Ramanathan [65].

Remark 4.3 (For experts in tight closure theory). The test ideal defined here is the "big" test ideal in the tight closure terminology.[10] If R is complete local, for example, the test ideal

[9] Our terminology differs slightly from the tight closure literature, where our test ideal would be called the "big test ideal" for "non-finitistic tight closure."

[10] Of course, all versions of test ideals in the tight closure theory are conjectured to be equal, and are known to be equal in many cases, including $\mathbb{Q}$-Gorenstein [4] and graded [61] cases.

we define here is the same as the annihilator of the non-finitistic tight closure of zero in the injective hull of the residue field of R [62]. See [78] for a proof.

Experts in tight closure can easily see how the definition of the test ideal here relates to the one in the literature, and why there is a unique smallest uniformly F-compatible ideal, at least in the Gorenstein local case. Let (R, m) be a Gorenstein local domain of dimension d. As is well-known, the test ideal is the annihilator of the tight closure of zero in $H^d_m(R)$. In [89] and [90], the Frobenius stable submodules of $H^d_m(R)$ (including the tight closure of zero) are analyzed and their annihilators in R are dubbed "F-ideals;" there it is shown (also using Hochster and Huneke's test elements!) that there is a unique largest proper Frobenius stable submodule of $H^d_m(R)$, hence a unique smallest non-zero F-ideal, namely test ideal of R. The uniformly F-compatible ideals are precisely the F-ideals—that is, annihilators of submodules of the top local cohomology module $H^d_m(R)$ stable under Frobenius. This is not hard to check using Lemma 4.4; SeF-compatiblee [78] or [24, Thm 4.1]. In the non-Gorenstein case the uniformly F-compatible ideals are the annihilators of the $\mathcal{F}(E)$-modules of [62]; see [78].

The lattice of uniformly F-compatible ideals is especially nice in a Frobenius split ring. For a fixed splitting φ of Frobenius, the set of φ-compatibly split ideals is *finite.* See [56, 75, 85], or [24] for a related dual result.

It follows from the definitions that if R is Frobenius split and J is uniformly F-compatible, then the quotient R/J is Frobenius split. This is an analog of the fact that a log canonical center of a log canonical scheme is itself log canonical. Indeed, Schwede calls the prime uniformly F-compatible ideals *centers of F-purity* and shows that these can be viewed as "characteristic p analogs" of Kawamata's centers of log canonicity [78]. [All of these statements have corresponding versions for pairs; see the references for exact statements.] Schwede also shows that these centers of F-purity satisfy an analog of Kawamata's subadjunction [52]; see [75]. For a local ring, there is a maximal proper uniformly F-compatible ideal—this is the **splitting prime** of Aberbach and Enescu [1].

4.2. Trace of Frobenius. An elementary but powerful observation is that often uniform F-compatibility can be checked by checking compatibility with just one morphism. The following is a simple consequence of the fact that the canonical module of a local Gorenstein ring is cyclic:

Lemma 4.4. *If R is an F-finite Gorenstein local ring, then $\mathrm{Hom}_R(R^{1/p}, R)$ is a cyclic $R^{1/p}$-module.*

It is easy to check that composing the generator (e times) for $\mathrm{Hom}_R(F_*R,R)$ gives a generator for $\mathrm{Hom}_R(F^e_*R,R)$. So an ideal J in a local Gorenstein ring is uniformly F-compatible if and only if it is compatible with a $R^{1/p}$-module generator Ψ for $\mathrm{Hom}_R(R^{1/p},R)$.

For any F-finite[11] ring R, we can dualize the Frobenius map $R \to F_*R$ into ω_R:

$$\mathrm{Hom}_R(F_*R, \omega_R) \longrightarrow \mathrm{Hom}_R(R, \omega_R)$$

which produces an R-module map

$$F_*\omega_R \to \omega_R,$$

[11] F-finite rings always admit a canonical module [28, 13.6].

called the *trace* of Frobenius.[12] For smooth projective varieties, this is called the Cartier map. If R is local and Gorenstein, this trace map Ψ_e generates $\mathrm{Hom}_R(F^e_* R, R)$. See the surveys [14], [84] or [20], for more on the trace map.

Remark 4.5. Blickle's *Cartier algebras* give another point of view [10]. An R-module map $F^e_* R \to R$ is an additive map $R \xrightarrow{\phi} R$ satisfying $\phi(r^{p^e} x) = r\phi(x)$ for any $r, x \in R$ [11]. The **Cartier algebra**[13] $\mathcal{C}(R)$ is the subalgebra of $\mathrm{Hom}_{\mathbb{Z}}(R, R)$ generated by all p^{-e}-linear maps (as we range over all e). Clearly R is a module over $\mathcal{C}(R)$, and clearly its $\mathcal{C}(R)$-submodules are precisely the uniformly F-compatible ideals. The trace map can also be easily interpreted in this language: in the Gorenstein local case, the trace Ψ_e of Lemma 4.4 is literally the composition of Ψ with itself e-times, so that Ψ generates $\mathcal{C}(R)$ as an R-algebra. Generalizations of uniformly F-compatible ideals also come up in the work of Blickle (*e.g.* [10]) under the name of Cartier-submodules and crystals; see the survey [14].

5. Test ideals for pairs

Let R be an F-finite ring, and let $\mathfrak{a}$ be an ideal of R. For each non-negative real number t, we associate an ideal

$$t \in \mathbb{R}_{\geq 0} \ \rightsquigarrow \ \tau(R, \mathfrak{a}^t).$$

In the classical commutative algebra case, $\mathfrak{a} = R$, and all $\tau(R, \mathfrak{a}^t)$ produce the same ideal, the "absolute test ideal" $\tau(R)$. With the introduction of tight closure for pairs, test ideals for pairs naturally followed [37], but the original definition was quite technical. Schwede's definition is much nicer:

Definition 5.1 ([78]). Let R be a reduced F-finite ring and let $\mathfrak{a}$ be an ideal of R. The test ideal $\tau(R, \mathfrak{a}^t)$ is defined to be the smallest ideal J not contained in any minimal prime that satisfies

$$\varphi((\mathfrak{a}^{\lceil t(p^e-1)\rceil} J)^{1/p^e}) \subseteq J$$

for all $\varphi \in \mathrm{Hom}_R(R^{1/p^e}, R)$ (ranging over all $e \geq 1$).

The existence of such a smallest nonzero ideal is a non-trivial statement; again, the crucial point due to Hochster and Huneke in their proof of the existence of completely stable test elements. See [35, 83].

Just as multiplier ideals of pairs are particularly appealing to work with when the ambient scheme is regular, the same is true of test ideals. Although it is not obvious, the following characterization of test ideals below (from [12]) is equivalent to Schwede's in this more restrictive setting.

5.1. Test ideals in regular ambient rings. Let R be an F-finite regular domain, and $\mathfrak{a}$ any ideal of R. For each R-linear map $\phi : F^e_* R \to R$, we consider the image of $\mathfrak{a}$ under ϕ.

[12] This map is only as canonical as the choice of ω_R, so the "the" is slightly misleading. Of course in geometric situations where the canonical module is defined by differential forms, there is a canonical choice.

[13] Here we assume that R is reduced and of dimension greater than zero. In general, the definition of Cartier algebra is slightly more technical, but it reduces to this under very mild conditions. See [10].

Ranging over all $\phi \in \mathrm{Hom}_R(F^e_* R, R)$, we get an ideal

$$\mathfrak{a}^{[1/p^e]} := \sum_{\phi \in \mathrm{Hom}_R(F^e_* R, R)} \phi(\mathfrak{a}).$$

Lemma 5.2. *For any ideal $\mathfrak{a}$ in a Frobenius split ring R, we have*

$$\mathfrak{a}^{[1/p^e]} \subset (\mathfrak{a}^p)^{[1/p^{e+1}]}.$$

The lemma implies that given a rational number $t = n/p^e$ whose denominator is a power of p, there is an increasing sequence of ideals:

$$(\mathfrak{a}^n)^{[1/p^e]} \subset (\mathfrak{a}^{np})^{[1/p^{e+1}]} \subset (\mathfrak{a}^{np^2})^{[1/p^{e+2}]} \subset \cdots \tag{5.1}$$

which must eventually stabilize by the Noetherian property of the ring.

Definition 5.3 ([12]). Let R be an F-finite regular ring of characteristic p and let $\mathfrak{a}$ be an ideal of R. For each $t \in \mathbb{R}_{\geq 0}$, we define

$$\tau(R, \mathfrak{a}^t) := \bigcup_{e \in \mathbb{N}} (\mathfrak{a}^{\lceil tp^e \rceil})^{[\frac{1}{p^e}]}.$$

The sequence $\frac{\lceil tp^e \rceil}{p^e}$ could be replaced by any sequence of rational numbers (whose denominators are a power of p) converging to t from above: the lemma guarantees that all give an ascending chain of ideals stabilizing to the test ideal.

5.2. Properties of test ideals. All the properties of multiplier ideals on smooth ambient varieties carry over to test ideals with exceptionally simple proofs in this setting [12, 97]:

Theorem 5.4. *Let R be an F-finite regular ring of characteristic p, with ideals $\mathfrak{a}, \mathfrak{b}$. The following properties of the test ideal hold:*

(1) $\mathfrak{a} \subseteq \mathfrak{b} \ \Rightarrow\ \tau(R, \mathfrak{a}^t) \subseteq \tau(R, \mathfrak{b}^t)$ *for all* $t \in \mathbb{R}_{>0}$.

(2) $t \geq t' \ \Rightarrow\ \tau(R, \mathfrak{a}^t) \subseteq \tau(R, \mathfrak{a}^{t'})$.

(3) $\tau(R, (\mathfrak{a}^n)^t) = \tau(R, \mathfrak{a}^{nt})$ *for each positive integer n and each* $t \in \mathbb{R}_{>0}$.

(4) *Let W be a multiplicatively closed set in R, then*

$$W^{-1}\tau(R, \mathfrak{a}^t) = \tau(W^{-1}R, (W^{-1}\mathfrak{a})^t).$$

(5) *Let $\overline{\mathfrak{a}}$ denote the integral closure of $\mathfrak{a}$ in R. Then*

$$\tau(R, \overline{\mathfrak{a}}^t) = \tau(R, \mathfrak{a}^t) \text{ for all } t.$$

(6) $\mathfrak{a} \subseteq \tau(R, \mathfrak{a})$.

(7) *For each $t \in \mathbb{R}_{>0}$, there exists an $\varepsilon > 0$ such that $\tau(R, \mathfrak{a}^{t'}) = \tau(R, \mathfrak{a}^t)$ for all $t' \in [t, t + \varepsilon)$.*

(8) (Briançon-Skoda Theorem[14]) *If $\mathfrak{a}$ can be generated by r elements, then for each integer $\ell \geq r$ we have*

$$\tau(R, \mathfrak{a}^\ell) = \mathfrak{a}\tau(R, \mathfrak{a}^{\ell-1}).$$

[14] Also called Skoda's Theorem, or "Briançon-Skoda theorem with coefficients." See *e.g.* [2].

(9) (Restriction Theorem) *Let $x \in R$ be a regular parameter and $\mathfrak{a} \bmod x$ denote the image of $\mathfrak{a}$ in $R/(x)$, then*

$$\tau(R/(x), (\mathfrak{a} \bmod x)^t) \subseteq \tau(R, \mathfrak{a}^t) \bmod x.$$

(10) (Subadditivity Theorem) *If R is essentially of finite type over a perfect field, then $\tau(R, \mathfrak{a}^{tn}) \subseteq \tau(R, \mathfrak{a}^t)^n$ for all $t \in \mathbb{R}_{\geq 0}$ and all $n \in \mathbb{N}$.*[15]

Remark 5.5. Elementary proofs of all these properties are gathered together in [97]. The key fact used is the flatness of Frobenius. Most of these properties hold more generally, though most require some sort of restriction on the singularities of R and the proofs are considerably more technical. See *e.g.* [37, 98, 100].

5.3. Asymptotic test ideals and an application to symbolic powers. Asymptotic test ideal can be defined analogous to the asymptotic multiplier ideal first defined in [21]. This is quite simple and elegant in the case of a regular ambient scheme. See also [34, 100] for a more general setting.

Definition 5.6 ([21]). A sequence of ideals $\{\mathfrak{a}_n\}_{n\in\mathbb{N}}$ is called a *graded sequence* of ideals if

$$\mathfrak{a}_n \mathfrak{a}_m \subseteq \mathfrak{a}_{n+m}$$

for all n, m.

Graded sequences arise naturally in many contexts. For example, the sequence of base loci of the powers of a fixed line bundle form a graded sequence of ideals on a variety. The symbolic powers $\{\mathfrak{a}^{(n)}\}_{n\in\mathbb{N}}$ of any ideal $\mathfrak{a}$ in any ring form a graded sequence.

Given any graded sequence of ideals $\{\mathfrak{a}_n\}$, it follows from the definition and Property 5.4(1) that

$$\tau(R, \mathfrak{a}_n) = \tau(R, (\mathfrak{a}_n^m)^{1/m}) \subseteq \tau(R, \mathfrak{a}_{mn}^{1/m}).$$

In other words, the collection

$$\{\tau(R, \mathfrak{a}_m^{1/m})\}_{m\in\mathbb{N}}$$

has the property that any two ideals are dominated by a third in the collection. Since R is noetherian, this collection must have a maximal element; this stable ideal is called the **asymptotic test ideal:**

Definition 5.7. The **n-th asymptotic test ideal** of the graded sequence $\{\mathfrak{a}_n\}_{n\in\mathbb{N}}$ is the ideal

$$\tau_\infty(R, \mathfrak{a}_n) := \sum_{\ell\in\mathbb{N}} \tau(R, \mathfrak{a}_{\ell n}^{1/\ell}),$$

which is equal to

$$\tau(R, \mathfrak{a}_{mn}^{1/m})$$

for sufficiently large and divisible m.

By definition, it is clear that $\tau_\infty(R, \mathfrak{a}_n)$ satisfies appropriate analogs of all the properties listed in Theorem 5.4. In particular, we have the following consequence of the subadditivity theorem:

[15] More generally, the subadditivity property guarantees that for the *mixed test ideal* $\tau(\mathfrak{a}^t \mathfrak{b}^s)$ defined analogously as $\tau(\mathfrak{a}^{\lceil sp^e \rceil} \mathfrak{b}^{\lceil tp^e \rceil})^{[1/p^e]}$ for $e \gg 0$, we have $\tau(\mathfrak{a}^t \mathfrak{b}^s) \subseteq \tau(\mathfrak{a}^t)\tau(\mathfrak{b}^s)$ for all $t, s \in \mathbb{R}_{\geq 0}$.

Corollary 5.8. *For any graded sequence in an F-finite regular ring R, we have $\tau_\infty(R, \mathfrak{a}_{nm}) \subset (\tau_\infty(R, \mathfrak{a}_n))^m$ for all $n, m \in \mathbb{N}$.*

As an application, we prove

Theorem 5.9 (Ein-Lazasfeld-Smith; Hochster-Huneke). *Let I be an unmixed (e.g. prime) ideal in $k[x_1, \ldots, x_d]$. Then*

$$I^{(dn)} \subseteq I^n \text{ for all } n \in \mathbb{N}.$$

Proof of Theorem 5.9. The characteristic zero case follows from the prime characteristic case by a standard argument. We consider the graded sequence of ideals $\{I^{(n)}\}_{n\in\mathbb{N}}$. According to Theorem 5.4(3), we have $I^{(dN)} \subseteq \tau_\infty(R, I^{(dN)})$. By Corollary 5.8, we have

$$\tau_\infty(R, I^{(dN)}) \subseteq \tau_\infty(R, I^{(d)})^N$$

for all N. Hence it is enough to check that $\tau_\infty(I^{(d)}) \subseteq I$. For this, we can check at each associated prime $\mathfrak{p}$ of I, which means essentially that we can assume that R is local and that I is primary to the maximal ideal; that is, we need to show that

$$\tau_\infty(R_\mathfrak{p}, (I^d R_\mathfrak{p})) \subset I R_\mathfrak{p}.$$

In $R_\mathfrak{p}$, there is a reduction of I that can be generated by $\dim(R_\mathfrak{p}) \leq d$ elements, and hence according to Properties 5.4(5) we may assume that I itself can be generated by d elements. Then the Briançon-Skoda property 5.4(8) tells us

$$\tau_\infty(R_\mathfrak{p}, (I^d R_\mathfrak{p})) \subseteq I.$$

This finishes the proof. □

This theorem was first proved in [21] in characteristic zero, using asymptotic multiplier ideals. Later Hochster and Huneke gave a tight closure proof in the characteristic p case [46]. Takagi-Yoshida ([100]) generalized this result using test ideals. Our proof here is a straightforward adaptation of the original multiplier ideal proof in [21].

5.4. F-pure thresholds and F-jumping exponents. Having defined test ideals of a pair, analogs of the log canonical threshold and the jumping exponents (Cf. [22]) are the next obvious step. For simplicity, we restrict attention to the case an an ambient regular ring; the general case is much more technical.

Definition 5.10. Let R be an F-finite regular ring, and $\mathfrak{a}$ an ideal.

(1) The F-pure threshold $(R, \mathfrak{a})$ is the supremum, over all positive t, such that $\tau(R, \mathfrak{a}^t) = R$ [37];

(2) More generally, an F-jumping exponent is a real number ξ such that for all $\varepsilon > 0$, $\tau(R, \mathfrak{a}^{\xi-\varepsilon})$ is strictly larger than $\tau(R, \mathfrak{a}^\xi)$ [22].

Given a pair defined over a field of characteristic zero, one may "reduce mod p" and compare the F-pure threshold that arise to the log canonical threshold. The F-pure threshold of any characteristic p model is always less than or equal to the log canonical threshold; also as p goes to infinity, the F-pure thresholds converge to the log canonical threshold (this

follows from [36, 37]). In all known examples, there are in fact infinitely many p for which the F-pure threshold *equals* the log canonical threshold. An open question for over fifteen years is to show that this is always the case. If true, it follows that log canonical pairs (of characteristic zero) have dense Frobenius split type. Mustata and Srinivas have recently shown that this conjecture would follow from the following *weak ordinarily conjecture*: if X is a projective variety over a field of characteristic zero, then the Frobenius map acts injectively on $H^{\dim X}(X, \mathcal{O}_X)$ for infinitely many "mod p reductions" [71] (the extension to the singular setting is in [8]). The difficulty of these conjectures likely lies in some hard number theory. See the survey [70].

The F-pure threshold is very difficult to compute, with a fractal-like behavior in many cases, see [38, 39] and [40] for concrete computations of F-thresholds. See also [88]. See [5] for a beginners guide to the subject of F-pure threshold.

Discreteness and rationality of the F-jumping exponents has been another active research topic; it is vexing that the analogous properties for multiplier ideals are more-or-less obvious in characteristic zero. The F-jumping exponents are shown to be discrete and rational in the case of an ambient regular ring of finite type [12]. Since then, these results have been generalized to the $\mathbb{Q}$-Gorenstein case [15, 79]. The paper [86] gives an exceptionally well-written account of the state of the art. See also [13, 51, 87].

Acknowledgements. Deep thanks to my good friend Jeffrey Lagarias, who convinced be to write this paper when the demands of life threatened to cause me to punt, and to my dear fiancé Kai Rajala, who relieved me for enough hours to pull it off. Huge thanks also to my faithful post-doc Angelica Benito, who heroically took on massive editing tasks at the last minute, and my good friends Daniel Hernandez and Emily Witt for their careful proofreading.

3. Number Theory

Motivic periods and $\mathbb{P}^1\backslash\{0,1,\infty\}$

Francis Brown

Abstract. This is a review of the theory of the motivic fundamental group of the projective line minus three points, and its relation to multiple zeta values.

Mathematics Subject Classification (2010). Primary 11M32; Secondary 14C15.

Keywords. Belyi's theorem, multiple zeta values, mixed Tate motives, modular forms.

1. Introduction

The role of the projective line minus three points $X = \mathbb{P}^1\backslash\{0,1,\infty\}$ in relation to Galois theory can be traced back to Belyi's theorem [4] (1979):

Theorem 1.1. *Every smooth projective algebraic curve defined over $\overline{\mathbb{Q}}$ can be realised as a ramified cover of $\mathbb{P}^1$, whose ramification locus is contained in $\{0,1,\infty\}$.*

Belyi deduced that the absolute Galois group of $\mathbb{Q}$ acts faithfully on the profinite completion of the fundamental group of X, i.e., the map

$$\mathrm{Gal}(\overline{\mathbb{Q}}/\mathbb{Q}) \to \mathrm{Aut}(\widehat{\pi}_1(X(\mathbb{C}), b)) \tag{1.1}$$

where $b \in X(\mathbb{Q})$, is injective. In his famous proposal '*Esquisse d'un programme*' in 1984 [21], Grothendieck suggested studying the absolute Galois group of $\mathbb{Q}$ via its action on completions of fundamental groups of moduli spaces of curves $\mathcal{M}_{g,n}$ of genus g with n ordered marked points (X being isomorphic to $\mathcal{M}_{0,4}$) and their interrelations. A few years later, at approximately the same time, these ideas were developed in somewhat different directions in three enormously influential papers due to Drinfeld, Ihara, and Deligne [10, 15, 26]. Ihara's 1990 ICM talk gives a detailed account of the subject at that time [27]. However, the problem of determining the image of the map (1.1) remains completely open to this day.

In this talk I will mainly consider the pro-unipotent completion of the fundamental group of X, which seems to be a more tractable object than its profinite version, and closely follow the point of view of Deligne, and Ihara (see [27], §5).

1.1. Unipotent completion. Deligne showed [10] that the pro-unipotent completion of $\pi_1(X)$ carries many extra structures corresponding to the realisations of an (at the time) hypothetical category of mixed Tate motives over the integers. Since then, the motivic framework has now been completely established due to the work of a large number of different authors including Beilinson, Bloch, Borel, Levine, Hanamura, and Voevodsky. The definitive reference is [14], §§1-2.

Proceedings of the International Congress of Mathematicians, Seoul, 2014

1. There exists an abstract Tannakian category $\mathcal{MT}(\mathbb{Z})$ of mixed Tate motives unramified over $\mathbb{Z}$. It is a $\mathbb{Q}$-linear subcategory of the category $\mathcal{MT}(\mathbb{Q})$ of mixed Tate motives over $\mathbb{Q}$ obtained by restricting certain Ext groups. It is equivalent to the category of representations of an affine group scheme G^{dR} which is defined over $\mathbb{Q}$ and is a semi-direct product
$$G^{dR} \cong U^{dR} \rtimes \mathbb{G}_m \ .$$
The subgroup U^{dR} is pro-unipotent, and its graded Lie algebra (for the action of $\mathbb{G}_m$) is isomorphic to the free graded Lie algebra with one generator
$$\sigma_3, \sigma_5, \sigma_7, \ldots$$
in every odd negative degree ≤ -3. The essential reason for this is that the algebraic K-theory of the integers $K_{2n-1}(\mathbb{Z})$ has rank 1 for $n = 3, 5, 7, \ldots$, and rank 0 otherwise, as shown by Borel [2, 3]. Note that the elements σ_{2n+1} are only well-defined modulo commutators.
2. The pro-unipotent completion $\pi_1^{un}(X, \vec{1}_0, -\vec{1}_1)$ is the Betti realisation of an object, called the motivic fundamental groupoid (denoted by π_1^{mot}), whose affine ring is a limit of objects in the category $\mathcal{MT}(\mathbb{Z})$.

The majority of these notes will go into explaining 2 and some of the ideas behind the following motivic analogue of Belyi's injectivity theorem (1.1):

Theorem 1.2. *G^{dR} acts faithfully on the de Rham realisation of $\pi_1^{mot}(X, \vec{1}_0, -\vec{1}_1)$.*

This theorem has an ℓ-adic version which can be translated into classical Galois theory ([27], §5.2), and relates to some questions in the literature cited above. Unlike Belyi's theorem, which is geometric, the proof of theorem 1.2 is arithmetic and combinatorial. The main ideas came from the theory of multiple zeta values.

1.2. Multiple zeta values. Let $n_1, \ldots, n_r$ be integers ≥ 1 such that $n_r \geq 2$. Multiple zeta values are defined by the convergent nested sums
$$\zeta(n_1, \ldots, n_r) = \sum_{1 \leq k_1 < \ldots < k_r} \frac{1}{k_1^{n_1} \ldots k_r^{n_r}} \quad \in \mathbb{R} \ .$$
The quantity $N = n_1 + \ldots + n_r$ is known as the weight, and r the depth. Multiple zeta values were first studied by Euler (at least in the case $r = 2$) and were rediscovered independently in mathematics by Zagier and Ecalle, and in perturbative quantum field theory by Broadhurst and Kreimer. They satisfy a vast array of algebraic relations which are not completely understood at the time of writing.

The relationship between these numbers and the fundamental group comes via the theory of iterated integrals, which are implicit in the work of Picard and were rediscovered by Chen and Dyson. In general, let M be a differentiable manifold and let $\omega_1, \ldots, \omega_n$ be smooth 1-forms on M. Consider a smooth path $\gamma : (0, 1) \to M$. The iterated integral of $\omega_1, \ldots, \omega_n$ along γ is defined (when it converges) by
$$\int_\gamma \omega_1 \ldots \omega_n = \int_{0 < t_1 < \ldots < t_n < 1} \gamma^*(\omega_1)(t_1) \ldots \gamma^*(\omega_n)(t_n) \ .$$

Kontsevich observed that when $M = X(\mathbb{C})$ and $\gamma(t) = t$ is simply the inclusion $(0,1) \subset X(\mathbb{R})$, one has the following integral representation

$$\zeta(n_1,\ldots,n_r) = \int_\gamma \omega_1 \underbrace{\omega_0\ldots\omega_0}_{n_1-1}\omega_1\underbrace{\omega_0\ldots\omega_0}_{n_2-1}\ldots\omega_1\underbrace{\omega_0\ldots\omega_0}_{n_r-1} \tag{1.2}$$

where $\omega_0 = \frac{dt}{t}$ and $\omega_1 = \frac{dt}{1-t}$. I will explain in §2.1 that this formula allows one to interpret multiple zeta values as periods of the pro-unipotent fundamental groupoid of X. The action of the motivic Galois group G^{dR} on the (de Rham version of) the latter should translate, via Grothendieck's period conjecture, into an action on multiple zeta values themselves. Thus one expects multiple zeta values to be a basic example in a Galois theory of transcendental numbers ([1], §23.5); the action of the Galois group should preserve all their algebraic relations.

Of course, Grothendieck's period conjecture is not currently known, so there is no well-defined group action on multiple zeta values. This can be circumvented using motivic multiple zeta values. The action of G^{dR} on the de Rham fundamental group of X can then be studied via its action on these objects.

1.3. Motivic periods. Let T be a neutral Tannakian category over $\mathbb{Q}$ with two fiber functors $\omega_B, \omega_{dR} : T \to \mathrm{Vec}_{\mathbb{Q}}$. Define the ring of motivic periods to be the affine ring of functions on the scheme of tensor isomorphisms from ω_{dR} to ω_B

$$\mathcal{P}_T^{\mathfrak{m}} = \mathcal{O}(\underline{\mathrm{Isom}}_T(\omega_{dR},\omega_B)) \ .$$

Every motivic period can be constructed from an object $M \in T$, and a pair of elements $w \in \omega_{dR}(M), \sigma \in \omega_B(M)^\vee$. Its matrix coefficient is the function

$$\phi \mapsto \langle \phi(w), \sigma\rangle : \underline{\mathrm{Isom}}_T(\omega_{dR},\omega_B) \to \mathbb{A}^1_{\mathbb{Q}}$$

where $\mathbb{A}^1_{\mathbb{Q}}$ is the affine line over $\mathbb{Q}$, and defines an element denoted $[M,w,\sigma]^{\mathfrak{m}} \in \mathcal{P}_T^{\mathfrak{m}}$. It is straightforward to write down linear relations between these symbols as well as a formula for the product of two such symbols. If, furthermore, there is an element $\mathrm{comp}_{B,dR} \in \underline{\mathrm{Isom}}_T(\omega_{dR},\omega_B)(\mathbb{C})$ we can pair with it to get a map

$$\mathrm{per} : \mathcal{P}_T^{\mathfrak{m}} \longrightarrow \mathbb{C} \tag{1.3}$$

called the period homomorphism. The ring $\mathcal{P}_T^{\mathfrak{m}}$ admits a left action of the group $G^{dR} = \underline{\mathrm{Isom}}_T(\omega_{dR},\omega_{dR})$, or equivalently, a left coaction

$$\mathcal{P}_T^{\mathfrak{m}} \longrightarrow \mathcal{O}(G^{dR}) \otimes_{\mathbb{Q}} \mathcal{P}_T^{\mathfrak{m}} \ . \tag{1.4}$$

Example 1.3. Let T be any category of mixed Tate motives over a number field. It contains the Lefschetz motive $\mathbb{L} = \mathbb{Q}(-1)$, which is the motive $H^1(\mathbb{P}^1\backslash\{0,\infty\})$. Its de Rham cohomology is the $\mathbb{Q}$-vector space spanned by the class $[\frac{dz}{z}]$ and its Betti homology is spanned by a small positive loop γ_0 around 0. The Lefschetz motivic period is

$$\mathbb{L}^{\mathfrak{m}} = [\mathbb{L}, [\tfrac{dz}{z}], [\gamma_0]] \in \mathcal{P}_T^{\mathfrak{m}} \ .$$

Its period is $\mathrm{per}(\mathbb{L}^{\mathfrak{m}}) = 2\pi i$. It transforms, under the rational points of the de Rham Galois group of T, by $\mathbb{L}^{\mathfrak{m}} \mapsto \lambda\mathbb{L}^{\mathfrak{m}}$, for any $\lambda \in \mathbb{Q}^\times$.

This construction can be applied to any pair of fiber functors to obtain different notions of motivic periods. Indeed, the elements of $\mathcal{O}(G^{dR})$ can be viewed as 'de Rham' motivic periods, or matrix coefficients of the form $[M, w, v]^{dR}$, where $w \in \omega_{dR}(M)$ and $v \in \omega_{dR}(M)^\vee$ (called framings). Whenever the fiber functors carry extra structures (such as 'complex conjugation' on ω_B or a 'weight' grading on ω_{dR}), then the ring of motivic periods inherits similar structures.

1.3.1. Motivic MZV's. Let $T = \mathcal{MT}(\mathbb{Z})$. The Betti and de Rham realisations provide functors ω_B, ω_{dR}, and integration defines a canonical element

$$\mathrm{comp}_{B,dR} \in \underline{\mathrm{Isom}}_T(\omega_{dR}, \omega_B)(\mathbb{C}).$$

Since the de Rham functor ω_{dR} is graded by the weight, the ring of motivic periods $\mathcal{P}^{\mathfrak{m}}_{\mathcal{MT}(\mathbb{Z})}$ is also graded.[1] It contains graded subrings

$$\mathcal{P}^{\mathfrak{m},+}_{\mathcal{MT}(\mathbb{Z}),\mathbb{R}} \subset \mathcal{P}^{\mathfrak{m},+}_{\mathcal{MT}(\mathbb{Z})} \subset \mathcal{P}^{\mathfrak{m}}_{\mathcal{MT}(\mathbb{Z})}$$

of geometric periods (periods of motives whose weights are ≥ 0), denoted by a superscript $+$, and those which are also invariant under complex conjugation (denoted by a subscript $\mathbb{R}$, since their periods lie in $\mathbb{R}$ as opposed to $\mathbb{C}$).

Next, one has to show that the integral (1.2) defines a period of an object M in $\mathcal{MT}(\mathbb{Z})$ (this can be done in several ways: [14, 20, 36]. This defines a matrix coefficient $[M, w, \sigma]^{\mathfrak{m}}$, where w encodes the integrand, and σ the domain of integration, which we call a motivic multiple zeta value (§2.2)

$$\zeta^{\mathfrak{m}}(n_1, \ldots, n_r) \in \mathcal{P}^{\mathfrak{m}}_{\mathcal{MT}(\mathbb{Z})} \,.$$

Its weight is $n_1 + \ldots + n_r$ and its period is (1.2). Most (but not all) of the known algebraic relations between multiple zeta values are also known to hold for their motivic versions. Motivic multiple zeta values generate a graded subalgebra

$$\mathcal{H} \subset \mathcal{P}^{\mathfrak{m},+}_{\mathcal{MT}(\mathbb{Z}),\mathbb{R}} \,. \tag{1.5}$$

The description §1.1, (1) of U^{dR} enables one to compute the dimensions of the motivic periods of $\mathcal{MT}(\mathbb{Z})$ in each degree by a simple counting argument:

$$\text{if} \quad d_N := \dim_{\mathbb{Q}} \left(\mathcal{P}^{\mathfrak{m},+}_{\mathcal{MT}(\mathbb{Z}),\mathbb{R}}\right)_N \quad \text{then} \quad \sum_{N\geq 0} d_N t^N = \frac{1}{1-t^2-t^3} \,. \tag{1.6}$$

This implies a theorem proved independently by Goncharov and Terasoma [14],[36].

Theorem 1.4. *The $\mathbb{Q}$-vector space spanned by multiple zeta values of weight N has dimension at most d_N, where the integers d_N are defined in* (1.6).

So far, this does not use the action of the motivic Galois group, only a bound on the size of the motivic periods of $\mathcal{MT}(\mathbb{Z})$. The role of $\mathbb{P}^1\backslash\{0, 1, \infty\}$ is that the automorphism group of its fundamental groupoid yields a formula for the coaction (1.4) on the motivic multiple zeta values (§2.5). The main theorem uses this coaction in an essential way, and is inspired by a conjecture of M. Hoffman [25].

[1] In the field of multiple zeta values, the 'weight' refers to one half of the Hodge-theoretic weight, so that $\mathbb{L}^{\mathfrak{m}}$ has degree 1 instead of 2. I shall adopt this terminology from here on.

Theorem 1.5. *The following set of motivic MZV's are linearly independent:*

$$\{\zeta^{\mathfrak{m}}(n_1,\ldots,n_r) \quad \textit{for} \quad n_i=\{2,3\}\}\ . \tag{1.7}$$

From the enumeration (1.6) of the dimensions, we deduce that $\mathcal{H}=\mathcal{P}^{\mathfrak{m},+}_{\mathcal{MT}(\mathbb{Z}),\mathbb{R}}$, and that (1.7) is a basis for $\mathcal{H}$. From this, one immediately sees that U^{dR} acts faithfully on $\mathcal{H}$, and theorem 1.2 follows easily. As a bonus we obtain that U^{dR} has canonical generators σ_{2n+1} (defined in §3.1), and, furthermore, by applying the period map we obtain the

Corollary 1.6. *Every multiple zeta value of weight N is a $\mathbb{Q}$-linear combination of $\zeta(n_1,\ldots,n_r)$, where $n_i\in\{2,3\}$ and $n_1+\ldots+n_r=N$.*

The point of motivic periods is that they give a mechanism for obtaining information on the action of G^{dR}, via the period map, from arithmetic relations between real numbers. For theorem 1.5, the required arithmetic information comes from a formula for $\zeta(2,\ldots,2,3,2,\ldots,2)$ proved by Zagier [38] using analytic techniques.

1.4. Transcendence of motivic periods. With hindsight, theorem 1.5 has less to do with mixed Tate motives, or indeed $\mathbb{P}^1\backslash\{0,1,\infty\}$, than one might think. Define a category H whose objects are given by the following data:

1. A finite-dimensional $\mathbb{Q}$-vector space M_B equipped with an increasing filtration called the weight, which is denoted by W.
2. A finite-dimensional $\mathbb{Q}$-vector space M_{dR} equipped with an increasing filtration W and a decreasing filtration F (the Hodge filtration).
3. An isomorphism $\mathrm{comp}_{B,dR}\ :\ M_{dR}\otimes\mathbb{C}\ \tilde{\to}\ M_B\otimes\mathbb{C}$ which respects the weight filtrations. The vector space M_B, equipped with W and the filtration F on $M_B\otimes\mathbb{C}$ induced by $\mathrm{comp}_{B,dR}$ is a $\mathbb{Q}$-mixed Hodge structure.

The category H is Tannakian ([10], 1.10), with two fiber functors, so it has a ring of motivic periods $\mathcal{P}^{\mathfrak{m}}_H$. Furthermore, the Betti and de Rham realisations define a functor $M\mapsto(M_B,M_{dR},\mathrm{comp}_{B,dR}):\mathcal{MT}(\mathbb{Z})\to H$, and hence a homomorphism

$$\mathcal{P}^{\mathfrak{m}}_{\mathcal{MT}(\mathbb{Z})}\longrightarrow\mathcal{P}^{\mathfrak{m}}_H\ . \tag{1.8}$$

This map is known to be injective, but we do not need this fact. The main theorem 1.5 is equivalent to saying that the images $\zeta^H(n_1,\ldots,n_r)\in\mathcal{P}^{\mathfrak{m}}_H$ of (1.7) for $n_i\in\{2,3\}$ are linearly independent. In this way, we could have dispensed with motives altogether and worked with objects in $\mathcal{P}^{\mathfrak{m}}_H$, which are elementary.[2] This leads to the following philosophy for a theory of transcendence of motivic periods in H (or another suitable category of mixed Hodge structures). It differs from standard approaches which emphasise finding relations between periods [28].

- Write down arithmetically interesting elements in, say $\mathcal{P}^{\mathfrak{m}}_H$, which come from geometry (i.e., which are periods in the sense of [28]).

[2] In fact, we should never need to compute relations explicitly using 'standard operations' such as those described in [28]; these are taken care of automatically by the Tannakian formalism, and the bound on the Ext groups of $\mathcal{MT}(\mathbb{Z})$ coming from Borel's theorems on algebraic K-theory.

- Compute the coaction (1.4) on these motivic periods, and use it to prove algebraic independence theorems.

Indeed, there is no reason to restrict oneself to mixed Tate objects, as the category H does not rely on any conjectural properties of mixed motives. The role of $\mathbb{P}^1\backslash\{0,1,\infty\}$ was to give an integral representation for the numbers (1.2) and provide a formula for the coaction.

1.4.1. Multiple modular values. Therefore, in the final part of this talk I want to propose changing the underlying geometry altogether, and replace a punctured projective line with (an orbifold) $M = \Gamma\backslash\backslash\mathbb{H}$, where $\mathbb{H}$ is the upper half plane, and $\Gamma \leq \mathrm{SL}_2(\mathbb{Z})$ is a subgroup of finite index. Because of Belyi's theorem 1.1, every smooth connected projective algebraic curve over a number field is isomorphic to an $\overline{\Gamma\backslash\mathbb{H}}$. Therefore the (pure) motivic periods obtained in this way are extremely rich[3]. It is reasonable to hope that the action of the Tannaka group on the *mixed* motivic periods of M should be correspondingly rich and should generate a large class of new periods suitable for applications in arithmetic and theoretical physics. Many of these periods can be obtained as regularised iterated integrals on $M = \Gamma\backslash\mathbb{H}$ (building on those considered by Manin in [32, 33]), and the philosophy of §1.4 concerning their Galois action can be carried out by computing a suitable automorphism group of non-abelian group cocyles. There still remains a considerable amount of work to put this general programme in its proper motivic context and extract all the arithmetic consequences.

1.5. Contents. In §2, I review the motivic fundamental group of X from its Betti and de Rham view points, define motivic multiple zeta values, and derive their Galois action from first principles. The only novelty is a direct derivation of the infinitesimal coaction from Ihara's formula. In §3, I state some consequences of theorem 1.5. In §4 I explain some results of Deligne concerning the motivic fundamental group of the projective line minus N^{th} roots of unity, and in §5 discuss the depth filtration on motivic multiple zeta values and its conjectural connection with modular forms. In §6 I mention some new results on multiple modular values for $\mathrm{SL}_2(\mathbb{Z})$, which forms a bridge between multiple zeta values and modular forms.

For reasons of space, it was unfortunately not possible to review the large recent body of work relating to associators, double shuffle equations ([1] §25, [16], [34]) and applications to knot theory, the Kashiwara-Vergne problem, and related topics such as deformation quantization; let alone the vast range of applications of multiple zeta values to high-energy physics and string theory. Furthermore, there has been recent progress in p-adic aspects of multiple zeta values, notably by H. Furusho and G. Yamashita, and work of M. Kim on integral points and the unit equation, which is also beyond the scope of these notes.

Many technical aspects of mixed Tate motives have also been omitted. See [14], §1-2 for the definitive reference.

2. The motivic fundamental group of $\mathbb{P}^1\backslash\{0,1,\infty\}$

Let $X = \mathbb{P}^1\backslash\{0,1,\infty\}$, and for now let $x, y \in X(\mathbb{C})$. The motivic fundamental groupoid of X (or rather, its Hodge realisation) consists of the following data:

[3]Grothendieck refers to $\mathrm{SL}_2(\mathbb{Z})$ as '*une machine à motifs*'

1. (Betti). A collection of schemes $\pi_1^B(X,x,y)$ which are defined over $\mathbb{Q}$, and which are equipped with the structure of a groupoid:

$$\pi_1^B(X,x,y)\times\pi_1^B(X,y,z)\longrightarrow\pi_1^B(X,x,z)$$

for any $x,y,z\in X(\mathbb{C})$. There is a natural homomorphism

$$\pi_1^{top}(X,x,y)\longrightarrow\pi_1^B(X,x,y)(\mathbb{Q}) \tag{2.1}$$

where the fundamental groupoid on the left is given by homotopy classes of paths relative to their endpoints. The previous map is Zariski dense.

2. (de Rham). An affine group scheme[4] over $\mathbb{Q}$ denoted by $\pi_1^{dR}(X)$.
3. (Comparison). A canonical isomorphism of schemes over $\mathbb{C}$

$$\mathrm{comp}_{B,dR}:\pi_1^B(X,x,y)\times_{\mathbb{Q}}\mathbb{C}\xrightarrow{\sim}\pi_1^{dR}(X)\times_{\mathbb{Q}}\mathbb{C}\,. \tag{2.2}$$

These structures are described below. Deligne has explained ([10], §15) how to replace ordinary base points with tangential base points in various settings. Denote such a tangent vector by

$$\overrightarrow{v}_x=\text{the tangent vector } v\in T_x(\mathbb{P}^1(\mathbb{C}))\text{ at the point } x\,.$$

Identifying $T_x(\mathbb{P}^1(\mathbb{C}))$ with $\mathbb{C}$, one obtains natural tangent vectors $\overrightarrow{1}_0$ and $-\overrightarrow{1}_1$ at the points 0 and 1 respectively, and a canonical path, or 'droit chemin'

$$\mathrm{dch}\in\pi_1^{top}(X,\overrightarrow{1}_0,-\overrightarrow{1}_1)$$

given by the straight line which travels from 0 to 1 in $\mathbb{R}$ with unit speed.

The reason for taking the above tangential base points is to ensure that the corresponding motive (theorem 2.1) has good reduction modulo all primes p: in the setting of $\mathbb{P}^1\backslash\{0,1,\infty\}$ there are no ordinary base points with this property.

The following theorem states that the structures $1-3$ are motivic.

Theorem 2.1. *There is an ind-object (direct limit of objects)*

$$\mathcal{O}(\pi_1^{mot}(X,\overrightarrow{1}_0,-\overrightarrow{1}_1))\in\mathrm{Ind}\,(\mathcal{MT}(\mathbb{Z})) \tag{2.3}$$

whose Betti and de Rham realisations are the affine rings $\mathcal{O}(\pi_1^B(X,\overrightarrow{1}_0,-\overrightarrow{1}_1))$*, and* $\mathcal{O}(\pi_1^{dR}(X))$*, respectively.*

Proof. (Sketch) The essential idea is due to Beilinson ([18], theorem 4.1) and Wojtkowiak [39]. Suppose, for simplicity, that M is a connected manifold and $x,y\in M$ are distinct points. Consider the submanifolds in $M\times\ldots\times M$ (n factors):

$$N_i=M^{i-1}\times\Delta\times M^{n-i-1}\qquad\text{for } i=1,\ldots,n-1$$

[4] It shall also be written $\pi_1^{dR}(X,x,y)$ but does not depend on the choice of base points. The fact that there is a canonical isomorphism $\pi_1^{dR}(X,x,y)=\pi_1^{dR}(X)$ is equivalent to saying that there is a 'canonical de Rham path' between the points x and y.

where Δ is the diagonal $M \subset M \times M$. Set $N_0 = \{x\} \times M^{n-1}$ and $N_n = M^{n-1} \times \{y\}$, and let $N \subset M^n$ be the union of the N_i, for $i = 0, \ldots, n$. Then

$$H_k(M^n, N) = \begin{cases} \mathbb{Q}[\pi_1^{top}(M, x, y)]/I^{n+1} & \text{if } k = n \\ 0 & \text{if } k < n \end{cases} \tag{2.4}$$

where the first line is the n^{th} unipotent truncation of the fundamental torsor of paths from x to y (I is the image of the augmentation ideal in $\mathbb{Q}[\pi_1^{top}(M, x)]$; see below). In the case when $M = \mathbb{P}^1 \backslash \{0, 1, \infty\}$, the left-hand side of (2.4) defines a mixed Tate motive. The case when $x = y$, or when x or y are tangential base points, is more delicate [14], §3. □

The Betti and de Rham realisations can be described concretely as follows.

1. (Betti). The Betti fundamental groupoid is defined to be the pro-unipotent completion of the ordinary topological fundamental groupoid. For simplicity, take $x = y \in X(\mathbb{C})$. Then there is an exact sequence

   $$0 \longrightarrow I \longrightarrow \mathbb{Q}[\pi_1^{top}(X(\mathbb{C}), x)] \longrightarrow \mathbb{Q} \longrightarrow 0$$

   where the third map sends the homotopy class of any path γ to 1 (thus I is the augmentation ideal). Then one has (Malčev, Quillen)

   $$\mathcal{O}(\pi_1^B(X, x)) = \lim_{N \to \infty} \left(\mathbb{Q}[\pi_1^{top}(X, x)]/I^{N+1} \right)^{\vee}$$

   The case when $x \neq y$ is defined in a similar way, since $\mathbb{Q}[\pi_1^{top}(X(\mathbb{C}), x, y)]$ is a rank one module over $\mathbb{Q}[\pi_1^{top}(X(\mathbb{C}), x)]$.
2. (de Rham). When $X = \mathbb{P}^1 \backslash \{0, 1, \infty\}$, one verifies that

   $$\mathcal{O}(\pi_1^{dR}(X)) \cong \bigoplus_{n \geq 0} H^1_{dR}(X)^{\otimes n}$$

   which is isomorphic to the tensor coalgebra on the two-dimensional graded $\mathbb{Q}$-vector space $H^1_{dR}(X) \cong \mathbb{Q}(-1) \oplus \mathbb{Q}(-1)$. We can take as basis the elements

   $$[\omega_{i_1} | \ldots | \omega_{i_n}] \quad \text{where } \omega_{i_k} \in \{\tfrac{dt}{t}, \tfrac{dt}{1-t}\}$$

   where the bar notation denotes a tensor product $\omega_{i_1} \otimes \ldots \otimes \omega_{i_n}$. It is a Hopf algebra for the shuffle product and deconcatenation coproduct and is graded in degrees ≥ 0 by the degree which assigns $\frac{dt}{t}$ and $\frac{dt}{1-t}$ degree 1.

Denoting $\overrightarrow{1}_0$ and $-\overrightarrow{1}_1$ by 0 and 1 respectively, one can write, for $x, y \in \{0, 1\}$

$${}_x\Pi_y^{\bullet} = \mathrm{Spec}(\mathcal{O}(\pi_1^{\bullet}(X, x, y)) \qquad \text{where} \quad \bullet \in \{B, dR, \mathrm{mot}\} .$$

It is convenient to write ${}_x\Pi_y$ instead of ${}_x\Pi_y^{dR}$. It does not depend on x or y, but admits an action of the motivic Galois group G^{dR} which is sensitive to x and y. If R is any commutative unitary $\mathbb{Q}$-algebra,

$${}_x\Pi_y(R) \cong \{S \in R\langle\langle x_0, x_1 \rangle\rangle^{\times} : \Delta S = S \otimes S\}$$

is isomorphic to the group of invertible formal power series in two non-commuting variables x_0, x_1, which are group-like for the completed coproduct Δ defined by $\Delta(x_i) = x_i \otimes 1 + 1 \otimes x_i$. The group law is given by concatenation of series.

2.1. Periods. The periods of the motivic fundamental groupoid of $\mathbb{P}^1\backslash\{0,1,\infty\}$ are the coefficients of the comparison isomorphism $\mathrm{comp}_{B,dR}$ (2.2) with respect to the $\mathbb{Q}$-structures on the Betti and de Rham sides. Let

$$ {}_0 1_1^B \quad \in \quad \pi_1^B(X, \vec{1}_0, -\vec{1}_1)(\mathbb{Q}) \quad \subset \quad \mathcal{O}(\pi_1^B(X, \vec{1}_0, -\vec{1}_1))^\vee $$

denote the image of dch under the natural map (2.1). It should be viewed as a linear form on the affine ring of the Betti π_1. For all $\omega_{i_k} \in \{\frac{dt}{t}, \frac{dt}{1-t}\}$,

$$ \langle \mathrm{comp}_{B,dR}([\omega_{i_1}|\dots|\omega_{i_n}]), {}_0 1_1^B \rangle = \int_{\mathrm{dch}} \omega_{i_1} \dots \omega_{i_n} \tag{2.5} $$

The right-hand side is the iterated integral from 0 to 1, *regularised* with respect to the tangent vectors 1 and -1 respectively, of the one-forms ω_{i_k}. No regularisation is necessary in the case when $\omega_{i_1} = \frac{dt}{1-t}$ and $\omega_{i_n} = \frac{dt}{t}$, and in this case the right-hand side reduces to the formula (1.2). In general, one can easily show:

Lemma 2.2. *The integrals* (2.5) *are $\mathbb{Z}$-linear combinations of MZV's of weight n.*

The *Drinfeld associator* is the de Rham image of dch

$$ \mathcal{Z} = \mathrm{comp}_{B,dR}({}_0 1_1^B) \in {}_0\Pi_1(\mathbb{C}) $$

Explicitly, it is the non-commutative generating series of the integrals (2.5)

$$ \mathcal{Z} = \sum_{i_k \in \{0,1\}} x_{i_1} \dots x_{i_n} \int_{\mathrm{dch}} \omega_{i_1} \dots \omega_{i_n} \tag{2.6} $$

$$ = 1 + \zeta(2)[x_1, x_0] + \zeta(3)([x_0, [x_0, x_1]] + [x_1, [x_1, x_0]]) + \cdots \tag{2.7} $$

It is an exponential of a Lie series.

2.2. Motivic multiple zeta values. By the previous paragraph, the affine ring of the de Rham fundamental group is the graded Hopf algebra

$$ \mathcal{O}({}_x\Pi_y) \cong \mathbb{Q}\langle e_0, e_1 \rangle $$

independently of $x, y \in \{0,1\}$. Its product is the shuffle product, and its coproduct is deconcatenation. Its basis elements can be indexed by words in $\{0,1\}$. By a general fact about shuffle algebras, the antipode is the map $w \mapsto w^*$ where

$$ (a_1 \dots a_n)^* = (-1)^n a_n \dots a_1 $$

is signed reversal of words. Thus any word w in $\{0,1\}$ defines a de Rham element in $\mathcal{O}({}_x\Pi_y)$. The augmentation map $\mathbb{Q}\langle e_0, e_1\rangle \to \mathbb{Q}$ corresponds to the unit element in the de Rham fundamental group and defines a linear form ${}_x 1_y^{dR} \in \mathcal{O}({}_x\Pi_y)^\vee$.

Define Betti linear forms ${}_x 1_y^B \in \mathcal{O}({}_x\Pi_y^B)^\vee$ to be the images of the paths

$$ \mathrm{dch} \text{ if } x = 0, y = 1 \quad ; \quad \mathrm{dch}^{-1} \text{ if } y = 1, x = 0 \quad ; \quad c_x \text{ if } x = y \,, $$

where dch is the straight path from 0 to 1, dch^{-1} is the reversed path from 1 to 0, and c_x is the constant (trivial) path based at x.

Out of this data we can construct the following motivic periods.

Definition 2.3. Let $x, y \in \{0,1\}$ and let w be any word in $\{0,1\}$. Let

$$I^{\mathfrak{m}}(x;w;y) = [\mathcal{O}({}_x\Pi_y^{\mathrm{mot}}), w, {}_x1_y^B]^{\mathfrak{m}} \qquad \in \quad \mathcal{P}^{\mathfrak{m},+}_{\mathcal{MT}(\mathbb{Z}),\mathbb{R}} \tag{2.8}$$

We call the elements $I^{\mathfrak{m}}$ motivic iterated integrals. The 'de Rham' motivic period is the matrix coefficient $[\mathcal{O}({}_x\Pi_y^{\mathrm{mot}}), w, {}_x1_y^{dR}]$ on $\mathcal{MT}(\mathbb{Z})$ with respect to the fiber functors ω_{dR}, ω_{dR}. It defines a function on G^{dR}. Its restriction to the prounipotent group U^{dR} defines an element $I^{\mathfrak{u}}(x;w;y) \in \mathcal{O}(U^{dR})$. The latter are equivalent to objects defined by Goncharov (which he also called motivic iterated integrals).

Definition 2.4. Define motivic (resp. unipotent) multiple zeta values by

$$\zeta^{\bullet}(n_1,\ldots,n_r) = I^{\bullet}(0;10^{n_1-1}\cdots 10^{n_r-1};1)\ , \quad \bullet = \mathfrak{m},\mathfrak{u}$$

It is important to note that $\zeta^{\mathfrak{m}}(2)$ is non-zero, whereas $\zeta^{\mathfrak{u}}(2) = 0$.[5] We immediately deduce from the definitions that

$$\begin{aligned} &\text{(i)} \quad I^{\mathfrak{m}}(x;w;x) = \delta_{w,\emptyset} \qquad \text{for } x \in \{0,1\} \\ &\text{(ii)} \quad I^{\mathfrak{m}}(x;w;y) = I^{\mathfrak{m}}(y;w^*;x) \end{aligned} \tag{2.9}$$

The first property holds because the constant path is trivial, the second follows from the antipode formula and because $\mathrm{dch}\circ\mathrm{dch}^{-1}$, or $\mathrm{dch}^{-1}\circ\mathrm{dch}$, is homotopic to a constant path. Finally, replacing multiple zeta values with their motivic versions, we can define a motivic version of the Drinfeld associator

$$\mathcal{Z}^{\mathfrak{m}} = \sum_{i_1,\ldots,i_n\in\{0,1\}} x_{i_1}\ldots x_{i_n} I^{\mathfrak{m}}(0;i_1,\ldots,i_n;1)\ . \tag{2.10}$$

It satisfies the associator equations defined by Drinfeld [15], on replacing $2\pi i$ by $\mathbb{L}^{\mathfrak{m}}$ (using the fact that $\zeta^{\mathfrak{m}}(2) = \frac{-(\mathbb{L}^{\mathfrak{m}})^2}{24}$), and the double shuffle equations of [34].

2.3. Action of the motivic Galois group. The category $\mathcal{MT}(\mathbb{Z})$ is a Tannakian category with respect to the de Rham fiber functor. Therefore the motivic Galois group acts on the affine ring $\mathcal{O}({}_0\Pi_1)$ of the de Rham realisation of the motivic fundamental torsor of path (2.3). A slight generalisation of theorem 2.1 shows that G^{dR} acts on the de Rham fundamental schemes

$${}_x\Pi_y \qquad \text{for all } x,y \in \{0,1\}$$

and furthermore, is compatible with the following structures:

- (Groupoid structure). The multiplication maps

$${}_x\Pi_y \times {}_y\Pi_z \longrightarrow {}_x\Pi_z$$

  for all $x,y,z \in \{0,1\}$.
- (Inertia). The action of U^{dR} fixes the elements

$$\exp(x_0) \text{ in } {}_0\Pi_0(\mathbb{Q}) \qquad \text{and} \qquad \exp(x_1) \text{ in } {}_1\Pi_1(\mathbb{Q})$$

[5] One can define a homomorphism $\mathcal{P}^{\mathfrak{m},+}_{\mathcal{MT}(\mathbb{Z}),\mathbb{R}} \to \mathcal{P}^{\mathfrak{u}}_{\mathcal{MT}(\mathbb{Z})}$ which sends $\zeta^{\mathfrak{m}}(n_1,\ldots,n_r)$ to $\zeta^{\mathfrak{u}}(n_1,\ldots,n_r)$ and prove that its kernel is the ideal generated by $\zeta^{\mathfrak{m}}(2)$.

The groupoid structure is depicted in figure 2.1.

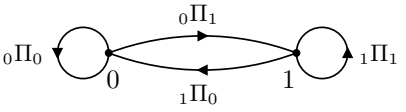

Figure 2.1. The groupoid ${}_x\Pi_y$ for $x, y \in \{0,1\}$. The diagram only represents the groupoid structure; the paths shown do not accurately depict the tangential base points.

The local monodromy map $\pi_1^{top}(\mathbb{G}_m, \vec{1}_0) \to \pi_1^{top}(X, \vec{1}_0)$ (where we write $\mathbb{G}_m$ for $\mathbb{P}^1\backslash\{0,\infty\}$), corresponding to monodromy around 0, has a motivic analogue which gives rise to the inertial condition. Its de Rham realisation is the map

$$\pi_1^{dR}(\mathbb{G}_m, \vec{1}_0) \to \pi_1^{dR}(X, \vec{1}_0) = {}_0\Pi_0$$

and is respected by G^{dR}. One shows that U^{dR} acts trivially on $\pi_1^{dR}(\mathbb{G}_m, \vec{1}_0)$, and furthermore that the element $\exp(x_0) \in {}_0\Pi_0(\mathbb{Q})$ is in the image of the previous map. This gives the first inertial condition.

Remark 2.5. It is astonishing that one obtains much useful information at all from such symmetry considerations. Nonetheless, it is enough to show the faithfulness of the action of G^{dR} (below). There are further structures respected by G^{dR}, such as compatibilities with automorphisms of $\mathbb{P}^1\backslash\{0,1,\infty\}$. They are not required.

2.4. Ihara action. Let $\mathcal{A}$ denote the group of automorphisms of the groupoid ${}_x\Pi_y$ for $x, y \in \{0,1\}$ which respects the structures $1, 2$ described in §2.3.

Proposition 2.6. *The scheme ${}_0\Pi_1$ is an $\mathcal{A}$-torsor. In particular, the action of $\mathcal{A}$ on $1 \in {}_0\Pi_1$ defines an isomorphism of schemes*

$$a \mapsto a(1) : \mathcal{A} \longrightarrow {}_0\Pi_1 \ . \tag{2.11}$$

The action of $\mathcal{A}$ on ${}_0\Pi_1$ defines, via this isomorphism, a new group law

$$\circ : {}_0\Pi_1 \times {}_0\Pi_1 \to {}_0\Pi_1 \ .$$

It is given explicitly on formal power series by Ihara's formula

$$A(x_0, x_1) \circ G(x_0, x_1) = G(x_0, Ax_1A^{-1})A \tag{2.12}$$

Proof. For the basic geometric idea, see [27], §2.3. Let $\mathfrak{a} \in \mathcal{A}$, and write $a_{xy}(\xi)$ for the action of $\mathfrak{a}$ on $\xi \in {}_x\Pi_y$. Write $a = a_{01}(1)$. Since ${}_0\Pi_0$ is a group, $\mathfrak{a}$ acts trivially on its identity element, and so $a_{00}(1) = 1$. Via the map ${}_0\Pi_1 \times {}_1\Pi_0 \to {}_0\Pi_0$ we have $a_{01}(1)a_{10}(1) = a_{00}(1)$ and hence $a_{10}(1) = a^{-1}$. The inertial conditions give

$$a_{00}(\exp(x_0)) = \exp(x_0) \quad \text{and} \quad a_{11}(\exp(x_1)) = \exp(x_1) \tag{2.13}$$

Now the composition of paths ${}_1\Pi_0 \times {}_0\Pi_0 \times {}_0\Pi_1 \to {}_1\Pi_1$ gives rise to an equation $1.\exp(x_1).1 = \exp(x_1)$. Applying $\mathfrak{a}$ to this gives by the second equation in (2.13)

$$a_{00}(\exp(x_1)) = a\exp(x_1)a^{-1} = \exp(ax_1a^{-1}) \tag{2.14}$$

which completely determines the action of $\mathcal{A}$ on ${}_0\Pi_0$. Via the map ${}_0\Pi_0 \times {}_0\Pi_1 \to {}_0\Pi_1$ we have the equation $g.1 = g$, and hence

$$a_{01}(g) = a_{00}(g).a\ . \tag{2.15}$$

Formula (2.12) follows from (2.13), (2.14), (2.15). One easily checks that a uniquely determines $\mathfrak{a}$, and so (2.11) is an isomorphism (see also [14], 5.9.) □

The groupoid and inertia structures are preserved by U^{dR}, giving a morphism

$$\rho : U^{dR} \longrightarrow \mathcal{A} \overset{(2.11)}{\cong} {}_0\Pi_1 \tag{2.16}$$

such that the following diagram commutes

$$\begin{array}{ccc} U^{dR} \times {}_0\Pi_1 & \longrightarrow & {}_0\Pi_1 \\ {\scriptstyle \rho\times \mathrm{id}}\downarrow & & \downarrow{\scriptstyle \mathrm{id}} \\ {}_0\Pi_1 \times {}_0\Pi_1 & \overset{\circ}{\longrightarrow} & {}_0\Pi_1 \end{array} \tag{2.17}$$

In principle this describes the action of the motivic Galois group on ${}_0\Pi_1$. Note, however, that the map (2.16) is mysterious and very little is known about it.

2.5. Dual formula. The coaction on motivic iterated integrals is dual to Ihara's formula. Dualising (2.17), we have

$$\Delta : \mathcal{O}({}_0\Pi_1) \longrightarrow \mathcal{O}(U^{dR}) \otimes \mathcal{O}({}_0\Pi_1)$$

It is equivalent, but more convenient, to consider the infinitesimal coaction

$$D\ :\ \mathcal{O}({}_0\Pi_1) \longrightarrow \mathcal{L} \otimes \mathcal{O}({}_0\Pi_1) \qquad \big(D(x) = \Delta(x) - 1 \otimes x \mod \mathcal{O}(U^{dR})^2_{>0}\big)$$

where $\mathcal{L} = \mathcal{O}(U^{dR})_{>0}/\big(\mathcal{O}(U^{dR})_{>0}\big)^2$ is the Lie coalgebra of indecomposables in $\mathcal{O}(U^{dR})$. The following formula is an infinitesimal variant of a formula due to Goncharov [19], relating to slightly different objects. In order to fill a gap in the literature, I will sketch how it follows almost immediately from Ihara's formula.

Proposition 2.7. *Let $a_0, \ldots, a_{n+1} \in \{0, 1\}$. The coaction D is given by*

$$\begin{aligned} D(I^{\mathfrak{m}}(a_0; a_1, \ldots, a_n; a_{n+1})) = \sum_{0\leq p<q\leq n} & \big[I^{\mathfrak{u}}(a_p; a_{p+1}, \ldots, a_q; a_{q+1})\big] \\ & \otimes I^{\mathfrak{m}}(a_0; a_1, \ldots, a_p, a_{q+1}, \ldots, a_n; a_{n+1})\ . \end{aligned} \tag{2.18}$$

where the square brackets on the left denote the map $[\ ] : \mathcal{O}(U^{dR})_{>0} \to \mathcal{L}$.

Proof. Denote the action of $\mathrm{Lie}\,\mathcal{A}$ on $\mathrm{Lie}\,{}_0\Pi_0$ by $\circ_0$. By (2.11), $\mathrm{Lie}\,\mathcal{A} \cong \mathrm{Lie}\,{}_0\Pi_1$ is the set of primitive elements in its (completed) universal enveloping algebra which we denote simply by $\mathcal{U}({}_0\Pi_1)$. By (2.13) and (2.14) we have $a \circ_0 x_0 = 0$ and $a \circ_0 x_1 = ax_1 - x_1a$. The antipode on $\mathcal{U}({}_0\Pi_1)$ is given by the signed reversal $*$. Since $a \in \mathcal{U}({}_0\Pi_1)$ is primitive, $a = -a^*$ and also

$$a \circ_0 x_0 = 0 \qquad \text{and} \qquad a \circ_0 x_1 = ax_1 + x_1a^*\ .$$

This extends to an action on $\mathcal{U}({}_0\Pi_0)$ via $a \circ_0 w_1w_2 = (a \circ_0 w_1)w_2 + w_1(a \circ_0 w_2)$. Now consider the action $a \circ_0 \cdot$ on the following words. All terms are omitted except those terms where a or a^* is inserted in-between the two bold letters:

$$\begin{aligned}
a \circ_0 w_1\mathbf{x_0x_0}w_2 &= \cdots + 0 + \cdots \\
a \circ_0 w_1\mathbf{x_0x_1}w_2 &= \cdots + w_1\mathbf{x_0ax_1}w_2 + \cdots \\
a \circ_0 w_1\mathbf{x_1x_0}w_2 &= \cdots + w_1\mathbf{x_1a^*x_0}w_2 + \cdots \\
a \circ_0 w_1\mathbf{x_1x_1}w_2 &= \cdots + \underbrace{w_1\mathbf{x_1ax_1}w_2 + w_1\mathbf{x_1a^*x_1}w_2}_{0} + \cdots
\end{aligned}$$

These four equations are dual to all but the first and last terms in (2.18), using the fact that $I^{\mathrm{u}}(x;w;x) = 0$ for $x = 0, 1$ (first and fourth lines), and the fact that $I^{\mathrm{u}}(1;w^*;0) = I^{\mathrm{u}}(0;w;1)$ (third line). A straightforward modification of the above argument taking into account the initial and final terms (using (2.15)) shows that the action $\circ_1$ of $\mathrm{Lie}\,\mathcal{A}$ on ${}_0\Pi_1$ is dual to the full expression (2.18). □

Armed with this formula, we immediately deduce that for all $n \geq 2$,

$$D\,\zeta^{\mathfrak{m}}(n) = [\zeta^{\mathfrak{u}}(n)] \otimes 1 \tag{2.19}$$

where we recall that $\zeta^{\mathfrak{u}}(2n) = 0$. One easily shows that $\zeta^u(2n+1) \neq 0$ for $n \geq 1$. See also [22]. Denote the map $w \mapsto [I^{\mathrm{u}}(0;w;1)] : \mathcal{O}({}_0\Pi_1)_{>0} \to \mathcal{L}$ simply by $\xi \mapsto [\xi^{\mathrm{u}}]$. From the structure §1.1, 1 of G^{dR} we have the following converse to (2.19) ([5], §3.2).

Theorem 2.8. *An element $\xi \in \mathcal{O}({}_0\Pi_1)$ of weight $n \geq 2$ satisfies $D\xi = [\xi^{\mathrm{u}}] \otimes 1$ if and only if $\xi \in \mathbb{Q}\,\zeta^{\mathfrak{m}}(n)$.*

This theorem, combined with (2.18), provides a powerful method for proving identities between motivic multiple zeta values. Applications are given in [6].

3. The main theorem and consequences

Theorem 1.5 is a result about linear independence. There is an analogous statement for algebraic independence of motivic multiple zeta values.

Definition 3.1. Let X be an alphabet (a set) and let $X^\times$ denote the free associative monoid generated by X. Suppose that X has a total ordering $<$, and extend it to $X^\times$ lexicographically. An element $w \in X^\times$ is said to be a Lyndon word if

$$w < u \quad \text{whenever} \quad w = uv \quad \text{and} \quad u, v \neq \emptyset\,.$$

For an ordered set X, let $\mathrm{Lyn(X)}$ denote the set of Lyndon words in X.

Theorem 3.2. *Let $X_{3,2} = \{2, 3\}$ with the ordering $3 < 2$. The set of elements*

$$\zeta^{\mathfrak{m}}(w) \quad \textit{where } w \in \mathrm{Lyn}(X_{3,2}^\times) \tag{3.1}$$

are algebraically independent over $\mathbb{Q}$, and generate the algebra $\mathcal{H}$ of motivic multiple zeta values.

Theorem 3.2 implies that every motivic multiple zeta value is equal to a unique polynomial with rational coefficients in the elements (3.1). It is often convenient to modify this generating family by replacing $\zeta^{\mathfrak{m}}(3,2,\ldots,2)$ (a three followed by $n-1$ two's) with $\zeta^{\mathfrak{m}}(2n+1)$ (by theorem 3.6). Taking the period yields the

Corollary. *Every multiple zeta value is a polynomial, with coefficients in $\mathbb{Q}$, in*

$$\zeta(w) \quad \text{where } w \in \mathrm{Lyn}(X_{3,2}^{\times}) \,. \tag{3.2}$$

Corollary. *The category $\mathcal{MT}(\mathbb{Z})$ is generated by $\pi_1^{mot}(\mathbb{P}^1\backslash\{0,1,\infty\}, \overrightarrow{1}_0, -\overrightarrow{1}_1)$ in the following sense. Every mixed Tate motive over $\mathbb{Z}$ is isomorphic, up to a Tate twist, to a direct sum of copies of sub-quotients of*

$$\mathcal{O}(\pi_1^{mot}(\mathbb{P}^1\backslash\{0,1,\infty\}, \overrightarrow{1}_0, -\overrightarrow{1}_1)) \,.$$

Corollary. *The periods of mixed Tate motives over $\mathbb{Z}$ are polynomials with rational coefficients of $(2\pi i)^{-1}$ and* (3.2).

More precisely [13], if $M \in \mathcal{MT}(\mathbb{Z})$ has non-negative weights (i.e. $W_{-1}M = 0$), then the periods of M are polynomials in (3.2) and $2\pi i$.

3.1. Canonical generators. Recall that the unipotent zeta values $\zeta^{\mathfrak{u}}$ are elements of $\mathcal{O}(U^{dR})$. As a consequence of theorem 3.2:

Corollary. *For every $n \geq 1$ there is a canonical element $\sigma_{2n+1} \in \mathrm{Lie}\, U^{dR}(\mathbb{Q})$ which is uniquely defined by $\langle \exp(\sigma_{2n+1}), \zeta^{\mathfrak{u}}(2m+1)\rangle = \delta_{m,n}$, and*

$$\langle \exp(\sigma_{2n+1}), \zeta^{\mathfrak{u}}(w)\rangle = 0 \qquad \text{for all } w \in \mathrm{Lyn}(X_{3,2}) \text{ such that } \deg_3 w > 1 \,.$$

The elements σ_{2n+1} can be taken as generators in §1.1 (1). It is perhaps surprising that one can define canonical elements of the motivic Galois group at all. These should perhaps be taken with a pinch of salt, since there may be other natural generators for the algebra of motivic multiple zeta values.

Corollary. *There is a unique homomorphism $\tau : \mathcal{H} \to \mathbb{Q}$ (see* (1.5)*) such that:*

$$\langle \tau, \zeta^{\mathfrak{m}}(2)\rangle = -\tfrac{1}{24}$$

and $\langle \tau, \zeta^{\mathfrak{m}}(w)\rangle = 0$ for all $w \in \mathrm{Lyn}(X_{3,2})$ such that $w \neq 2$.

Applying this map to the motivic Drinfeld associator defines a canonical (but not explicit!) rational associator:

$$\tau(\mathcal{Z}^{\mathfrak{m}}) \in {}_0\Pi_1(\mathbb{Q}) = \mathbb{Q}\langle\langle x_0, x_1\rangle\rangle$$

By acting on the canonical rational associator with elements σ_{2n+1}, one deduces that there exists a huge space of rational associators (which forms a torsor over $G^{dR}(\mathbb{Q})$). Such associators have several applications (see, for example [16]).

3.2. Transcendence conjectures.

Conjecture 3.3. *A variant of Grothendieck's period conjecture states that*

$$\mathrm{per} : \mathcal{P}^{\mathfrak{m}}_{\mathcal{MT}(\mathbb{Z})} \longrightarrow \mathbb{C}$$

is injective. In particular, its restriction to $\mathcal{H}$ is injective also.

The last statement, together with theorem 1.5, is equivalent to

Conjecture 3.4 (Hoffman). *The elements $\zeta(n_1,\ldots,n_r)$ for $n_i \in \{2,3\}$ are a basis for the $\mathbb{Q}$-vector space spanned by multiple zeta values.*

This in turn implies a conjecture due to Zagier, stating that the dimension of the $\mathbb{Q}$-vector space of multiple zeta values of weight N is equal to d_N (1.6), and furthermore that the ring of multiple zeta values is graded by the weight. Specialising further, we obtain the following folklore

Conjecture 3.5. *The numbers $\pi, \zeta(3), \zeta(5), \zeta(7), \ldots$ are algebraically independent.*

3.3. Idea of proof of theorem 1.5. The proof of linear independence is by induction on the number of 3's. In the case where there are no 3's, one can easily show by adapting an argument due to Euler that

$$\zeta(\underbrace{2,\ldots,2}_{n}) = \frac{\pi^{2n}}{(2n+1)!}\,.$$

The next interesting case is where there is one 3.

Theorem 3.6 (Zagier [38]). *Let $a, b \geq 0$. Then*

$$\zeta(\underbrace{2,\ldots 2}_{a},3,\underbrace{2,\ldots,2}_{b}) = 2\sum_{r=1}^{a+b+1}(-1)^r(A^r_{a,b}-B^r_{a,b})\,\zeta(2r+1)\,\zeta(\underbrace{2,\ldots,2}_{a+b+1-r})$$

where, for any $a,b,r \in \mathbb{N}$, $A^r_{a,b} = \binom{2r}{2a+2}$, and $B^r_{a,b} = \left(1-2^{-2r}\right)\binom{2r}{2b+1}$.

Zagier's proof of this theorem involves an ingenious mixture of analytic techniques. The next step in the proof of theorem 1.5 is to lift Zagier's theorem to the level of motivic multiple zeta values by checking its compatibility with the coaction (2.18) and using theorem 2.8. Since then, the proof of theorem 3.6 was simplified by Li [31], and Terasoma [37] has verified that it can be deduced from associator equations. Since the associator equations are known to hold between motivic multiple zeta values, it follows that, in principle, this part of the proof can now be deduced directly by elementary methods (i.e., without using theorem 2.8).

From the motivic version of theorem 3.6, one can compute the action of the abelianization of U^{dR} on the vector space built out of the elements $\zeta^{\mathfrak{m}}(n_1,\ldots,n_r)$, with $n_i = 2,3$, graded by the number of 3's. This action can be expressed by certain matrices constructed out of the combinatorial formula (2.18), whose entries are linear combinations of the coefficients $A^r_{a,b}$ and $B^r_{a,b}$ of theorem 3.6. The key point is that these matrices have non-zero determinant 2-adically, and are hence invertible. At its heart, this uses the fact that the $B^r_{a,b}$ terms in theorem 3.6 dominate with respect to the 2-adic norm due to the factor 2^{-2r}.

4. Roots of unity

There are a handful of exceptional cases when one knows how to generate certain categories of mixed Tate motives over cyclotomic fields and write down their periods. These results are due to Deligne [11], inspired by numerical computations due to Broadhurst in 1997 relating to computations of Feynman integrals.

Let $N \geq 2$ and let μ_N be the group of N^{th} roots of unity, and consider

$$\mathbb{P}^1 \backslash \{0, \mu_N, \infty\} \tag{4.1}$$

Fix a primitive N^{th} root ζ_N. One can consider the corresponding motivic fundamental groupoid (with respect to suitable tangential base points) and ask whether it generates the category $\mathcal{MT}(\mathcal{O}_N[\frac{1}{N}])$, where $\mathcal{O}_N$ is the ring of integers in the field $\mathbb{Q}(\zeta_N)$. Goncharov has shown that for many primes N, and in particular, for $N = 5$, this is false: already in weight two, there are motivic periods of this category which cannot be expressed as motivic iterated integrals on $\mathbb{P}^1 \backslash \{0, \mu_N, \infty\}$.

In certain exceptional cases, Deligne has proven a stronger statement:

Theorem 4.1. *For $N = 2, 3, 4, 6$ (resp. $N = 8$) the motivic fundamental group*

$$\pi_1^{mot}(\mathbb{P}^1 \backslash \{0, 1, \infty\}, \vec{1}_0, \zeta_N) \qquad \big(\textit{resp. } \pi_1^{mot}(\mathbb{P}^1 \backslash \{0, \pm 1, \infty\}, \vec{1}_0, \zeta_8)\big)$$

generates the categories $\mathcal{MT}(\mathcal{O}_N[\frac{1}{N}])$ for $N = 2, 3, 4, 8$, and $\mathcal{MT}(\mathcal{O}_N)$ for $N = 6$.

Iterated integrals on (4.1) can be expressed in terms of cyclotomic multiple zeta values[6] which are defined for $(n_r, \varepsilon_r) \neq (1, 1)$ by the sum

$$\zeta(n_1, \ldots, n_r; \varepsilon_1, \ldots, \varepsilon_r) = \sum_{0 < k_1 < k_2 < \ldots < k_r} \frac{\varepsilon_1^{k_1} \ldots \varepsilon_r^{k_r}}{k_1^{n_1} \ldots k_r^{n_r}}$$

where $\varepsilon_1, \ldots, \varepsilon_r$ are roots of unity. The weight is defined as the sum of the indices $n_1 + \ldots + n_r$ and the depth is the increasing filtration defined by the integer r. It is customary to use the notation

$$\zeta(n_1, \ldots, n_{r-1}, n_r \zeta_N) = \zeta(n_1, \ldots, n_r; \underbrace{1, \ldots, 1}_{r-1}, \zeta_N) \, .$$

One can define motivic versions relative to the canonical fiber functor ω ([14], §1.1) playing the role of what was previously the de Rham fiber functor (the two are related by $\omega_{dR} = \omega \otimes \mathbb{Q}(\zeta_N)$), and the Betti realisation functor which corresponds to the embedding $\mathbb{Q}(\zeta_N) \subset \mathbb{C}$. Denote these motivic periods by a superscript $\mathfrak{m}$. Recall that $\mathbb{L}^{\mathfrak{m}}$ is the motivic Lefschetz period of example 1.3, whose period is $2\pi i$. Let $X_{odd} = \{1, 3, 5, \ldots\}$ with the ordering $1 > 3 > 5 \ldots$. Rephrased in the language of motivic periods, Deligne's results for $N = 2, 3, 4$ yield:

1. ($N = 2$; algebra generators). The following set of motivic periods:

$$\{\mathbb{L}^{\mathfrak{m}}\} \cup \{\zeta^{\mathfrak{m}}(n_1, \ldots, n_{r-1}, -n_r) \text{ where } (n_r, \ldots, n_1) \in \mathrm{Lyn}(X_{odd})\}$$

[6] The conventions in [11] are opposite to the ones used here

are algebraically independent over $\mathbb{Q}$. The monomials in these quantities form a basis for the ring of geometric motivic periods[7] of $\mathcal{MT}(\mathbb{Z}[\frac{1}{2}])$.

2. ($N = 3, 4$; linear basis). The set of motivic periods

$$\zeta^{\mathfrak{m}}(n_1, \ldots, n_{r-1}, n_r\zeta_N)(\mathbb{L}^{\mathfrak{m}})^p \qquad \text{where } n_i \geq 1, p \geq 0$$

are linearly independent over $\mathbb{Q}$. They form a basis for the space of geometric motivic periods of $\mathcal{MT}(\mathcal{O}_N[\frac{1}{N}])$, for $N = 3, 4$ respectively.

By applying the period map, each case gives a statement about cyclotomic multiple zeta values. In the case $N = 2$, the underlying field is still $\mathbb{Q}$, and it follows from (i) that every multiple zeta value at 2^{nd} roots of unity (sometimes called an Euler sum) is a polynomial with rational coefficients in

$$(2\pi i)^2 \quad \text{and} \quad \zeta(n_1, \ldots, n_{r-1}, -n_r) \qquad \text{where} \quad (n_1, \ldots, n_r) \in \mathrm{Lyn}(X_{odd})\ .$$

This decomposition respects the weight and depth, where the depth of $(2\pi i)^n$ is 1. Thus an Euler sum of weight N and depth r can be expressed as a polynomial in the above elements, of total weight N and total depth $\leq r$.

5. Depth

The results of the previous section for $N = 2, 3, 4, 6, 8$ crucially use the fact that the depth filtration is dual to the lower central series of the corresponding motivic Galois group. A fundamental difference with the case $N = 1$ is that this fact is false for $\mathbb{P}^1\backslash\{0,1,\infty\}$, due to a defect closely related to modular forms.

Recall that ${}_0\Pi_1$ is a group for the Ihara action $\circ$. Let $\mathrm{Lie}({}_0\Pi_1)$ denote its Lie algebra. Its bracket is denoted by $\{\ ,\ \}$. Denote the images of the canonical generators §3.1 by $\sigma_{2n+1} \in \mathrm{Lie}({}_0\Pi_1)(\mathbb{Q})$, for $n \geq 1$. They are elements of the free graded Lie algebra on two generators x_0, x_1, and we have, for example

$$\sigma_3 = [x_0, [x_0, x_1]] + [x_1, [x_1, x_0]]$$

The higher σ_{2n+1} are of the form $\sigma_{2n+1} = ad(x_0)^{2n}(x_1)$ plus terms of degree ≥ 2 in x_1, but are not known explicitly except for small n. By theorem 1.2, the σ_{2n+1} freely generate a graded Lie subalgebra of $\mathrm{Lie}({}_0\Pi_1)(\mathbb{Q})$ which we denote by $\mathfrak{g}$. The depth filtration $\mathcal{D}$ on $\mathfrak{g}$ is the decreasing filtration given by the degree in the letter x_1. In 1993, Ihara and Takao observed that

$$\{\sigma_3, \sigma_9\} - 3\{\sigma_5, \sigma_7\} = \frac{691}{144}\, e_\Delta \tag{5.1}$$

where e_Δ is an element with integer coefficients of depth ≥ 4 (degree ≥ 4 in x_1), and the coefficient 691 on the right-hand side is the numerator of the Bernoulli number B_{12}. The element e_Δ is sparse:[8] indeed, computations in the early days gave the impression that the right-hand side is zero, although we now know that the σ_{2n+1} generate a free Lie algebra.

[7] recall that this is the subring of all motivic periods of the category $\mathcal{MT}(\mathbb{Z}[\frac{1}{2}])$ which is generated by motives M which have non-negative weights, i.e., $W_{-1}M = 0$.

[8] 'most' of its coefficients are zero, see [7], §8 for a closed formula for this element.

Relations such as (5.1) show that the structure of $\mathfrak{g}$ is related to arithmetic, but more importantly show that the associated depth-graded Lie algebra $\mathrm{gr}_{\mathcal{D}}\,\mathfrak{g}$ is not free, since the left-hand side of (5.1) vanishes in $\mathrm{gr}^2_{\mathcal{D}}\,\mathfrak{g}$. The depth filtration on $\mathfrak{g}$ corresponds, dually, to the depth filtration on motivic multiple zeta values, and (5.1) implies that motivic multiple zeta values of depth ≤ 2 are insufficient to span the space of all (real geometric) motivic periods of $\mathcal{MT}(\mathbb{Z})$ in weight 12 (one needs to include elements of depth ≥ 4 such as $\zeta^{\mathfrak{m}}(2,2,2,3,3)$ in a basis). By counting dimensions, this can be interpreted as a relation, viz:

$$28\,\zeta^{\mathfrak{m}}(3,9) + 150\,\zeta^{\mathfrak{m}}(5,7) + 168\,\zeta^{\mathfrak{m}}(7,5) = \frac{5197}{691}\zeta^{\mathfrak{m}}(12) \tag{5.2}$$

The corresponding relation for multiple zeta values was found in [17] and generalised to an infinite family corresponding to cuspidal cohomology classes of $\mathrm{SL}_2(\mathbb{Z})$. In particular, the family of motivic multiple zeta values

$$\zeta^{\mathfrak{m}}(2n_1+1,\ldots,2n_r+1)\zeta^{\mathfrak{m}}(2k)$$

cannot be a basis for $\mathcal{H}$, although it has the right dimensions in each weight (1.6). The Hoffman basis (1.7) gets around such pathologies, since, for example, its elements in weight 12 have depths between four and six.

In 1997, Broadhurst and Kreimer made exhaustive numerical computations on the depth filtration of multiple zeta values, which led them to the following conjecture, translated into the language of motivic multiple zeta values.

Conjecture 5.1 (Motivic version of the Broadhurst-Kreimer conjecture). *Let $\mathcal{D}$ denote the increasing filtration on $\mathcal{H}$ induced by the depth. Then*

$$\sum_{N,d\geq 0} \dim_{\mathbb{Q}}\left(gr^{\mathcal{D}}_d\mathcal{H}_N\right) s^d t^N = \frac{1+\mathbb{E}(t)s}{1-\mathbb{O}(t)s+\mathbb{S}(t)s^2-\mathbb{S}(t)s^4}\,, \tag{5.3}$$

where $\mathbb{E}(t) = \frac{t^2}{1-t^2}$, $\mathbb{O}(t) = \frac{t^3}{1-t^2}$, *and* $\mathbb{S}(t) = \frac{t^{12}}{(1-t^4)(1-t^6)}$.

Note that equation (5.3) specializes to (1.6) on setting s equal to 1. The series $\mathbb{E}(t)$ and $\mathbb{O}(t)$ are the generating series for the dimensions of the spaces of even and odd single motivic zeta values. The interpretation of $\mathbb{S}(t)$ as the generating series for cusp forms for $\mathrm{SL}_2(\mathbb{Z})$ suggests a deeper connection with modular forms which is well understood in depth two. By work of Zagier, and Goncharov, formula (5.3) has been confirmed in depths 2 and 3 (i.e., modulo s^4).

An interpretation for conjecture (5.3) in terms of the structure of $\mathrm{gr}_{\mathcal{D}}\mathfrak{g}$, as well as a complete conjectural description of generators and relations of $\mathrm{gr}_{\mathcal{D}}\mathfrak{g}$ in terms of modular forms for $\mathrm{SL}_2(\mathbb{Z})$ was given in [7]. A deeper geometric understanding of this conjecture would seem to require a framework which places multiple zeta values and modular forms on an equal footing, which is the topic of §6.

6. Multiple modular values

In this final paragraph, I want suggest applying the philosophy of §1.4 to iterated integrals on (orbifold) quotients of the upper half plane

$$\mathbb{H} = \{\tau \in \mathbb{C} : \mathrm{Im}\,(\tau) > 0\}$$

by finite index subgroups $\Gamma \leq \mathrm{SL}_2(\mathbb{Z})$. Iterated integrals of modular forms were first studied by Manin [32, 33]. Here, I shall only consider the case $\Gamma = \mathrm{SL}_2(\mathbb{Z})$.

6.1. Eichler-Shimura integrals. Denote the space of homogenous polynomials of degree $n \geq 0$ with rational coefficients by

$$V_n = \bigoplus_{i+j=n} \mathbb{Q} X^i Y^j$$

It admits a right action of Γ via the formula $(X,Y)|_\gamma = (aX + bY, cX + dY)$, where $\gamma = \left(\begin{smallmatrix} a & b \\ c & d \end{smallmatrix}\right)$. Let $f(\tau)$ be a modular form of weight k for Γ. Define

$$\underline{f}(\tau) = (2\pi i)^{k-1} f(\tau)(X - \tau Y)^{k-2} d\tau \qquad \in \qquad \Gamma(\mathbb{H}, \Omega^1_{\mathbb{H}} \otimes V_{k-2})$$

It satisfies the invariance property $\underline{f}(\gamma(\tau))\big|_\gamma = \underline{f}(\tau)$ for all $\gamma \in \Gamma$. For f a cusp form, the classical Eichler-Shimura integral (see, e.g., [29]) is

$$\int_0^\infty \underline{f}(\tau) = \sum_{n=1}^{k-1} c_n L(f,n) X^{k-n-1} Y^{n-1} \tag{6.1}$$

where c_n are certain explicit constants (rational multiples of a power of π) and $L(f,s)$ is the analytic continuation of the L-function $L(f,s) = \sum_{n\geq 1} \frac{a_n}{n^s}$ of f, where $f(\tau) = \sum_{n\geq 1} a_n q^n$ and $q = e^{2\pi i \tau}$. Manin showed that if f is a Hecke eigenform, there exist $\omega_f^+, \omega_f^- \in \mathbb{R}$ such that

$$\int_0^\infty \underline{f}(\tau) = \omega_f^+ P_f^+(X,Y) + \omega_f^- P_f^-(X,Y)$$

where $P_f^\pm(X,Y) \in V_{k-2} \otimes \overline{\mathbb{Q}}$ are polynomials with algebraic coefficients which are invariant (resp. anti-invariant) with respect to $(X,Y) \mapsto (-X,Y)$.

Recall that the Eisenstein series of weight $2k$, for $k \geq 2$, is defined by

$$e_{2k}(q) = -\frac{B_{2k}}{2k} + \sum_{n\geq 1} \sigma_{2k-1}(n) q^n \,, \qquad q = e^{2\pi i \tau}$$

where B_{2k} is the $2k^{\text{th}}$ Bernoulli number, and σ denotes the divisor function. The corresponding integrals for Eisenstein series diverges. Zagier showed how to extend the definition of the Eichler-Shimura integrals to the case e_{2k}, giving [29]

$$\frac{(2k-2)!}{2}\zeta(2k-1)(X^{2k-2} - Y^{2k-2}) - \frac{(2\pi i)^{2k-1}}{4k(2k-1)} \sum_{\substack{a+b=2k \\ a,b\geq 1}} \binom{2k}{a} B_a B_b X^{a-1} Y^{b-1} \tag{6.2}$$

Manipulating this formula leads to expressions for the odd Riemann zeta values in terms of Lambert series similar to the following formula due to Ramanujan:

$$\zeta(3) = \frac{7}{180}\pi^3 - 2\sum_{n\geq 1} \frac{1}{n^3(e^{2n\pi} - 1)} \,.$$

It converges very rapidy. One wants to think of (6.2) as pointing towards a modular construction of $\zeta^{\mathfrak{m}}(2k-1)$.

6.2. Regularisation. The theory of tangential base points ([10], §15) gives a general procedure for regularising iterated integrals on curves. If one applies this to the orbifold $\Gamma\backslash\backslash\mathbb{H}$, where $\Gamma = \mathrm{SL}_2(\mathbb{Z})$, one can show that it yields the completely explicit formulae below, which generalise Zagier's formula for a single Eisenstein series. I shall only state the final answer. Via the map

$$\tau \mapsto q = \exp(2i\pi\tau) : \mathbb{H} \longrightarrow \{q \in \mathbb{C} : 0 < |q| < 1\} = D^\times$$

a natural choice of tangential base point (denoted $\vec{1}_\infty$) corresponds to the tangent vector 1 at $q = 0$. Since in this case we have explicit models $\mathbb{H} \subset \mathbb{C}$ for a universal covering space of $\Gamma\backslash\backslash\mathbb{H}$, and $\mathbb{C}$ for the universal covering of $D^\times$, one can compute all regularised iterated integrals by pulling them back to $\mathbb{C}$ as follows.

First, if $f = \sum_{n\geq 0} f_n q^n$ is the Fourier expansion of f, write

$$\underline{f}^\infty(\tau) = (2\pi i)^{k-1} f_0 (X - \tau Y)^{k-2} d\tau \qquad \in \qquad \Gamma(\mathbb{C}, \Omega^1_{\mathbb{C}} \otimes V_{k-2}) \tag{6.3}$$

Define a linear operator R on the tensor coalgebra on $\Gamma(\mathbb{C}, \Omega^1_{\mathbb{C}} \otimes V)$ by

$$\begin{aligned} R[\omega_1|\ldots|\omega_n] &= \sum_{i=0}^{n} (-1)^{n-i} [\omega_1|\ldots|\omega_i] \,\text{ш}\, [\omega_n^\infty|\ldots|\omega_{i+1}^\infty] \\ &= \sum_{i=1}^{n} (-1)^{n-i} \Big[[\omega_1|\ldots|\omega_{i-1}] \,\text{ш}\, [\omega_n^\infty|\ldots|\omega_{i+1}^\infty] \Big| \omega_i - \omega_i^\infty \Big] \,. \end{aligned}$$

where $V = \bigoplus_k V_k$ and ω^∞ is the 'residue at infinity' of ω defined by (6.3). The regularised iterated integral can be expressed as *finite* integrals

$$\int_\tau^{\vec{1}_\infty} [\underline{\omega}_1|\ldots|\underline{\omega}_n] = \sum_{i=0}^{n} \int_\tau^\infty R[\underline{\omega}_1|\ldots|\underline{\omega}_i] \int_\tau^0 [\underline{\omega}_{i+1}^\infty|\ldots|\underline{\omega}_n^\infty]$$

It takes values in $V_{k_1-2} \otimes \ldots \otimes V_{k_n-2} \otimes \mathbb{C}$ if $\omega_1, \ldots, \omega_n$ are of weights $k_1, \ldots k_n$, and hence admits a right action of Γ. The integrals in the right factor on the right-hand side are simply polynomials in τ and can be computed explicitly.

6.3. Cocycles. Choose a basis of Hecke normalised eigenforms f_i indexed by non-commuting symbols A_i, and form the generating series

$$I(\tau;\infty) = \sum_{i_k, n\geq 0} A_{i_1} \ldots A_{i_n} \int_\tau^{\vec{1}_\infty} [\underline{\omega}_{i_1}|\ldots|\underline{\omega}_{i_n}]$$

For every $\gamma \in \Gamma$, there exists a formal power series C_γ in the A_i such that

$$I(\tau;\infty) = I(\gamma(\tau);\infty)|_\gamma \, C_\gamma \tag{6.4}$$

which does not depend on τ. It satisfies the cocycle relation

$$C_{gh} = C_g\big|_h \, C_h \quad \text{ for all } g, h \in \Gamma \,.$$

The part of the cocycle C which involves iterated integrals of cusp forms was previously considered by Manin [32, 33]. Since the group Γ is generated by

$$S = \begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix} \quad , \quad T = \begin{pmatrix} 1 & 1 \\ 0 & 1 \end{pmatrix} ,$$

the cocycle C is determined by C_S and C_T. The series C_T can be computed explicitly and its coefficients lie in $\mathbb{Q}[2\pi i]$.

Definition 6.1. Define the ring of multiple modular values with respect to the group $\Gamma = \mathrm{SL}_2(\mathbb{Z})$ to be the subring of $\mathbb{C}$ generated by the coefficients of C_S.

The series C_S is a kind of analogue of Drinfeld's associator $\mathcal{Z}$. Its terms of degree 1 in the A_i are precisely the Eichler-Shimura integrals (6.1) and (6.2). Setting $\tau = i$ in (6.4) gives integrals which converge extremely fast and are very well suited to numerical computation.

6.4. Galois action. One can mimic the Betti-de Rham aspects of the theory of the motivic fundamental group of $\mathbb{P}^1\backslash\{0,1,\infty\}$ as follows:

1. The coefficients of C_S can be interpreted as certain periods of the relative unipotent completion of Γ. This was defined by Deligne as follows. Let k be a field of characteristic 0 and S a reductive algebraic group over k. Suppose that Γ is a discrete group equipped with a Zariski dense homomorphism $\rho : \Gamma \to S(k)$. The completion of Γ relative to ρ is an affine algebraic group scheme $\mathcal{G}_\Gamma$, which sits in an exact sequence
$$1 \longrightarrow \mathcal{U}_\Gamma \longrightarrow \mathcal{G}_\Gamma \longrightarrow S \longrightarrow 1$$
where $\mathcal{U}_\Gamma$ is pro-unipotent. There is a natural map $\Gamma \to \mathcal{G}_\Gamma(k)$ which is Zariski dense, and whose projection onto $S(k)$ is the map ρ.
2. In 'geometric' situations, one expects the relative completion to be the Betti realisation of something which is motivic. Indeed, Hain has shown [23, 24] that $\mathcal{O}(\mathcal{G}_\Gamma)$ carries a mixed Hodge structure in this case. As a result, one can define Hodge-motivic periods and try to carry out §1.4.
3. The action of the unipotent radical of the Tannaka group of mixed Hodge structures acts via the automorphism group of a space of non-abelian cocyles of Γ with coefficients in $\mathcal{U}_\Gamma$. It is a certain semi-direct product of $\mathcal{U}_\Gamma$ with a group of non-commutative substitutions $\mathrm{Aut}(\mathcal{U}_\Gamma)^S$. An inertia condition corresponds, in the case $\Gamma = \mathrm{SL}_2(\mathbb{Z})$, to the fact that C_T is fixed, and there are further constraints coming from the action of Hecke operators. The explicit expression for C_T yields precise information about the action of the Hodge-Galois group.

The following key example illustrates how multiple modular values for $\mathrm{SL}_2(\mathbb{Z})$ resolve the depth-defect for multiple zeta values as discussed in §5.

Example 6.2. On $\mathbb{P}^1\backslash\{0,1,\infty\}$ there are 2^{12} integrals of weight 12, namely

$$\int_{dch} \omega_{i_1} \ldots \omega_{i_{12}} \quad \text{where} \quad \omega_{i_j} \in \left\{ \frac{dt}{t}, \frac{dt}{1-t} \right\} .$$

However the space of multiple zeta values $\mathcal{Z}_{12}$ in weight 12 has dimension at most $d_{12} = 12$, so there are a huge number of relations. Indeed, modulo products of multiple zeta values of

lower weights, there are at most two elements of weight 12:

$$\zeta(3,3,2,2,2) \qquad \text{and} \qquad \zeta(3,2,3,2,2) \tag{6.5}$$

by the corollary to theorem 3.2. They are conjectured to be algebraically independent. Note that multiple zeta values of depths ≤ 2 (or ≤ 3 for that matter) will not suffice to span $\mathcal{Z}_{12}$ by equation (5.2).

On the other hand, we can consider the coefficients of C_S corresponding to regularised iterated integrals of Eisenstein series

$$\int_0^{\vec{1}_\infty} \underline{e}_{2a}(X,Y)\underline{e}_{2b}(X,Y) \in \mathbb{C}[X,Y] \tag{6.6}$$

If we are interested in periods modulo products, there are just two relevant cases: $(2a,2b) \in \{(4,10),(6,8)\}$. The description 3 above enables one to extract the relevant numbers from the coefficients of these polynomials. One finds experimentally that one obtains exactly the elements (6.5) modulo products, and that this is consistent with the coaction on the corresponding Hodge-motivic periods. Thus $\mathcal{Z}_{12}$ is spanned by exactly the right number of multiple modular values (which are linear combinations of the coefficients of (6.6).

The example shows that in weight 12, there are exactly two multiple modular values (modulo products) which are multiple zeta values, and they conjecturally satisfy no relations. By contrast, multiple zeta values in weight 12 are hugely over-determined, and satisfy a vast number of relations. Furthermore, the depth-defect described in §5 can be directly related to the appearance of special values of L-functions of cusp forms amongst certain coefficients of (6.6).

In conclusion, a rather optimistic hope is that a theory of motivic multiple modular values for congruence subgroups of $\mathrm{SL}_2(\mathbb{Z})$ might provide a more natural construction of the periods of mixed Tate motives over cyclotomic fields (and much more) than the motivic fundamental groupoid of the projective line minus Nth roots of unity, which suffers from the depth defect in the case $N = 1$ (§5), and from absent periods in non-exceptional cases such as $N = 5$ (§4).

Completed cohomology and the p-adic Langlands program

Matthew Emerton

Abstract. We discuss some known and conjectural properties of the completed cohomology of congruence quotients associated to reductive groups over $\mathbb{Q}$. We also discuss the conjectural relationships to local and global Galois representations, and a possible p-adic local Langlands correspondence.

Mathematics Subject Classification (2010). Primary 11F70; Secondary 22D12.

Keywords. p-adic Langlands program, p-adic Hodge theory, completed cohomology, Galois representations.

1. Introduction

The idea that there could be a p-adic version of the local Langlands correspondence was originally proposed by C. Breuil, in the case of the group $\mathrm{GL}_2(\mathbb{Q}_p)$, in his papers [11–13]. In [13], he also proposed a local-global compatibility between this (at the time conjectural) correspondence and p-adically completed cohomology of modular curves. Since then, the theory of p-adic Langlands has been extensively developed in the case of the group GL_2 over $\mathbb{Q}$; see e.g. [6, 29, 30, 32, 46, 50, 52]. Since excellent expositions of much of this material already exist [5, 14, 15], we have decided here to describe some aspects of the p-adic Langlands program that make sense for arbitrary groups. This has led us to focus on completed cohomology, since this is a construction that makes sense for arbitrary groups, and about which it is possible to establish some general results, and make some general conjectures.

Many of these conjectures are very much motivated by the conjectural relationship with Galois representations, and we have also tried to outline our expectations regarding this relationship, while trying not get bogged down in the myriad technical details that would necessarily attend a more careful discussion of this topic. Finally, we have tried to indicate how completed cohomology may be related, by the principle of local-global compatibility, to a still largely conjectural p-adic local Langlands correspondence for groups other than $\mathrm{GL}_2(\mathbb{Q}_p)$. Our focus is on drawing inferences about the possible structure of the local correspondence by interpolating from our expectations regarding completed cohomology. In this regard we mention also the paper [27], which somewhat literally interpolates p-adically completed cohomology (via the Taylor–Wiles–Kisin method) in order to construct a candidate for the p-adic local Langlands correspondence for GL_n of an arbitrary p-adic field.

Proceedings of the International Congress of Mathematicians, Seoul, 2014

We close this introduction by simply listing a number of additional important papers [17–20] which also have the goal of extending the p-adic local Langlands correspondence, and local-global compatibility, beyond the case of $\mathrm{GL}_2(\mathbb{Q}_p)$. Unfortunately, lack of space prevents us from saying more about them here.

1.1. Notation. Throughout, we fix a prime p. We also fix a finite extension L of $\mathbb{Q}_p$, contained inside some given algebraic closure $\overline{\mathbb{Q}}_p$. We let $\mathcal{O}$ denote the ring of integers of L, and let ϖ denote a uniformizer of $\mathcal{O}$. The ring $\mathcal{O}$, and field L, will serve as our coefficients.

As usual, $\mathbb{A}$ denotes the ring of adèles over $\mathbb{Q}$, while $\mathbb{A}_f$ denotes the ring of finite adèles, and $\mathbb{A}_f^p$ denotes the ring of prime-to-p finite adèles.

2. Completed cohomology

Ideally, in the p-adic Langlands program, we would like to define spaces of p-adic automorphic forms, to serve as p-adic analogues of spaces of classical automorphic forms in the usual Langlands program. Unfortunately, for general reductive groups, no such definition is currently available. For groups that are compact at infinity, we can make such a definition (see (2.2.4) below), while for groups giving rise to Shimura varieties, we can use algebro-geometric methods to define spaces of p-adic automorphic forms, which however seem less representation-theoretic in nature than classical automorphic forms. Since one of our main goals is to employ representation-theoretic methods, we are thus led to find an alternative approach.

The approach we take here is to work with p-adically completed cohomology. This has the advantages of being definable for arbitrary groups, and of being of a representation-theoretic nature. For our purposes, it will thus serve as a suitable surrogate for a space of p-adic automorphic forms. For groups that are compact at infinity, it does recover the usual notion of p-adic automorphic forms that was already mentioned. (Its relationship to algebro-geometric notions of p-adic automorphic forms in the Shimura variety context is less clear; P. Scholze's paper [53] makes fundamental progress in this — and many other! — directions, but we won't attempt to discuss this here.) We therefore begin our discussion of global p-adic Langlands by recalling the basic definitions and facts related to completed cohomology, referring to [24] and [31] for more details.

2.1. Definitions and basic properties. Let us suppose that $\mathbb{G}$ is a reductive linear algebraic group over $\mathbb{Q}$. We write $G_\infty := \mathbb{G}(\mathbb{R})$ for the group of real-valued points of $\mathbb{R}$; this is a reductive Lie group. We let A_∞ denote the $\mathbb{R}$-points of the maximal $\mathbb{Q}$-split torus in the centre of $\mathbb{G}$, and let K_∞ denote a choice of maximal compact subgroup of G_∞. For any Lie group H, we let H° denote the subgroup consisting of the connected component of the identity.

The quotient $G_\infty/A_\infty^\circ K_\infty^\circ$ is a symmetric space on which G_∞ acts. We denote its dimension by d. We also write $l_0 :=$ rank of $G_\infty -$ rank of $A_\infty K_\infty$, and $q_0 := (d - l_0)/2$. If G_∞ is semisimple (so that in particular A_∞ is trivial) then these quantities coincide with the quantities denoted by the same symbols in [10] (which is why we notate them as we do). We note that q_0 is in fact an integer. (For the role played by these two quantities in our discussion, see (2.1.6), as well as Conjectures 3.1 and 3.2, below.)

If $K_f \subset \mathbb{G}(\mathbb{A}_f)$ is a compact open subgroup, then we write

$$Y(K_f) := \mathbb{G}(\mathbb{Q})\backslash\mathbb{G}(\mathbb{A})/A_\infty^\circ K_\infty^\circ K_f.$$

The double quotient $Y(K_f)$ is a finite union of quotients of the symmetric space $G_\infty^\circ/A_\infty^\circ K_\infty^\circ$ by cofinite volume discrete subgroups of G_∞.

2.1.1. Definitions. We fix a tame level, i.e. a compact open subgroup $K_f^p \subset \mathbb{G}(\mathbb{A}_f^p)$. If $K_p \subset G := \mathbb{G}(\mathbb{Q}_p)$ is a compact open subgroup, then of course $K_pK_f^p$ is a compact open subgroup of $\mathbb{G}(\mathbb{A}_f)$, and so we may form the space $Y(K_pK_f^p)$. We define the completed (co)homology at the tame level K_f^p as follows [24]:

$$\widetilde{H}^i := \varprojlim_s \varinjlim_{K_p} H^i\big(Y(K_pK_f^p), \mathcal{O}/\varpi^s\big) \quad \text{and} \quad \widetilde{H}_i := \varprojlim_{K_p} H_i\big(Y(K_pK_f^p), \mathcal{O}\big), \tag{2.1}$$

where in both limits K_p ranges over all compact open subgroups of $\mathbb{G}(\mathbb{Q}_p)$.

We equip each of $\widetilde{H}^i$ and $\widetilde{H}_i$ with its evident projective limit topology. In the case of $\widetilde{H}^i$, each of the $\mathcal{O}/\varpi^s$-modules $\varinjlim_{K_p} H^i\big(Y(K_pK_f^p), \mathcal{O}/\varpi^s\big)$ appearing in the projective limit is equipped with its discrete topology, and the projective limit topology on $\widetilde{H}^i$ coincides with its ϖ-adic topology; $\widetilde{H}^i$ is complete with respect to this topology. In the case of $\widetilde{H}_i$, each of the terms $H_i\big(Y(K_pK_f^p), \mathcal{O}\big)$ (which is a finitely generated $\mathcal{O}$-module) appearing in the projective limit is equipped with its ϖ-adic topology. The topology on $\widetilde{H}_i$ is then a pro-finite topology, and so in particular $\widetilde{H}_i$ is compact.

The completed cohomology and homology are related to one another in the usual way by duality over $\mathcal{O}$ [24]. In particular, if we ignore $\mathcal{O}$-torsion, then $\widetilde{H}_i$ is the $\mathcal{O}$-dual of $\widetilde{H}^i$ (equipped with its weak topology), and $\widetilde{H}^i$ is the continuous $\mathcal{O}$-dual of $\widetilde{H}_i$.

We can also form the limit

$$H^i := \varinjlim_{K_p} \varprojlim_s H^i\big(Y(K_pK_f^p), \mathcal{O}/\varpi^s\big) \cong \varinjlim_{K_p} H^i\big(Y(K_pK_f^p), \mathcal{O}\big). \tag{2.2}$$

There is a natural morphism

$$H^i \to \widetilde{H}^i, \tag{2.3}$$

which induces an embedding

$$\widehat{H}^i \hookrightarrow \widetilde{H}^i, \tag{2.4}$$

whose source is the ϖ-adic completion of H^i. Note that the morphism (2.3) need not be injective: although each of the terms $H^i\big(Y(K_pK_f^p), \mathcal{O}\big)$ in the direct limit defining H^i is a finitely generated $\mathcal{O}$-module, the limit H^i is merely countably generated as an $\mathcal{O}$-module, and hence may contain divisible elements. These then become zero after we pass to the ϖ-adic completion to obtain the embedding (2.4). (We give an example of this in (2.2.3) below.)

We furthermore remark that the transition maps in the direct limits of (2.1) and (2.2) need not be injective. (This is also illustrated by the example of (2.2.3).) However, if $K_p' \subset K_p$, then a trace argument shows that the restriction map

$$H^i\big(Y(K_pK_f^p), \mathcal{O}\big) \to H^i\big(Y(K_p'K_f^p), \mathcal{O}\big)$$

becomes injective after tensoring with L. Thus the kernel of the natural map $H^i\big(Y(K_pK_f^p), \mathcal{O}\big) \to H^i$ consists of torsion classes.

On the other hand, the kernel of the natural map

$$H^i\big(Y(K_pK_f^p),\mathcal{O}\big) \to \widetilde{H}^i \tag{2.5}$$

need not consist only of torsion classes; it is possible for non-torsion classes to have infinitely divisible image in H^i, and hence have vanishing image in $\widehat{H}^i$ (and so also have vanishing image in $\widetilde{H}^i$). (Again, we refer to (2.2.3) for an example of this.).

The morphism (2.4), although injective, need not be surjective. Its cokernel is naturally identified with $T_pH^{i+1} := \varprojlim_s H^{i+1}[\varpi^s]$; in other words we have a short exact sequence

$$0 \to \widehat{H}^i \to \widetilde{H}^i \to T_pH^{i+1} \to 0. \tag{2.6}$$

(Here we have written $H^{i+1}[\varpi^s]$ to denote the submodule of ϖ^s-torsion elements in H^{i+1}, and the projective limit is taken with respect to the multiplication-by-ϖ map from $H^{i+1}[\varpi^{s+1}]$ to $H^{i+1}[\varpi^s]$. The notation "T_p" is for *Tate module*.) In particular, if all the cohomology modules $H^{i+1}\big(Y(K_pK_f^p),\mathcal{O}\big)$ are torsion free, so that H^{i+1} is torsion free, then the morphism (2.4) *is* an isomorphism.

Although the restriction maps (2.5) can have non-trivial kernels, one can recover the cohomology at the various finite levels $K_pK_f^p$ via the Hochschild–Serre spectral sequence discussed in (2.1.3) below. The precise manner in which the cohomology at finite levels gets encoded in the completed cohomology is somewhat complicated in general. For instance, infinitely divisible torsion elements in H^i give rise to elements of T_pH^i, which by the discussion of the previous paragraph is naturally a quotient of $\widetilde{H}^{i-1}$. However, infinitely divisible non-torsion elements of H^i have no obvious incarnation as elements of completed cohomology, and the manner in which they are recovered by the Hochschild–Serre spectral sequence can be subtle.

2.1.2. Group actions. There is a natural continuous action of $G := \mathbb{G}(\mathbb{Q}_p)$ on each of $\widetilde{H}^i$ and $\widetilde{H}_i$, whose key property is encapsulated in the following result.

Theorem 2.1 ([24, 31]). *The G-action on $\widetilde{H}^i$ makes it a ϖ-adically admissible representation of G; i.e. it is ϖ-adically complete as an $\mathcal{O}$-module, and each quotient $\widetilde{H}^i/\varpi^s$ (which is a smooth representation of G over $\mathcal{O}/\varpi^s$) is admissible in the usual sense (for each compact open subgroup $K_p \subset G$, the submodule of K_p-invariants is finitely generated over $\mathcal{O}$).*

If $K_p \subset G$ is compact open, then we write $\mathcal{O}[[K_p]] := \varprojlim_{K_p'} \mathcal{O}[K_p/K_p']$, where the projective limit is taken over all open normal subgroups $K_p' \subset K_p$. Since G acts continuously on $\widetilde{H}^i$ and $\widetilde{H}_i$, it follows that for any such K_p, the K_p-action on each of these modules may be promoted to an action of $\mathcal{O}[[K_p]]$. One then has the following reformulation of the admissibility of the G-action on $\widetilde{H}^i$.

Theorem 2.2. *Each of the $\mathcal{O}[[K_p]]$-modules $\widetilde{H}_i$ is finitely generated.*

(We remark that if this finite generation statement holds for one choice of K_p then it holds for any such choice.)

2.1.3. Cohomology of local systems and the Hochschild–Serre spectral sequence. If W is a finitely generated $\mathcal{O}$-module equipped with a continuous representation of an open subgroup $K_p \subset G$, and K_p is sufficiently small, so that $\mathbb{G}(\mathbb{Q})$ acts with trivial stabilizers

on $\mathbb{G}(\mathbb{A})/A_\infty^\circ K_\infty^\circ K_p K_f^p$, then, for each open subgroup $K_p' \subset K_p$, the representation W determines a local system $\mathcal{W}$ of $\mathcal{O}$-modules on $Y(K_p K_f^p)$, defined via

$$\mathcal{W} := \mathbb{G}(\mathbb{Q})\backslash\Big(\big(\mathbb{G}(\mathbb{A}_f)/A_\infty^\circ K_\infty^\circ K_f^p\big) \times W\Big)/K_p'.$$

Suppose that W is furthermore torsion-free as an $\mathcal{O}$-module, and let $W^\vee$ denote the $\mathcal{O}$-dual of W, endowed with the contragredient K_p-action. There is then [24, 31] a Hochschild–Serre spectral sequence

$$E_2^{i,j} = \mathrm{Ext}^i_{\mathcal{O}[[K_p]]}(W^\vee, \widetilde{H}^j) \implies H^{i+j}\big(Y(K_p K_f^p), \mathcal{W}\big).$$

This gives a precise sense to the idea that p-adically completed cohomology captures *all* the cohomology (with arbitrary coefficients) at finite levels. It is the realization, in the context of completed cohomology, of the general philosophy (brought out especially in Hida's work, e.g. [45]) that when working with p-adic automorphic forms, by passing to infinite p-power level one automatically encompasses automorphic forms of all possible weights. (For the precise relationship with classical automorphic forms, see (2.1.6) below.)

In particular, if we take $W = \mathcal{O}$ (with the trivial K_p-action), we obtain a spectral sequence $E_2^{i,j} = H^i\big(K_p, \widetilde{H}^j\big) \implies H^{i+j}\big(Y(K_p K_f^p), \mathcal{O}\big)$ (where H^i denotes continuous cohomology), which recovers the cohomology at the finite level $K_p K_f^p$ from the completed cohomology. If we take a direct limit over all K_p, we obtain a spectral sequence $E_2^{i,j} = \varinjlim_{K_p} H^i\big(K_p, \widetilde{H}^j\big) \implies H^{i+j}$, which recovers the limits H^{i+j} of the cohomology at finite levels. The edge map $H^i \to \varinjlim_{K_p} (\widetilde{H}^i)^{K_p}$ is induced by the morphism (2.3). As already noted, the relationship between this spectral sequence, the morphism (2.3), and the exact sequence (2.6) is subtle. (See the example of (2.2.3) below.)

More generally, if we write $H^i(\mathcal{W}) := \varinjlim_{K_p'} H^i\big(Y(K_p' K_f^p), \mathcal{W}\big)$ (where K_p' runs over all open subgroups of the fixed K_p, of which W is a representation), then we have an edge map $H^i(\mathcal{W}) \to \varinjlim_{K_p'} \mathrm{Hom}_{K_p'}\big(W^\vee, \widetilde{H}^i\big)$ which relates the cohomology at finite levels with coefficients in $\mathcal{W}$ to the $W^\vee$-isotypic parts (for open subgroups K_p' of K_p) of $\widetilde{H}^i$.

2.1.4. Hecke actions. There is a finite set of primes Σ_0 (containing p) such that for $\ell \notin \Sigma_0$, we may factor $K_f^p = K_f^{p,\ell} K_\ell$ where $K_f^{p,\ell}$ is compact open in $\mathbb{G}(\mathbb{A}_f^{p,\ell})$, and K_ℓ is a hyperspecial maximal compact subgroup of $\mathbb{G}(\mathbb{Q}_\ell)$. (In particular, $\mathbb{G}$ is unramified at such a prime ℓ, so that it admits a hyperspecial maximal compact subgroup.) We may then consider the spherical Hecke algebra (i.e. the double coset algebra) $\mathcal{H}_\ell := \mathcal{H}\big(\mathbb{G}(\mathbb{Q}_\ell)//K_\ell, \mathcal{O}\big)$ with coefficients in $\mathcal{O}$. This algebra is commutative [41, 42], and acts naturally (by continuous operators) on any of the cohomology groups $H^i\big(Y(K_p K_f^p), \mathcal{W}\big)$ considered in (2.1.3).

If we let i range over all cohomological degrees, let K_p range over all compact open subgroups of G, and let W range over all representations of K_p on finitely generated *torsion* $\mathcal{O}$-modules, then $\prod_i \prod_{K_p} \prod_W \mathrm{End}\, H^i\big(Y(K_p K_f^p), \mathcal{W}\big)$ is a profinite ring. We fix a set of primes Σ containing Σ_0, and we define the global Hecke algebra $\mathbb{T}_\Sigma$ to be the closure in this profinite ring of the $\mathcal{O}$-subalgebra generated by the image of $\mathcal{H}_\ell$ for all $\ell \notin \Sigma$. (The reasons for allowing the possibility of Σ being larger than Σ_0 are essentially technical; it is not misleading to simply imagine that Σ is equal to Σ_0 and is fixed once and for all, e.g. by being taken to be as small as possible, given our fixed choice of tame level K_f^p.) By construction, $\mathbb{T}_\Sigma$ acts on each of the cohomology groups $H^i\big(Y(K_p K_f^p), \mathcal{W}\big)$ considered

in (2.1.3) (this is obvious if W is torsion, and follows in general by writing W as a projective limit $W \cong \varprojlim_s W/\varpi^s$), and also on $\widetilde{H}^i$ and $\widetilde{H}_i$. (In the case of $\widetilde{H}^i$ this follows from its definition in terms of limits of cohomology groups $H^i\big(Y(K_pK_f^p), \mathcal{O}/\varpi^s\big)$. It then follows for $\widetilde{H}_i$ by duality; more precisely, we can write $\widetilde{H}_i$ as the projective limit over s and K_p of $H_i\big(Y(K_pK_f^p), \mathcal{O}/\varpi^s\big)$, and this latter module is the $\mathcal{O}/\varpi^s$-dual of $H^i\big(Y(K_pK_f^p), \mathcal{O}/\varpi^s\big)$.)

These Hecke actions on $\widetilde{H}^i$ and $\widetilde{H}_i$ commute with the action of G. Thus there is an action of Hecke on the E_2-terms, as well the E_∞-terms, of the various Hochschild–Serre spectral sequences considered in (2.1.3), and these are in fact spectral sequences of $\mathbb{T}_\Sigma$-modules.

The $\mathcal{O}$-algebra $\mathbb{T}_\Sigma$ is a complete semi-local ring, i.e. it is a product of finitely many factors $\mathbb{T}_\mathfrak{m}$, each of which is a complete local ring. (This finiteness statement is proved via the methods of [3].) The topology on $\mathbb{T}_\Sigma$ is the product of the $\mathfrak{m}$-adic topologies on each of the complete local rings $\mathbb{T}_\mathfrak{m}$.

2.1.5. Variants in the non-compact case, and Poincaré duality. There are some variants of completed (co)homology which are useful in the case when the quotients $Y(K_f)$ are non-compact. (We recall that the quotients $Y(K_f)$ are compact precisely when the semisimple part of the group $\mathbb{G}$ is *anisotropic*, i.e. contains no torus that is split over $\mathbb{Q}$.)

Namely, replacing cohomology by cohomology with compact supports, we can define G-representations $\widetilde{H}^i_c$, H^i_c, $\widehat{H}^i_c$, and $T_pH^i_c$, and we have Hochschild–Serre spectral sequences for compactly supported cohomology. Similarly, we can define completed Borel–Moore homology $\widetilde{H}_i^{\mathrm{BM}}$, which is related to $\widetilde{H}^i_c$ by duality over $\mathcal{O}$.

There is a more subtle duality over $\mathcal{O}[[K_p]]$ (for a compact open subgroup $K_p \subset G$) which relates the usual and compactly supported variants of completed cohomology. It is most easily expressed on the homology side, where it takes the form of the Poincaré duality spectral sequence

$$E_2^{i,j} := \mathrm{Ext}^i_{\mathcal{O}[[K_p]]}(\widetilde{H}_j, \mathcal{O}[[K_p]]) \implies \widetilde{H}^{\mathrm{BM}}_{d-(i+j)}. \tag{2.7}$$

Of course, when the quotients $Y(K_f)$ are compact, compactly supported and usual cohomology coincide, as do usual and Borel–Moore homology. In general, we can relate them by considering the Borel–Serre compactifications $\overline{Y}(K_f)$. If we let $\partial(K_f)$ denote the boundary of $\overline{Y}(K_f)$, then we may compute the compactly supported cohomology of $Y(K_f)$ as the relative cohomology

$$H^i_c\big(Y(K_f), \mathcal{O}/\varpi^s\big) = H^i\big(\overline{Y}(K_f), \partial(K_f); \mathcal{O}/\varpi^s\big)$$

(and similarly we may compute Borel–Moore homology as relative homology), and so we obtain the long exact sequence of the pair relating the cohomology of $Y(K_f)$, the compactly supported cohomology of $Y(K_f)$, and the cohomology of $\partial(K_f)$. Passing to the various limits, we obtain a long exact sequence

$$\cdots \to \widetilde{H}^i_c \to \widetilde{H}^i \to \widetilde{H}^i(\partial) := \varprojlim_s \varinjlim_{K_p} H^i\big(\partial(K_pK_f^p), \mathcal{O}/\varpi^s\big) \to \widetilde{H}^{i+1}_c \to \cdots .$$

The completed cohomology of the boundary $\widetilde{H}^i(\partial)$ can be computed in terms of completed cohomology of the various Levi subgroups of $\mathbb{G}$; see [24] for more details.

We also mention that there is a $\mathbb{T}_\Sigma$-action on each of the objects introduced here, and that the various spectral sequences and long exact sequences considered here are all compatible with these actions.

2.1.6. The relationship to automorphic forms. We fix an isomorphism $\imath : \overline{\mathbb{Q}}_p \cong \mathbb{C}$. Since $L \subset \overline{\mathbb{Q}}_p$, we obtain induced embeddings $\mathcal{O} \subset L \hookrightarrow \mathbb{C}$.

Suppose that V is an algebraic representation of $\mathbb{G}$ defined over L, and suppose further that W is a K_p-invariant $\mathcal{O}$-lattice in V, for some compact open subgroup K_p of $G := \mathbb{G}(\mathbb{Q}_p) \subset \mathbb{G}(L)$. Write $V_{\mathbb{C}} := \mathbb{C} \otimes_L V = \mathbb{C} \otimes_{\mathcal{O}} W$ (the tensor products being taken with respect to the embeddings induced by $\imath$). If, for any compact open subgroup K'_p of K_p, we let $\mathcal{V}_{\mathbb{C}}$ denote the local system of $\mathbb{C}$-vector spaces on $Y(K'_pK^p_f)$ associated to $V_{\mathbb{C}}$, then we obtain a natural isomorphism

$$\mathbb{C} \otimes_{\mathcal{O}} H^i(\mathcal{W}) \cong \varinjlim_{K'_p} H^i\big(Y(K'_pK^p_f), \mathcal{V}_{\mathbb{C}}\big) =: H^i(\mathcal{V}_{\mathbb{C}}).$$

We may compute this cohomology using the space of automorphic forms on $\mathbb{G}$ [39].

Precisely, write $\mathcal{A}(K_f)$ for the space of automorphic forms on $\mathbb{G}(\mathbb{Q})\backslash\mathbb{G}(\mathbb{A})/K_f$, for any compact open subgroup $K_f \subset \mathbb{G}(\mathbb{A}_f)$, and write $\mathcal{A}(K^p_f) = \varinjlim_{K_p} \mathcal{A}(K_pK^p_f)$, where the direct limit is taken (as usual) over the compact open subgroups $K_p \subset G := \mathbb{G}(\mathbb{Q}_p)$. For simplicity, suppose that A°_∞ acts on $V_{\mathbb{C}}$ through some character χ (this will certainly hold if V is absolutely irreducible), and let $\mathcal{A}(K^p_f)_{\chi^{-1}}$ denote the subspace of $\mathcal{A}(K^p_f)$ on which A°_∞ acts through the character χ^{-1}. Let $\widetilde{G}_\infty$ denote the group of real points of the intersection of the kernels of all the rational characters of $\mathbb{G}$, and let $\widetilde{\mathfrak{g}}$ and $\mathfrak{k}$ denote the Lie algebras of $\widetilde{G}_\infty$ and K_∞ respectively. Then it is proved by J. Franke in [39] that there is a natural isomorphism

$$H^i(\mathcal{V}_{\mathbb{C}}) \cong H^i\big(\widetilde{\mathfrak{g}}, \mathfrak{k}; \mathcal{A}(K^p_f)_{\chi^{-1}} \otimes V_{\mathbb{C}}\big). \tag{2.8}$$

(In the case when the the quotients $Y(K_f)$ are compact, this result is known as *Matsushima's formula* [49]. In the case when $\mathbb{G} = \mathrm{GL}_2$ and $i = 1$, it is known as the *Eichler–Shimura isomorphism* [54].) The action of $\mathbb{T}_\Sigma$ on $H^i(\mathcal{W})$ induces an action of $\mathbb{T}_\Sigma$ on $H^i(\mathcal{V}_{\mathbb{C}})$, and the resulting systems of Hecke eigenvalues that appear in $H^i(\mathcal{V}_{\mathbb{C}})$ (which we may think of as being simultaneously $\mathbb{C}$-valued and $\overline{\mathbb{Q}}_p$-valued, by employing the isomorphism $\imath$) are automorphic, i.e. arise as systems of Hecke eigenvalues on the space of automorphic forms $\mathcal{A}(K^p_f)$.

Thus, to first approximation, we may regard the Hecke algebra $\mathbb{T}_\Sigma$ (or, more precisely, the $\overline{\mathbb{Q}}_p$-valued points of its Spec) as being obtained by ϖ-adically interpolating the automorphic systems of Hecke eigenvalues that occur in H^i. However, as we already noted, the map from H^i to $\widehat{H}^i$ can have a non-trivial kernel. More significantly (given that the Hochschild–Serre spectral sequence shows that, despite this possibility, the systems of Hecke eigenvalues appearing in H^i can be recovered from the completed cohomology), the inclusion $\widehat{H}^i \hookrightarrow \widetilde{H}^i$ can have a non-trivial cokernel T_pH^{i+1}, which arises from infinitely divisible torsion in H^{i+1}. Thus $\mathrm{Spec}\,\mathbb{T}_\Sigma$ sees not only the systems of eigenvalues arising from classical automorphic forms (and their ϖ-adic interpolations), but also systems of Hecke eigenvalues arising from torsion cohomology classes (and *their* ϖ-adic interpolations). We will discuss this point further in (3.1.3) below.

It will be helpful to say a little more about how one can use (2.8) to analyze cohomology. To this end, we decompose the space of automorphic forms $\mathcal{A}(K^p_f)_{\chi^{-1}}$ as the direct sum

$$\mathcal{A}(K^p_f)_{\chi^{-1}} = \mathcal{A}_{\mathrm{cusp}}(K^p_f)_{\chi^{-1}} \oplus \mathcal{A}_{\mathrm{Eis}}(K^p_f)_{\chi^{-1}} \tag{2.9}$$

of the cuspforms and the forms which are orthogonal to the cuspforms (in $\mathcal{A}(K^p_f)_\chi$) under the Petersson inner product (i.e. the L^2 inner product of functions on $\mathbb{G}(\mathbb{Q})\backslash\mathbb{G}(\mathbb{A})/A^\circ_\infty K^p_f$).

We label this complement to the space of cuspforms with the subscript Eis for *Eisenstein*, although its precise relationship with the space of Eisenstein series can be complicated; see e.g. [39, 40, 47]. Note that if the quotients $Y(K_f)$ are compact, then $\mathcal{A}(K_f^p)_{\chi^{-1}} = \mathcal{A}_{\mathrm{cusp}}(K_f^p)_{\chi^{-1}}$.

The decomposition (2.9) is a direct sum of $G_\infty \times G$-representations, and so the cohomology $H^i\big(\widetilde{\mathfrak{g}}, \mathfrak{k}; \mathcal{A}_{\mathrm{cusp}}(K_f^p)_{\chi^{-1}} \otimes V_{\mathbb{C}}\big)$ is a G-invariant direct summand of the cohomology $H^i\big(\widetilde{\mathfrak{g}}, \mathfrak{k}; \mathcal{A}(K_f^p)_{\chi^{-1}} \otimes V_{\mathbb{C}}\big)$, which via the isomorphism (2.8) we identify with a G-invariant direct summand $H^i_{\mathrm{cusp}}(\mathcal{V}_{\mathbb{C}})$ of $H^i(\mathcal{V}_{\mathbb{C}})$. It is also $\mathbb{T}_\Sigma$-invariant.

We may choose an everywhere positive element of $\mathcal{A}(K_f^p)$ on which $\mathbb{G}(\mathbb{A})$ acts via a character extending χ^2, multiplication by which induces an isomorphism between $\mathcal{A}_{\mathrm{cusp}}(K_f^p)_{\chi^{-1}}$ and $\mathcal{A}_{\mathrm{cusp}}(K_f^p)_{\chi}$. The Petersson (i.e. the L^2) inner product between $\mathcal{A}_{\mathrm{cusp}}(K_f^p)_{\chi^{-1}}$ and $\mathcal{A}_{\mathrm{cusp}}(K_f^p)_{\chi}$, taken together with this isomorphism, thus induces a pre-Hilbert space structure on $\mathcal{A}_{\mathrm{cusp}}(K_f^p)_{\chi^{-1}}$, with respect to which the $G_\infty \times G$-action is unitary up to a character. In particular, we find that $\mathcal{A}_{\mathrm{cusp}}(K_f^p)_{\chi^{-1}}$ is semisimple as a $G_\infty \times G$-representation, and so decomposes as a direct sum $\mathcal{A}_{\mathrm{cusp}}(K_f^p)_{\chi^{-1}} = \bigoplus_{\pi_\infty \otimes \pi_p} \pi_\infty \otimes \pi_p \otimes M(\pi_\infty \otimes \pi_p)$, where the direct sum is taken over (a set of isomorphism class representatives of) all the irreducible admissible representations of $G_\infty \otimes G$ over $\mathbb{C}$ on which A_∞° acts via χ^{-1} (which factor as the tensor product $\pi_\infty \otimes \pi_p$ of an irreducible admissible representation π_∞ of G_∞ on which A_∞° acts via χ^{-1}, and an irreducible admissible smooth representation π_p of G), and $M(\pi_\infty \otimes \pi_p) := \mathrm{Hom}_{G_\infty \times G}\big(\pi_\infty \otimes \pi_p, \mathcal{A}_{\mathrm{cusp}}(K_f^p)_{\chi^{-1}}\big)$ is the (finite-dimensional) multiplicity space of $\pi_\infty \otimes \pi_p$ in $\mathcal{A}_{\mathrm{cusp}}(K_f^p)_{\chi^{-1}}$. Consequently, we obtain a direct sum decomposition

$$\begin{aligned} H^i_{\mathrm{cusp}}(\mathcal{V}_{\mathbb{C}}) &\cong H^i\big(\widetilde{\mathfrak{g}}, \mathfrak{k}; \mathcal{A}_{\mathrm{cusp}}(K_f^p)_{\chi^{-1}} \otimes V_{\mathbb{C}}\big) \\ &\cong \bigoplus_{\pi_\infty \otimes \pi_p} H^i(\widetilde{\mathfrak{g}}, \mathfrak{k}; \pi_\infty \otimes V_{\mathbb{C}}) \otimes \pi_p \otimes M(\pi_\infty \otimes \pi_p) \end{aligned} \quad (2.10)$$

(the point here being that the $(\widetilde{\mathfrak{g}}, \mathfrak{k})$-cohomology depends only on the structure of $\pi_\infty \otimes \pi_p$ as a G_∞-representation, which is to say, only on π_∞).

In this way, we can speak of the contribution of each of the irreducible summands $\pi_\infty \otimes \pi_p$ of $\mathcal{A}_{\mathrm{cusp}}(K_f^p)_{\chi^{-1}}$ to the cohomology $H^i_{\mathrm{cusp}}(\mathcal{V}_{\mathbb{C}})$. In the case when $H^i(\widetilde{\mathfrak{g}}, \mathfrak{k}; \pi_\infty \otimes V_{\mathbb{C}})$ is non-zero, so that $\pi_\infty \otimes \pi_p$ actually does contribute to cohomology, the multiplicity space $M(\pi_\infty \otimes \pi_p)$ is naturally a $\mathbb{T}_\Sigma$-module, and the direct sum decomposition (2.10) is compatible with the actions of G and $\mathbb{T}_\Sigma$ (where G-acts on π_p, and $\mathbb{T}_\Sigma$ acts on $M(\pi_\infty \otimes \pi_p)$).

We can now explain the significance of the quantities l_0 and q_0 introduced above. Namely, q_0 is the lowest degree in which *tempered* π_∞ can admit non-trivial $(\widetilde{\mathfrak{g}}, \mathfrak{k})$-cohomology. Furthermore, among the tempered representations of G_∞, it is precisely the *fundamental tempered representations* (i.e. those which are induced from discrete series representations of the Levi subgroup of a fundamental parabolic subgroup of G_∞) which can admit non-zero cohomology at all, and they do so precisely in degrees between q_0 and $q_0 + l_0$ [10, Ch. III, Thm. 5.1]. (This is a range of degrees of length $l_0 + 1$ symmetric about $d/2$ — which is one-half of the dimension of the quotients $Y(K_f)$.) A fundamental theorem of Harish-Chandra states that, when $\mathbb{G}$ is semisimple, the group G_∞ admits discrete series representations precisely if $l_0 = 0$; in this case q_0 is equal to $d/2$, and the fundamental tempered representations are precisely the discrete series representations. Key examples for which $l_0 = 0$ are given by groups $\mathbb{G}$ for which G_∞ is compact, and (the semisimple parts of) groups giving rise to Shimura varieties.

One representation of $G_\infty \times G$ that always appears in $\mathcal{A}(K_f^p)$ is the trivial representation $\mathbb{1}$. Thus there are induced morphisms

$$H^i(\widetilde{\mathfrak{g}}, \mathfrak{k}; \mathbb{1}) \to H^i\big(\widetilde{\mathfrak{g}}, \mathfrak{k}; \mathcal{A}(K_f^p)_{\mathbb{1}}\big) \cong \mathbb{C} \otimes_{\mathcal{O}} H^i, \tag{2.11}$$

whose sources are naturally identified with the cohomology spaces of the compact dual to the symmetric space $G_\infty^\circ / A_\infty^\circ K_\infty^\circ$. If the $Y(K_f)$ are not compact, then $\mathbb{1}$ lies in $\mathcal{A}_{\mathrm{Eis}}(K_f^p)_{\mathbb{1}}$, but it is typically not a direct summand, and so the morphisms (2.11) are typically not injective. Nevertheless, when i is small they will be injective, and indeed (if e.g. $\mathbb{G}$ is split, semisimple, and simply connected) an isomorphism, and these isomorphisms play a key role in the theory of homological stability [9]. We discuss the interaction of these isomorphisms with the theory of completed cohomology (in the case when $\mathbb{G} = \mathrm{SL}_N$) in (2.2.3) below.

2.1.7. Dimension theory. For any compact open subgroup $K_p \subset G$, the completed group ring $\mathcal{O}[[K_p]]$ is (left and right) Noetherian, and of finite injective dimension as a module over itself; more precisely, its injective dimension is equal to $\dim \mathbb{G} + 1$. This allows us to consider a (derived) duality theory for finitely generated $\mathcal{O}[[K_p]]$-modules: to any such module M we associate the Ext-modules $E^i(M) := \mathrm{Ext}^i_{\mathcal{O}[[K_p]]}(M, \mathcal{O}[[K_p]])$, for $i \geq 0$ (which necessarily vanish if $i > \dim \mathbb{G} + 1$); these are again naturally $\mathcal{O}[[K_p]]$-modules. (We use the left $\mathcal{O}[[K_p]]$-module structure on $\mathcal{O}[[K_p]]$ to compute the E^i, and then use the right $\mathcal{O}[[K_p]]$-module structure on $\mathcal{O}[[K_p]]$, converted to a left module structure by the usual device of applying the anti-involution $k \mapsto k^{-1}$ on K_p, to give the E^i an $\mathcal{O}[[K_p]]$-module structure.)

An important point is that $E^i(M)$ is canonically independent of the choice of K_p (in the sense that we may regard M as an $\mathcal{O}[[K_p']]$-module, for any open subgroup K_p' of K_p, but $E^i(M)$ is canonically independent of which choice of K_p' we make to define it). This has the consequence that if the K_p-representation on M extends to a G-representation, then the $E^i(M)$ are also naturally G-representations.

The Poincaré duality spectral sequence (2.7) may thus be rewritten as

$$E_2^{i,j} = E^i(\widetilde{H}_j) \implies \widetilde{H}^{\mathrm{BM}}_{d-(i+j)}.$$

All the objects appearing in it are G-representations, and it is G-equivariant.

If K_p is p-torsion free (which will be true provided K_p is sufficiently small) then the ring $\mathcal{O}[[K_p]]$ is in fact Auslander regular [55]. If K_p is furthermore pro-p, then the ring $\mathcal{O}[[K_p]]$ is an integral domain (in the sense that it contains no non-trivial left or right zero divisors). This has various implications for the theory of finitely generated $\mathcal{O}[[K_p]]$-modules. For example, it is reasonable to define such a module to be *torsion* if every element has a non-zero annihilator in $\mathcal{O}[[K_p]]$ (where K_p is chosen small enough to be pro-p and p-torsion free). More generally, we may make the following definition.

Definition 2.3. If M is a finitely generated $\mathcal{O}[[K_p]]$-module, then the *codimension* $\mathrm{cd}(M)$ of M is defined to be the least value of i for which $E^i(M) \neq 0$; the dimension $\dim M$ of M is defined to be $\dim \mathbb{G} + 1 - \mathrm{cd}(M)$.

If $\mathbb{G}$ is a torus, so that K_p is commutative, then $\dim M$ is precisely the dimension of the support of the localization of M over $\mathrm{Spec}\, \mathcal{O}[[K_p]]$. In general $\mathcal{O}[[K_p]]$ is non-commutative, and hence doesn't have a Spec over which we can localize a finitely generated module M. Nevertheless, the quantity $\dim M$ behaves as if it were the dimension of the support of M in

the (non-existent) Spec of $\mathcal{O}[[K_p]]$. (See e.g. [55, Prop. 3.5].) As one example, we note that M is torsion (in the sense defined above) if and only if $\mathrm{cd}(M) \geq 1$. As another, we note that $\mathrm{cd}\, E^i(M) \geq i$, with equality when $i = \mathrm{cd}\, M$. Also, we note that $\mathrm{cd}\, M = \infty$ (so, morally, the support of M is empty) precisely when $M = 0$.

By Theorem 2.2, completed homology is finitely generated over $\mathcal{O}[[K_p]]$, and so these dimension-theoretic notions apply to it. Information about the (co)dimension of $\widetilde{H}_i$ can be obtained by analyzing the Poincaré duality spectral sequence, since the functors E^i appear explicitly in it, and there is a tension in this spectral sequence between the top degree for the duality of $\mathcal{O}[[K_p]]$-modules (which is $\dim \mathbb{G} + 1$) and the top degree for usual Poincaré duality (which is d), which can sometimes be exploited. (See e.g. (2.2.2) below.) In making any such analysis, it helps to have some *a priori* information about the (co)dimensions of the $\widetilde{H}^i$. This is provided by the following result.

Theorem 2.4 ([23]). *Suppose that $\mathbb{G}$ is semisimple. Then $\widetilde{H}^i$ is torsion* (*i.e. its codimension is positive*) *unless $l_0 = 0$ and $i = q_0$, in which case* $\mathrm{cd}\, \widetilde{H}_i = 0$.

We make a much more precise conjecture about the codimensions of the $\widetilde{H}^i$ in Conjecture 3.2 below.

2.2. Examples. We illustrate the preceding discussion with some examples.

2.2.1. $\mathbf{GL_2}$ of $\mathbb{Q}$. If $\mathbb{G} = \mathrm{GL}_2$, then the quotients $Y(K_f)$ are classical modular curves. In particular, they have non-vanishing cohomology only in degrees 0 and 1, and so we consider completed cohomology in degrees 0 and 1. Since the cohomology of a curve is torsion free, we have $\widetilde{H}^0 = \widehat{H}^0 \cong \mathcal{C}\big(\Delta \times \mathbb{Z}_p^\times, \mathcal{O}\big)$, the space of continuous $\mathcal{O}$-valued functions on the product $\Delta \times \mathbb{Z}_p^\times$, where Δ is a finite group that depends on the choice of tame level, and so $\widetilde{H}_0$ (which is simply the $\mathcal{O}$-dual of $\widehat{H}^0$) is isomorphic to $\mathcal{O}[[\Delta \times \mathbb{Z}_p^\times]]$, which is of dimension two as a module over $\mathcal{O}[[K_p]]$ (for any compact open $K_p \subset \mathrm{GL}_2(\mathbb{Q}_p)$). We also have $\widetilde{H}^1 = \widehat{H}^1$. Again, $\widetilde{H}_1$ is the $\mathcal{O}$-dual of $\widetilde{H}^1$, and Theorem 2.4 shows that $\mathrm{cd}\, \widetilde{H}_1 = 0$. (Strictly speaking, we have to apply the theorem to SL_2 rather than GL_2, but it is then easy to deduce the corresponding result for GL_2, by considering the cup-product action of H^0 on H^1.)

2.2.2. $\mathbf{SL_2}$ of an imaginary quadratic field. Suppose that $\mathbb{G} = \mathrm{Res}_{F/\mathbb{Q}}\, \mathrm{SL}_2$, where F is an imaginary quadratic extension of $\mathbb{Q}$. The quotients $Y(K_f)$ are then connected, non-compact three-manifolds. The relevant (co)homological degrees are thus $i = 0, 1$, and 2. Since the $Y(K_f)$ are connected we see that $\widetilde{H}^0 = \widetilde{H}_0 = \mathcal{O}$. Theorem 2.4 implies that $\widetilde{H}_1$ has positive codimension. A consideration of the Poincaré duality spectral sequence then shows that $\widetilde{H}_2 = 0$, and that $\widetilde{H}_1$ is of codimension 1. This computation exploits both the fact that $\widetilde{H}_0 \neq 0$, and the gap between 3 (the dimension of the $Y(K_f)$) and 6 (the dimension of $\mathbb{G}$).

Since H^1 with coefficients in $\mathcal{O}$ of any space is ϖ-torsion free, we see that $\widetilde{H}^1$ is ϖ torsion-free, and coincides with the $\mathcal{O}$-dual of $\widetilde{H}_1$, while $\widetilde{H}^2$ is ϖ-torsion, and is naturally identified with the Pontrjagin dual of the $\mathcal{O}$-torsion submodule of $\widetilde{H}_1$ [24, Thm. 1.1]. We conjecture that in fact $\widetilde{H}_1$ is ϖ-torsion free (see Conjecture 3.2), and thus that $\widetilde{H}^2 = 0$.

2.2.3. $\mathbf{SL_N}$ of $\mathbb{Q}$ in low degrees. We first discuss $\widetilde{H}^0$ and $\widetilde{H}^1$, before turning to a discussion of higher degree cohomology from the point of view of homological stability.

The quotients $Y(K_f)$ are connected, and so $\widetilde{H}_0 = \mathcal{O}$. If $N \geq 3$, then SL_N satisfies the

congruence subgroup property. Furthermore, the groups $\mathrm{SL}_N(\mathbb{Z}_\ell)$ are perfect for all values of ℓ. Combining these two facts, we see that if $\Gamma(p^r)$ denotes the usual congruence subgroup of level p^r (i.e. the kernel of the surjection $\mathrm{SL}_N(\mathbb{Z}) \to \mathrm{SL}_N(\mathbb{Z}/p^r)$), then $H_1\big(\Gamma(p^r), \mathcal{O}\big) = \mathcal{O} \otimes_{\mathbb{Z}_p} \Gamma(p^r)^{\mathrm{ab}} \cong \mathcal{O} \otimes_{\mathbb{Z}_p} \Gamma(p^r)/\Gamma(p^{2r})$. Thus, if we take the tame level to be trivial (i.e. "level one"), then we see that the transition maps in the projective system defining $\widetilde{H}_1$ are eventually zero, implying that $\widetilde{H}_1 = 0$. Similarly, we see that $H^1 = \widetilde{H}^1 = 0$. (If we allowed a more general tame level, then $\widetilde{H}_1$ could be non-zero, but would be finite. Since H^1 and $\widetilde{H}^1$ are always torsion free, they would continue to vanish.)

We now consider cohomology in higher degree, but in the stable range, in the sense that we now explain. (The tame level can now be taken to be arbitrary.) Borel's result [9] on homological stability for SL_N shows that when i is sufficiently small (compared to N), the cohomology $L \otimes_{\mathcal{O}} H^i$ is independent of N; indeed, it consists precisely of the contributions to cohomology arising from the trivial automorphic representation, in the sense discussed in (2.1.6). If we define H^i_{stab} to be the stable value of H^i, then Borel shows that $\bigoplus H^i_{\mathrm{stab}}$ (as an algebra under cup product) is isomorphic to an exterior algebra generated by a single element in each degree $i = 0, 5, 9, 13, \ldots$.

In fact, stability also holds for completed cohomology.

Theorem 2.5 ([25]). *If i is sufficiently small compared to N, then $\widetilde{H}^i$ is independent of N, is finitely generated as an $\mathcal{O}$-module, and affords the trivial representation of G.*

We write $\widetilde{H}^i_{\mathrm{stab}}$ to denote the stable value of $\widetilde{H}^i$. F. Calegari has succeeded in computing $\widetilde{H}^i_{\mathrm{stab}}$ modulo torsion, contingent on a natural non-vanishing conjecture for certain special values of the p-adic ζ-function (a conjecture which holds automatically if p is a regular prime).

Theorem 2.6 ([22, Theorem 2.3]). *Suppose either that p is a regular prime, or that appropriate special values of the p-adic zeta function are non-zero. Then there is an isomorphism of graded vector spaces $\bigoplus_{i \geq 0} L \otimes_{\mathcal{O}} \widetilde{H}^i_{\mathrm{stab}} \cong L[x_2, x_6, x_{10}, \ldots]$ (where $L[x_2, x_6, x_{10}, \ldots]$ denotes the graded ring generated by the indicated sequence of polynomial variables x_i, $i \equiv 2 \bmod 4$, with x_i placed in degree i).*

Note in particular that $\bigoplus_i L \otimes_{\mathcal{O}} \widetilde{H}^i_{\mathrm{stab}}$ vanishes in all odd degrees, while $\bigoplus_i L \otimes_{\mathcal{O}} H^i_{\mathrm{stab}}$ is generated by classes in odd degrees. Thus, when $\mathbb{G} = \mathrm{SL}_N$, the map (2.3) is identically zero (modulo torsion) when i lies in the stable range!

Assuming the hypotheses of the theorem, we conclude that the Borel classes (i.e. the non-zero elements of $L \otimes_{\mathcal{O}} H^i_{\mathrm{stab}}$) become infinitely divisible when we pull them back up the p-power level tower. It is interesting to consider how they reappear in the Hochschild–Serre spectral sequence. If we again ignore torsion, then $H^i\big(\mathrm{SL}_N(\mathbb{Z}_p), L\big)$ coincides with the Lie algebra cohomology of $\mathfrak{sl}_N$ [48], which is (stably in N) an exterior algebra on generators in degrees $3, 5, 7, \ldots$. Since all of the non-zero $\widetilde{H}^i_{\mathrm{stab}}$ have trivial G-action, we see that we obtain non-trivial Ext terms in odd degrees in the Hochschild–Serre spectral sequence, and the Borel classes are recovered from these.

If we consider the short exact sequence (2.6) for non-zero even degrees, we see that $\widehat{H}^i$ vanishes (modulo torsion), while $\widetilde{H}^i$ is non-zero. Thus the term $T_p H^{i+1}$ must be non-zero; this provides a rather compelling illustration of the manner in which torsion classes can accumulate as we pass to the limit of the p-power level tower.

2.2.4. Groups that are compact at infinity. If G_∞ (or, more generally, if the quotient G_∞/A_∞) is compact, then $A^\circ_\infty K^\circ_\infty$ equals G°_∞, and so the quotients $Y(K_f)$ are simply finite

sets. Thus the only interesting degree of cohomology is $i = 0$. In this case the inverse limit $Y(K^p_f) := \varprojlim_{K_p} Y(K_pK^p_f)$ is a pro-finite set, which is in fact a compact p-adic analytic manifold, equipped with an analytic action of G. If K_p is taken sufficiently small (small enough that the $\mathbb{G}(\mathbb{Q})$-action on $\mathbb{G}(\mathbb{A})/G^\circ_\infty K_pK^p_f$ is fixed-point free), then K_p acts with trivial stabilizers on $Y(K_pK^p_f)$, and $Y(K_pK^p_f)$ is the disjoint union of finitely many (say n) principal homogeneous spaces over K_p.

One immediately verifies that $\widetilde{H}^0 \cong \mathcal{C}\big(Y(K^p_f), \mathcal{O}\big)$, the space of continuous $\mathcal{O}$-valued functions on $Y(K^p_f)$, while $\widetilde{H}_0 \cong \mathcal{O}[[Y(K^p_f)]]$, the space of $\mathcal{O}$-valued measures on $Y(K^p_f)$ (which is the $\mathcal{O}$-dual of $\mathcal{C}\big(Y(K^p_f), \mathcal{O}\big)$). In particular, if K_p is sufficiently small, then we see that $\widetilde{H}_0$ is free of rank n over $\mathcal{O}[[K_p]]$.

It is natural (e.g. in light of Gross's definition of algebraic modular forms in this context [42]) to define $\mathcal{C}\big(Y(K^p_f), \mathcal{O}\big)$ to be the space of p-adic automorphic forms on $\mathbb{G}(\mathbb{A})$ of tame level K^p_f, and so in this case we see that completed cohomology does indeed coincide with the natural notion of p-adic automorphic forms.

3. *p*-adic Langlands

We describe the manner in which we expect completed cohomology, and the Hecke algebra acting on it, to be related to deformation rings of global Galois representations. This conjectural relationship suggests various further conjectures, as we explain, as well as a relationship to a hypothetical p-adic local Langlands correspondence.

3.1. The connection between completed cohomology and Galois representations. If π is an automorphic representation of $\mathbb{G}(\mathbb{A})$ for which $H^i(\widetilde{\mathfrak{g}}, \mathfrak{k}; \pi_\infty \otimes V_{\mathbb{C}}) \neq 0$ for some algebraic representation V of $\mathbb{G}$ and some degree i, then π is C-algebraic [21, Lemma 7.2.2]. Thus, we expect that associated to π there should be a continuous representation of $G_{\mathbb{Q}}$ into the $\overline{\mathbb{Q}}_p$-valued points of the C-group of $\mathbb{G}$ [21, Conj. 5.3.4]. In light of the isomorphism (2.8), we thus expect that the systems of Hecke eigenvalues that occur in $H^i(\mathcal{V})$ should have associated representations of $G_{\mathbb{Q}}$ into the C-group of $\mathbb{G}$. For systems of Hecke eigenvalues occurring on torsion classes in cohomology, conjectures of Ash [2] again suggest that there should be associated Galois representations.

These expectations have been proved correct in many cases; for example, if $\mathbb{G}$ is the restriction of scalars to $\mathbb{Q}$ of GL_n over a totally real or a CM number field. (See [44] in the case of characteristic zero systems of eigenvalues, and [53] in the case of torsion systems of eigenvalues. See also [43] for an overview of these results.)

Returning for a moment to the general case, one further expects that the Galois representations obtained should be *odd*, in the sense that complex conjugation in $G_{\mathbb{Q}}$ maps to a certain prescribed conjugacy class in the C-group of $\mathbb{G}$. (See [7, Prop. 6.1] for a description of the analogous conjugacy class in the L-group of $\mathbb{G}$.)

Let $\mathfrak{m}$ denote a maximal ideal in $\mathbb{T}_\Sigma$, write $\mathbb{F} := \mathbb{T}_\Sigma/\mathfrak{m}$, and let $\overline{\mathbb{F}}$ denote a chosen algebraic closure of $\mathbb{F}$. Then, by the above discussion, we believe that associated to $\mathfrak{m}$ there should be a continuous representation of $G_{\mathbb{Q}}$ into the $\overline{\mathbb{F}}$-valued points of the C-group of $\mathbb{G}$. Assuming that this representation exists, we will denote it by $\overline{\rho}_{\mathfrak{m}}$.

To be a little more precise: the representation $\overline{\rho}_{\mathfrak{m}}$ should have the property that it is unramified at the primes outside Σ, and that for any $\ell \notin \Sigma$, the semisimple part of $\overline{\rho}_{\mathfrak{m}}(\mathrm{Frob}_\ell)$ should

be associated to the local-at-ℓ part of the system of Hecke eigenvalues by a suitable form of the Satake isomorphism (see [21, 42]). In general, this condition may not serve to determine $\overline{\rho}_{\mathfrak{m}}$ uniquely; even in the case $\mathbb{G} = \mathrm{GL}_n$, it determines $\overline{\rho}_{\mathfrak{m}}$ only up to semisimplification; for other choices of $\mathbb{G}$, as well as this issue, one can have the additional phenomenon that even a representation which doesn't factor through any parabolic subgroup of the C-group is not determined by its pointwise conjugacy classes ("local conjugacy does not determine global conjugacy"). We do not attempt to deal with this issue in general here; rather we simply ignore it, and continue our discussion as if $\overline{\rho}_{\mathfrak{m}}$ were unambiguously defined.

As we observed above, we may regard $\mathbb{T}_{\mathfrak{m}}$ (or its Spec) as interpolating systems of Hecke eigenvalues associated to classical C-algebraic automorphic forms, and/or to torsion classes in cohomology. Since the deformations of $\overline{\rho}_{\mathfrak{m}}$ can be interpolated into a formal deformation space, it is then reasonable to imagine that we may deform $\overline{\rho}_{\mathfrak{m}}$ to a representation of $G_{\mathbb{Q}}$ into the $\mathbb{T}_{\mathfrak{m}}$-valued points of the C-group of $\mathbb{G}$. Here again there are many caveats: firstly, if $\overline{\rho}_{\mathfrak{m}}$ is "reducible" (i.e. factors through a proper parabolic of the C-group), then we would have to work with some form of *pseudo-character* or *determinant*, as in [28, 53]; also, there is a question of rationality, or "Schur index" — it may be that if we want $\overline{\rho}_{\mathfrak{m}}$ to be defined over $\mathbb{F}$, and its deformation to be defined over $\mathbb{T}_{\mathfrak{m}}$, then we may have to extend our scalars, or else replace the C-group by an inner twist. Again, we don't attempt to address these issues here.

Rather, we begin with some general conjectures about dimension and vanishing that are motivated by the preceding discussion, and then continue by discussing the relationships between completed cohomology and p-adic Hodge theory and a possible p-adic local Langlands correspondence. Finally, we turn to a discussion of some specific examples, where we can make our generalities more precise.

3.1.1. Conjectures on dimension and vanishing. We begin by making a somewhat vague conjecture, which can be thought of as a rough expression of our hopes for reciprocity in the context of global p-adic Langlands: namely (continuing with the notation introduced in the preceding discussion), we conjecture that $\mathbb{T}_{\mathfrak{m}}$ is universal (in some suitable sense) for parameterizing *odd* formal deformations of $\overline{\rho}_{\mathfrak{m}}$ whose ramification away from p is compatible with the tame level structure K^p_f (via some appropriate form of ϖ-adic local Langlands for the group $\mathbb{G}$ at primes $\ell \nmid p$ which, again, we won't attempt to formulate here; but see [36] in the case when $\mathbb{G} = \mathrm{GL}_n$). The global Euler characteristic formula for Galois cohomology lets us compute the expected dimension of such a universal deformation ring, and this motivates in large part the following concrete conjecture [24, §8].

Conjecture 3.1. *Each local factor $\mathbb{T}_{\mathfrak{m}}$ of $\mathbb{T}_{\Sigma}$ is Noetherian, reduced, and ϖ-torsion free, of Krull dimension equal to $\dim \mathbb{B} + 1 - l_0$, where $\dim \mathbb{B}$ denotes the dimension of a Borel subgroup $\mathbb{B}$ of $\mathbb{G}$.*

This is known in some cases (which we will recall below). We know of no way to prove the Noetherianness of $\mathbb{T}_{\mathfrak{m}}$, or the statement about its Krull dimension, other than to relate the Hecke algebra to a deformation ring of Galois representations, and then use techniques from the theory of Galois representations to compute the dimension.

In some situations we *can* prove that $\mathbb{T}_{\mathfrak{m}}$ is torsion free and reduced (see e.g. the discussion of (3.1.2) below), and it seems reasonable to conjecture these properties in general. Indeed, these properties are closely related to the following conjecture [24, Conj. 1.5].

Conjecture 3.2. *$\widetilde{H}_i = 0$ if $i > q_0$, while $\mathrm{cd}\, \widetilde{H}_{q_0} = l_0$, and $\mathrm{cd}\, \widetilde{H}_i > l_0 + q_0 - i$ if $i < q_0$. Furthermore, $\widetilde{H}_{q_0}$ is ϖ-torsion free, and $\mathbb{T}_{\Sigma}$ acts faithfully on $\widetilde{H}_{q_0}$.*

As noted in [24, Thm. 1.6], the truth of this conjecture for $\mathbb{G}$ and all its Levi subgroups implies the analogous statement for $\widetilde{H}_i^{\mathrm{BM}}$. Also, the vanishing conjecture for $\mathbb{G} \times \mathbb{G}$ implies (via the Künneth formula) the torsion-freeness of $\widetilde{H}_{q_0}$.

One of the ideas behind this conjecture is that "all the interesting Hecke eigenvalues should appear in degree q_0". This is inspired by the fact (recalled in (2.1.6)) that tempered automorphic representations don't contribute to cohomology in degrees below q_0, so that the Galois representations associated to the systems of Hecke eigenvalues appearing in degrees below q_0 should be "reducible" (i.e. factor through a proper parabolic subgroup of the C-group). In a Galois deformation space with unrestricted ramification at p, the reducible representations should form a proper closed subset, and so should be approximable by "irreducible" Galois representations (i.e. representations which don't factor through a proper parabolic). Thus we don't expect to see any systems of Hecke eigenvalues in degrees below q_0 which can't already be observed in degree q_0, and hence we expect that $\mathbb{T}_\Sigma$ will act faithfully on $\widetilde{H}_{q_0}$.

We also expect that $\widetilde{H}_i$ should be "small" if $i < q_0$, since the possible systems of Hecke eigenvalues which it can carry are (or should be) constrained. However, if the $\widetilde{H}_i$ are small enough for $i < q_0$, then the Poincaré duality spectral sequence (combined with an analysis of the completed cohomology of the boundary, which can be treated inductively, by reducing to the case of lower rank groups) implies the vanishing of $\widetilde{H}_i$ in degrees $> q_0$.

If we believe that $\mathbb{T}_\Sigma$ acts faithfully on $\widetilde{H}_{q_0}$, and that $\mathbb{T}_\Sigma$ has dimension $\dim \mathbb{B} + 1 - l_0$ (as predicted by Conjecture 3.1), then conjecturing that $\widetilde{H}_{q_0}$ has codimension l_0 is morally equivalent to conjecturing that the fibres of $\widetilde{H}_{q_0}$ over the points of $\operatorname{Spec} \mathbb{T}_\Sigma$ are of dimension $\dim \mathbb{G}/\mathbb{B}$. This latter statement fits nicely with the fact that generic irreducible representations of $G := \mathbb{G}(\mathbb{Q}_p)$ have Gelfand–Kirillov dimension equal to $\dim \mathbb{G}/\mathbb{B}$, and the analogy between the dimension of $\mathcal{O}[[K_p]]$-modules and Gelfand–Kirillov dimension [24, Remark 1.19]. Unfortunately, we don't know how to make this idea precise, since we don't know how to prove (in any generality) this relationship between the Krull dimension of $\mathbb{T}_\Sigma$, the dimension of $\widetilde{H}_{q_0}$, and the dimension of the fibres of the latter over points of $\operatorname{Spec} \mathbb{T}_\Sigma$, even assuming that $\mathbb{T}_\Sigma$ acts faithfully on $\widetilde{H}_{q_0}$. Nevertheless, the idea that these dimensions should be related is an important motivation for the conjecture.

We note that if $\mathbb{T}_\Sigma$ acts faithfully on $\widetilde{H}_{q_0}$, and $\widetilde{H}_{q_0}$ is ϖ-torsion free, then $\mathbb{T}_\Sigma$ is ϖ-torsion free. This motivates the conjecture of ϖ-torsion freeness in Conjecture 3.1.

Conjecture 3.2 has essentially been proved by P. Scholze in many cases for which the group $\mathbb{G}$ gives rise to Shimura varieties [53, Cor. IV.2.3]. (He has non-strict inequalities rather than strict inequalities for the codimension of the cohomology in degrees $< q_0$.)

We mention one more example here, namely the case when $\mathbb{G}$ is the restriction of scalars of SL_2 from an imaginary quadratic field. In this case we have $l_0 = 1$, and the codimension statement of Conjecture 3.2 follows from the computation sketched in (2.2.2).

3.1.2. Localization at a non-Eisenstein system of Hecke eigenvalues. Suppose that $\mathfrak{m}$ is a maximal ideal in $\mathbb{T}_\Sigma$, and that the associated representation $\overline{\rho}_\mathfrak{m}$ (which we assume exists) is "irreducible", i.e. does not factor through any proper parabolic subgroup of the C-group of $\mathbb{G}$. We refer to such a $\mathfrak{m}$ as *non-Eisenstein*. For any $\mathbb{T}_\Sigma$-module M, we write $M_\mathfrak{m} := \mathbb{T}_\mathfrak{m} \otimes_{\mathbb{T}_\Sigma} M$ to denote the localization of M at $\mathfrak{m}$.

As already noted, we expect that all the systems of Hecke eigenvalues appearing in cohomological degrees $< i$ are "reducible", i.e. do factor through a proper parabolic subgroup ,

and so we conjecture that, when $\mathfrak{m}$ is a non-Eisenstein maximal ideal, $H^i\big(Y(K_pK_f^p),\mathcal{W}\big)_{\mathfrak{m}} = 0$ for all $i < q_0$ and all local systems $\mathcal{W}$ associated to K_p-representations W on finitely generated $\mathcal{O}$-modules (where K_p is any sufficiently small compact open subgroup of G).

We remark that if we ignore torsion, then this follows (at least morally) from Arthur's conjectures [1]. (Namely, the result is true for the boundary cohomology, and hence it suffices to check it for the interior cohomology, i.e. the image of compactly supported cohomology in the usual cohomology. However, the interior cohomology is contained in the L^2-cohomology, and now Arthur's conjectures imply that any automorphic representation π contributing to L^2-cohomology that is non-tempered at ∞ — as must be the case for an automorphic representation that contributes to cohomology in degree $< q_0$ — is non-tempered at every prime, and hence should give rise to a reducible Galois representation.) We believe that this statement should be true for torsion cohomology as well.

Let us suppose, then, that $H^i\big(Y(K_pK^p),\mathcal{W}\big)_{\mathfrak{m}} = 0$ for all $i < q_0$. Just considering the case when $W = \mathcal{O}$ (the trivial representation), we find that $\widetilde{H}^i_{\mathfrak{m}} = 0$ for $i < q_0$. Certainly it should be the case that $H^i\big(\partial(K_pK_f^p),\mathcal{W}\big)_{\mathfrak{m}} = 0$ when $\mathfrak{m}$ is non-Eisenstein. We then find that $H^i_c\big(Y(K_pK_f^p),\mathcal{W}\big)_{\mathfrak{m}} = 0$ for all $i < q_0$ as well. *Suppose now that* $l_0 = 0$, so that $q_0 = d/2$. Classical Poincaré duality then gives that $H^i\big(Y(K_pK_f^p),\mathcal{W}\big)_{\mathfrak{m}} = 0$ for all $i > q_0$. Presuming that Conjecture 3.2 is true, so that $\widetilde{H}^i = 0$ for $i > q_0$ and $\widetilde{H}^{q_0}$ is ϖ-torsion free, a consideration of the Hochschild–Serre spectral sequence shows that $\mathrm{Ext}^i_{\mathcal{O}[[K_p]]}(W^\vee, \widetilde{H}^{q_0}_{\mathfrak{m}}) = 0$ for all $i > 0$ and all representations of K_p on finitely generated torsion free $\mathcal{O}$-modules. From this one easily deduces that $(\widetilde{H}_{q_0})_{\mathfrak{m}}$ is projective as an $\mathcal{O}[[K_p]]$-module.

In short, we have given a plausibility argument for the following conjecture, which refines Conjecture 3.2 in the context of localizing at a non-Eisenstein maximal ideal.

Conjecture 3.3. *If* $\mathfrak{m}$ *is a* non-Eisenstein *maximal ideal in* $\mathbb{T}_\Sigma$*, and if* $l_0 = 0$*, then* $(\widetilde{H}_i)_{\mathfrak{m}} = 0$ *for* $i \neq q_0$*, and* $(\widetilde{H}_{q_0})_{\mathfrak{m}}$ *is a projective* $\mathcal{O}[[K_p]]$*-module, for any sufficiently small subgroup* K_p *of* G*.* (*Here* sufficiently small *means that* $\mathbb{G}(\mathbb{Q})$ *acts with trivial stabilizers on* $\mathbb{G}(\mathbb{A})/A^\circ_\infty K^\circ_\infty K_pK_f^p$.)

If $l_0 = 0$, and if Conjecture 3.3 holds for some non-Eisenstein maximal ideal $\mathfrak{m}$, then we see (from the Hochschild–Serre spectral sequence) that for any sufficiently small K_p (as in the statement of the conjecture) and any representation of K_p on a finitely generated torsion free $\mathcal{O}$-module W, we have $H^i\big(Y(K_pK_f^p),\mathcal{W}\big)_{\mathfrak{m}} = 0$ if $i \neq q_0$, while $H^{q_0}\big(Y(K_pK_f^p),\mathcal{W}\big)_{\mathfrak{m}} \cong \mathrm{Hom}_{\mathcal{O}[[K_p]]}(W^\vee, \widetilde{H}^{q_0}_{\mathfrak{m}})$. In particular, we see that $H^{q_0}\big(Y(K_pK_f^p),\mathcal{W}\big)_{\mathfrak{m}}$ is ϖ-torsion free. We also see that $\widehat{H}^{q_0}_{\mathfrak{m}} = \widetilde{H}^{q_0}_{\mathfrak{m}}$ (since $H^{q_0+1}_{\mathfrak{m}}$ vanishes, and hence so does $T_pH^{q_0+1}_{\mathfrak{m}}$), and that $\mathbb{T}_{\mathfrak{m}}$ acts faithfully on $\widetilde{H}^{q_0}_{\mathfrak{m}}$.

Presuming that $H^i\big(\partial(K_pK_f^p),\mathcal{W}\big)_{\mathfrak{m}} = 0$ (which should certainly be true when $\mathfrak{m}$ is non-Eisenstein), we conclude that the natural map

$$H^{q_0}_c\big(Y(K_pK_f^p),\mathcal{W}\big)_{\mathfrak{m}} \to H^{q_0}\big(Y(K_pK_f^p),\mathcal{W}\big)_{\mathfrak{m}}$$

is an isomorphism, and thus that $H^{q_0}\big(Y(K_pK_f^p),\mathcal{W}\big)_{\mathfrak{m}}$ consists entirely of interior cohomology. In particular (being torsion free) it embeds into the L^2-cohomology. From this we deduce that the image of $\mathbb{T}_\Sigma$ acting on $H^{q_0}\big(Y(K_pK_f^p),\mathcal{W}\big)_{\mathfrak{m}}$ is reduced, and hence (considering all possible K_p and W) that $\mathbb{T}_{\mathfrak{m}}$ itself is reduced, as well as being ϖ-torsion free. This provides some evidence for the reducedness and torsion-freeness statements in Conjecture 3.1.

We now recall some known results in the direction of Conjecture 3.3. In the case when $\mathbb{G} = \mathrm{GL}_2$, the concept of a non-Eisenstein maximal ideal is well-defined, and the above conjecture holds [32, Cor. 5.3.19]. In the case when $\mathbb{G} = \mathrm{GL}_N$, this notion is again well-defined, and the vanishing of $(\widetilde{H}_i)_{\mathfrak{m}}$ is proved for i in the stable range in [25]. Again, if $\mathbb{G}$ is a form of $U(n-1,1)$ over $\mathbb{Q}$, then the notion of a non-Eisenstein maximal ideal is well-defined, and in [34] we prove vanishing of $(\widetilde{H}_i)_{\mathfrak{m}}$ for i in a range of low degrees, for certain maximal ideals $\mathfrak{m}$. In particular, in the case of $U(2,1)$, we are able to deduce Conjecture 3.3, provided not only that $\mathfrak{m}$ is non-Eisenstein, but that the associated Galois representation $\overline{\rho}_{\mathfrak{m}}$ has sufficiently large image, and is irreducible locally at p, satisfying a certain regularity condition.

As one more example, note that if G_∞/A_∞ is compact (in which case certainly $l_0 = 0$), then Conjecture 3.3 holds. Indeed, in this case we saw in (2.2.4), for sufficiently small K_p, that $\widetilde{H}_0$ is free over $\mathcal{O}[[K_p]]$, even without localizing at a non-Eisenstein maximal ideal.

If $l_0 \neq 0$, then we don't expect that $(\widetilde{H}_{q_0})_{\mathfrak{m}}$ should be projective over $\mathcal{O}[[K_p]]$; indeed, this would be incompatible with Conjecture 3.2. Rather, we expect that it should be pure of codimension l_0, in the sense of [55, Def. 3.1].

3.1.3. The relationship with p-adic Hodge theory. Let us continue to suppose that $l_0 = 0$ and that $\mathfrak{m}$ is a non-Eisenstein maximal ideal in $\mathbb{T}_\Sigma$, and let us suppose that Conjecture 3.3 holds. As we have observed, this implies that for any (sufficiently small) compact open subgroup K_p of G, and any representation W of K_p on a finitely generated torsion free $\mathcal{O}$-module, we have

$$H^i\big(Y(K_pK_f^p), \mathcal{W}\big)_{\mathfrak{m}} \cong \mathrm{Hom}_{\mathcal{O}[[K_p]]}(W^\vee, \widetilde{H}^{q_0}_{\mathfrak{m}}) \cong \mathrm{Hom}_{\mathcal{O}[[K_p]]}\big((\widetilde{H}_{q_0})_{\mathfrak{m}}, W\big)$$

(the first isomorphism being given by the Hochschild–Serre spectral sequence, and the second by duality).

We now suppose that W is an $\mathcal{O}$-lattice in an irreducible algebraic representation V of $\mathbb{G}$ over L. Since $H^i\big(Y(K_pK_f^p), \mathcal{W}\big)_{\mathfrak{m}}$ is ϖ-torsion free, it is a lattice in $H^i\big(Y(K_pK_f^p), \mathcal{V}\big)_{\mathfrak{m}}$. Considering the description of this cohomology in terms of automorphic forms (as in (2.1.6)) and the conjectures regarding Galois representations associated to automorphic forms [21, Conj. 5.3.4], we infer that the Galois representations associated to the systems of Hecke eigenvalues appearing in $H^i\big(Y(K_pK_f^p), \mathcal{V}\big)_{\mathfrak{m}}$ should be potentially semistable locally at p, with Hodge–Tate weights related to the highest weight of the algebraic representation V.

Since $\mathfrak{m}$ is non-Eisenstein, it should make sense to speak of the formal deformation ring $R_{\overline{\rho}_{\mathfrak{m}}}$ of $\overline{\rho}_{\mathfrak{m}}$, and we conjecture that there is a natural isomorphism $\mathbb{T}_{\mathfrak{m}} \cong R_{\overline{\rho}_{\mathfrak{m}}}$. We see that the $\mathbb{T}_{\mathfrak{m}}$-modules $H^i\big(Y(K_pK_f^p), \mathcal{W}\big)_{\mathfrak{m}}$ (where W ranges over the various lattices in the various algebraic representations V) should then be supported on the set of points of $\mathrm{Spec}\, R_{\overline{\rho}_{\mathfrak{m}}}$ corresponding to deformations of $\overline{\rho}_{\mathfrak{m}}$ that are potentially semistable at p.

The Fontaine–Mazur conjecture [38], when combined with Langlands reciprocity, should give a precise description of the support of $H^i\big(Y(K_pK_f^p), \mathcal{W}\big)_{\mathfrak{m}}$, in purely Galois-theoretic terms. Namely, any potentially semistable deformation of $\overline{\rho}_{\mathfrak{m}}$ of the appropriate Hodge–Tate weights should be motivic, and hence should be associated to an automorphic form on the quasi-split inner form of $\mathbb{G}$. Whether this automorphic form can then be transferred to $\mathbb{G}$, and can contribute to cohomology at level $K_pK_f^p$, should be answered by an analysis of the local Langlands correspondence for $\mathbb{G}$.

Conversely, if we can prove directly that the support of $H^i\big(Y(K_pK_f^p), \mathcal{W}\big)_{\mathfrak{m}}$ is as predicted by the Fontaine–Mazur–Langlands conjecture, then we can deduce this conjecture

for deformations of $\overline{\rho}_{\mathfrak{m}}$ that are classified by $\operatorname{Spec}\mathbb{T}_{\mathfrak{m}}$. We recall in (3.2.2) below how this strategy is compatible with an optimistic view-point on how p-adic local Langlands might behave. We briefly recall in (3.3.1) how this strategy was employed in [32] and [46] in the case when $\mathbb{G} = \mathrm{GL}_2$.

Let us fix a sufficiently small open subgroup K_p. Since $(\widetilde{H}_{q_0})_{\mathfrak{m}}$ is projective over $\mathcal{O}[[K_p]]$ by assumption, it is a direct summand of a finitely generated free $\mathcal{O}[[K_p]]$-module, and hence $\widetilde{H}^{q_0}_{\mathfrak{m}}$ is a direct summand of $\mathcal{C}(K_p,\mathcal{O})^{\oplus n}$, for some $n > 0$. Thus $L \otimes_{\mathcal{O}} \widetilde{H}^{q_0}_{\mathfrak{m}}$ is a direct summand of $\mathcal{C}(K_p, L)^{\oplus n}$, the space of continuous L-valued functions on K_p. Now the theory of Mahler expansions shows that the affine ring $L[\mathbb{G}]$ embeds with dense image in $\mathcal{C}(K_p, L)$ [51, Lemma A.1]. Recall that, as a $\mathbb{G}$-representation, we have $L[\mathbb{G}] \cong \bigoplus_V V \otimes_L \operatorname{Hom}_{\mathbb{G}}(V, L[\mathbb{G}])$, where V runs over (a set of isomorphism class representatives of) all irreducible representations of $\mathbb{G}$. (At this point, we assume for simplicity that L is chosen so that all the irreducible representations of $\mathbb{G}$ over $\overline{\mathbb{Q}}_p$ are in fact defined over L; thus these irreducible V are in fact absolutely irreducible.) Now the inclusion of $L[\mathbb{G}]$ into $\mathcal{C}(K_p, L)$ induces an isomorphism $\operatorname{Hom}_{\mathbb{G}}(V, L[\mathbb{G}]) \cong \operatorname{Hom}_{K_p}\big(V, \mathcal{C}(K_p, L)\big)$ (both are naturally identified with $V^\vee$, the contragredient of V). We conclude that the natural morphism $\bigoplus_V V \otimes_L \operatorname{Hom}_{K_p}\big(V, \mathcal{C}(K_p, L)\big) \to \mathcal{C}(K_p, L)$ is injective with dense image. This property is clearly preserved under passing to direct sums and direct summands, and hence the natural morphism $\bigoplus_V V \otimes_L \operatorname{Hom}_{K_p}(V, \widetilde{H}^{q_0}_{\mathfrak{m}} \otimes_{\mathcal{O}} L) \to \widetilde{H}^{q_0}_{\mathfrak{m}} \otimes_{\mathcal{O}} L$ is also injective with dense image. Replacing V by $V^\vee$ (which clearly changes nothing, since we are summing over all irreducible algebraic representations of $\mathbb{G}$), and recalling that (by Hochschild–Serre) $\operatorname{Hom}_{K_p}(V^\vee, \widetilde{H}^{q_0}_{\mathfrak{m}} \otimes_{\mathcal{O}} L) \cong H^{q_0}\big(Y(K_pK_f^p), \mathcal{V}\big)_{\mathfrak{m}}$, we find that $\mathbb{T}_{\mathfrak{m}}$ acts faithfully on $\bigoplus_V H^{q_0}\big(Y(K_pK_f^p), \mathcal{V}\big)_{\mathfrak{m}}$ (since, as we noted above, it follows from Conjecture 3.3 that $\mathbb{T}_{\mathfrak{m}}$ acts faithfully on $\widetilde{H}^{q_0}_{\mathfrak{m}}$).

Assuming that we can identify $\mathbb{T}_{\mathfrak{m}}$ with a deformation space of Galois representations, and that we know that $H^{q_0}\big(Y(K_pK_f^p), \mathcal{V}\big)_{\mathfrak{m}}$ is indeed supported on an appropriate locus of potentially semistable deformations, the preceding analysis shows that these loci (as V varies) are Zariski dense in $\operatorname{Spec}\mathbb{T}_{\mathfrak{m}}$.

In forthcoming work [37], the author and V. Paškūnas will apply a more sophisticated version of this argument to deduce additional Zariski density statements for various collections of potentially semistable loci in global Galois deformation spaces.

Note that these density results rely crucially on the projectivity statement of Conjecture 3.3 for their proof. As we already noted, we can't expect such a statement to be true when $l_0 > 0$, and (at least if $\mathbb{G}$ is semisimple, or, more generally, if the semisimple part of $\mathbb{G}$ satisfies $l_0 > 0$) we don't expect the potentially semistable points to be Zariski dense in global deformation spaces in this case. (See [26] for an elaboration on this point.) In particular, in such contexts, we don't expect that $\widehat{H}^{q_0}$ will equal $\widetilde{H}^{q_0}$, and so $\widetilde{H}^{q_0}$, and $\operatorname{Spec}\mathbb{T}_{\Sigma}$, should receive a non-trivial contribution from torsion classes (via the term $T_pH^{q_0+1}$ in the exact sequence (2.6)).

3.2. p-adic local Langlands. Until now, our discussion has been entirely global in nature. We now turn to describing how these global considerations might be related to a possible p-adic local Langlands correspondence.

3.2.1. The basic idea. Let us return for a moment to the direct sum decomposition (2.10). Local-global compatibility for classical Langlands reciprocity says that if $\pi_\infty \otimes \pi_p$ is a direct summand of $\mathcal{A}_{\mathrm{cusp}}(K_f^p)_{\chi^{-1}}$ which contributes to cohomology, lying in a Hecke eigenspace

that corresponds to some p-adic Galois representation ρ, then the local factor π_p and the Weil–Deligne representation attached to ρ (which should be defined, since ρ should be potentially semistable at p) should correspond via the local Langlands correspondence (or perhaps more generally via the local form of Arthur's conjectures [1], if π_∞ and π_p are not tempered). In particular, the local factor at p and the local Galois representation at p should be related in a purely local manner.

The basic idea of a p-adic local Langlands correspondence is that the same should be true when we take into account the structure of completed cohomology. To explain this, we continue the discussion of the preceding paragraph, and, in addition, we place ourselves in the context introduced in (3.1.3) (in particular, we continue to assume that the hypotheses and conclusions of Conjecture 3.3 hold). Thus, we assume that ρ is a deformation of $\overline{\rho}_{\mathfrak{m}}$, and that π_∞ and π_p are tempered, so that we have an embedding $\pi_p \hookrightarrow H^{q_0}(\mathcal{V})_{\mathfrak{m}} \cong \varinjlim_{K_p} \mathrm{Hom}_{K_p}(V^\vee, L \otimes_{\mathcal{O}} \widetilde{H}^{q_0}_{\mathfrak{m}})$. We may rewrite this as an embedding $V^\vee \otimes_L \pi_p \hookrightarrow L \otimes_{\mathcal{O}} \widetilde{H}^{q_0}_{\mathfrak{m}}$ and we can then take the closure of $V^\vee \otimes \pi_p$ in $H^{q_0}(\mathcal{V})_{\mathfrak{m}}$, to obtain a unitary Banach space representation $\widehat{V^\vee \otimes_L \pi_p}$ of G over L. A slightly more refined procedure is to form the intersection $(V^\vee \otimes_L \pi_p)^\circ := (V^\vee \otimes_L \pi_p) \cap \widetilde{H}^{q_0}_{\mathfrak{m}}$ (the intersection being taken in $L \otimes_{\mathcal{O}} \widetilde{H}^{q_0}_{\mathfrak{m}}$). This is a G-invariant $\mathcal{O}$-lattice contained in $V^\vee \otimes_L \pi_p$, and the Banach space $\widehat{V^\vee \otimes_L \pi_p}$ is then obtained by completing $V^\vee \otimes_L \pi_p$ with respect to this lattice. A natural question to ask, then, in the spirit of a local Langlands correspondence and local-global compatibility, is whether $\widehat{V^\vee \otimes_L \pi_p}$ depends only on the restriction to p of the associated Galois representation ρ. Since by assumption $\mathfrak{m}$ is non-Eisenstein, the Galois representation ρ should admit an essentially unique integral model ρ°, and we could further ask whether $(V^\vee \otimes_L \pi_p)^\circ$ depends only on the restriction to p of ρ°. This question goes back to C. Breuil's first work on the p-adic Langlands correspondence in the case when $\mathbb{G} = \mathrm{GL}_2$ (see especially the introduction of [13]). It has been largely resolved in that case, but remains open in general.

3.2.2. An optimistic scenario. The most optimistic conjecture that one might entertain regarding a p-adic local Langlands correspondence is that for any formal deformation ring $R_{\overline{r}}$ parameterizing the deformations of a representation $\overline{r}$ of the *local* Galois group $G_{\mathbb{Q}_p}$ into the $\overline{\mathbb{F}}$-valued points of the C-group of G, there is a profinite $R_{\overline{r}}$-module M, finitely generated over $R_{\overline{r}}[[K_p]]$ for some (and hence every) compact open subgroup $K_p \subset G$, equipped with a continuous G-action extending its K_p-module structure, which realizes the p-adic local Langlands correspondence for the group $\mathbb{G}$ in the following sense: in the context of (3.2.1) (and continuing with the notation of that discussion), the fibre over the restriction to p of ρ° (which is a point in $\mathrm{Spec}\, R_{\overline{r}}$, if $\overline{r}$ is the restriction of $\overline{\rho}_{\mathfrak{m}}$ to $G_{\mathbb{Q}_p}$) is isomorphic to the $\mathcal{O}$-dual of $(V^\vee \otimes_L \pi_p)^\circ$. (Here we suppress the issue of whether $R_{\overline{r}}$ should be understood to be a framed deformation ring, or a pseudo-deformation ring, or ....) In short, M should be a local analogue of the completed homology space $(\widetilde{H}_{q_0})_{\mathfrak{m}}$.

Since M is finitely generated over $R_{\overline{r}}[[K_p]]$, for any representation W of K_p on a finitely generated torsion free $\mathcal{O}$-module, the $R_{\overline{r}}$-module $\mathrm{Hom}^{\mathrm{cont}}_{K_p}(M, W)^d$ (where d denotes the continuous $\mathcal{O}$-dual) is a finitely generated $R_{\overline{r}}$-module. Another property one might require of M is that when W is a K_p-invariant $\mathcal{O}$-lattice in an irreducible algebraic $\mathbb{G}$-representation V, then $\mathrm{Hom}^{\mathrm{cont}}_{K_p}(M, W)^d$ is supported on an appropriate locus of potentially semistable

representations, corresponding to the fact that $\mathrm{Hom}_{\mathcal{O}[[K_p]]}\big((\widetilde{H}_{q_0})_{\mathfrak{m}}, W\big)$ (which is isomorphic to $H^{q_0}\big(Y(K_pK_f^p), \mathcal{W}\big)$) is supported on a locus of potentially semistable representations in $\mathrm{Spec}\,\mathbb{T}_{\mathfrak{m}}$.

Ideally, one might ask for the support of $\mathrm{Hom}_{K_p}^{\mathrm{cont}}(M, W)^d$ to be the full potentially semistable locus of appropriate Hodge–Tate weights (corresponding to the highest weight of V) and Weil–Deligne representations (corresponding to the particular choice of K_p and the nature of the local Langlands correspondence for $\mathbb{G}$). As we indicated in (3.1.3), such a result, combined with the local-global compatibility between M and $(\widetilde{H}_{q_0})_{\mathfrak{m}}$, would prove that any global Galois representation corresponding to a point of $\mathrm{Spec}\,\mathbb{T}_{\mathfrak{m}}$ which is potentially semistable of appropriate Hodge–Tate weights and with an appropriate Weil–Deligne representation, in fact arises from a system of Hecke eigenvalues occurring in $\widetilde{H}^{q_0}\big(Y(K_pK_f^p), \mathcal{V}\big)_{\mathfrak{m}}$, thus verifying the Fontaine–Mazur–Langlands conjecture for such points.

Note that a local Galois representation lies in the support of $\mathrm{Hom}_{K_p}^{\mathrm{cont}}(M, W)^d$ precisely if the dual to the fibre of M at this point receives a non-zero K_p-equivariant homomorphism from W. In particular, the dual to the fibre at such a point contains locally algebraic vectors. In the case of GL_2, the idea of describing p-adic local Langlands for potentially semistable representations in terms of locally algebraic vectors goes back to C. Breuil's first work on the subject [11, 12].

The optimistic scenario described here has been realized for the group $G = \mathrm{GL}_2(\mathbb{Q}_p)$; this is the theory of p-adic local Langlands for $\mathrm{GL}_2(\mathbb{Q}_p)$ [6, 29, 30, 50] (see also [5, 14]). Whether it can be realized for other groups, or is overly optimistic, remains to be seen.

3.3. Examples. We again illustrate our discussion with some examples.

3.3.1. $\mathbf{GL_2}$ of $\mathbb{Q}$. As already mentioned, the theory of p-adic local Langlands for $\mathrm{GL}_2(\mathbb{Q}_p)$ provides a structure satisfying all the desiderata of (3.2.2). The local-global compatibility between this structure and $\widetilde{H}^1_{\mathfrak{m}}$ (the localization of completed cohomology at a non-Eisenstein maximal ideal of the Hecke algebra) has been proved in [32] (see also [14, 15]), under a mild hypothesis on the local behaviour of $\overline{\rho}_{\mathfrak{m}}$. In particular, the strategy of (3.1.3) then applies to prove the Fontaine–Mazur–Langlands conjecture for points of $\mathrm{Spec}\,\mathbb{T}_{\mathfrak{m}}$.

Under the slightly stronger hypotheses that p is odd and $\overline{\rho}_{\mathfrak{m}}$ remains irreducible on restriction to $G_{\mathbb{Q}(\zeta_p)}$ (the *Taylor–Wiles condition*) one can prove that $\mathbb{T}_{\mathfrak{m}} \cong R_{\overline{\rho}_{\mathfrak{m}}}$ [8], [32, Thm. 1.2.3]. Since Conjecture 3.3 holds in this context [32, Cor. 5.3.19], the method of (3.1.3) (applied with $K_p = \mathrm{GL}_2(\mathbb{Z}_p)$) allows us to deduce the density of the crystalline loci in $\mathrm{Spec}\,R_{\overline{\rho}_{\mathfrak{m}}}$; the extension of this method to be described in [37] will allow us to deduce other density results about various potentially semistable loci. Here is one such simple variant: instead of considering the restriction to $\mathrm{GL}_2(\mathbb{Z}_p)$ of the family V of algebraic representations of GL_2, we instead consider the family of representations $\sigma \otimes V$, where σ is some fixed supercuspidal type and V is algebraic. This allows us to show that potentially crystalline points of (any fixed) supercuspidal type are Zariski dense in $\mathbb{T}_{\mathfrak{m}}$ (and hence in $R_{\overline{\rho}_{\mathfrak{m}}}$, if the Taylor–Wiles condition is satisfied).

3.3.2. A definite quaternion algebra ramified at p. Let D be the quaternion algebra over $\mathbb{Q}$ that is ramified at ∞ and p, and let $\mathbb{G} = D^\times$. Then G_∞/A_∞ is compact, and so, as noted above, Conjecture 3.3 holds. The classical Jacquet–Langlands correspondence allows us to attach odd two-dimensional Galois representations to systems of Hecke eigenvalues. In particular, if $\mathfrak{m}$ is non-Eisenstein, then $\mathbb{T}_{\mathfrak{m}}$ is a quotient of $R_{\overline{\rho}_{\mathfrak{m}}}$.

Assuming that p is odd and $\overline{\rho}_{\mathfrak{m}}$ satisfies the Taylor–Wiles condition, we conclude that in fact $\mathbb{T}_{\mathfrak{m}} \cong R_{\overline{\rho}_{\mathfrak{m}}}$. Indeed, we saw in the preceding example that the potentially crystalline points of supercuspidal type are Zariski dense in $R_{\overline{\rho}_{\mathfrak{m}}}$. Since Fontaine–Mazur–Langlands holds in this context, they all arise from classical modular forms, and hence (by Jacquet–Langlands) from classical automorphic forms on $D^\times$. Thus $\operatorname{Spec} \mathbb{T}_{\mathfrak{m}}$ contains a Zariski dense set of points in $\operatorname{Spec} R_{\overline{\rho}_{\mathfrak{m}}}$, and so the two Specs coincide. As one interesting consequence of this, we note that (assuming that the Taylor–Wiles condition holds) the Hecke algebras at $\mathfrak{m}$ for GL_2 and $D^\times$ are naturally isomorphic (both being isomorphic to $R_{\overline{\rho}_{\mathfrak{m}}}$). One can think of this as a p-adic interpolation of the classical Jacquet–Langlands correspondence. It is interesting to note that even though under the classical Jacquet–Langlands correspondence automorphic forms on GL_2 that are principal series at p don't match with a corresponding Hecke eigenform on $D^\times$, they are not excluded from this p-adic Jacquet–Langlands correspondence.

As another consequence, note that if we choose K_p to be the units in the maximal order of $(D \otimes \mathbb{Q}_p)^\times$, and apply the density argument of (3.1.3), we deduce that the representations which are *genuinely semistable* at p (i.e. semistable, and not crystalline) are Zariski dense in $\operatorname{Spec} \mathbb{T}_{\mathfrak{m}}$, and hence in $\operatorname{Spec} R_{\overline{\rho}_{\mathfrak{m}}}$, provided the Taylor–Wiles condition holds.

3.3.3. Definite quaternion algebras over totally real fields. Consider the case where G is the restriction of scalars to $\mathbb{Q}$ of the units $D^\times$ in a totally definite quaternion algebra D over a totally real field F; and suppose that F is unramified at p, and D is split at every prime in F above p. Put ourselves in the situation of (3.2.1), with the additional assumption that V is the trivial representation, and π_p is a tamely ramified principal series. In this case π_p contains, as a $\mathrm{GL}_2(\mathbb{Z}_p \otimes_{\mathbb{Z}} \mathcal{O}_F)$-subrepresentation, a principal series type σ, which is a representation of $\mathrm{GL}_2(\mathcal{O}_F/p)$ induced from a character of the Borel subgroup. In the paper [16], Breuil gave a conjectural description of the isomorphism class of the lattice $\sigma^\circ := \sigma \cap \widetilde{H}^0_{\mathfrak{m}}$, purely in terms of the restriction to p of ρ°. Under mild assumptions on $\overline{\rho}_{\mathfrak{m}}$, this was proved in [35]. This gives some evidence towards the possibility that $(V^\vee \otimes_L \pi_p)^\circ$ may be of a purely local nature.

3.3.4. Compact unitary groups. In [27], we apply Taylor–Wiles patching to pass from completed cohomology over a unitary group that is compact at infinity to a G-representation on a module M_∞ over the ring R_∞ obtained by adjoining a certain number of formal variables to a local deformation ring. More precisely: for any finite extension K of $\mathbb{Q}_p$, any n such that $p \nmid 2n$, and any representation $\overline{r} : G_K \to \mathrm{GL}_n(\overline{\mathbb{F}}_p)$ that admits a potentially crystalline lift which is *potentially diagonalizable* (in the sense of [4]), we can (by [33, Cor. A.7]) choose a unitary group $\mathbb{G}$ and Hecke maximal ideal $\mathfrak{m}$ so that $G := \mathbb{G}(\mathbb{Q}_p)$ is isomorphic to a product of copies of $\mathrm{GL}_n(K)$, and such that the restriction of $\overline{\rho}_{\mathfrak{m}}$ to G_K is equal to $\overline{r}$. The G-representation M_∞, which is a module over $R_{\overline{r}}[[x_1, \dots, x_n]]$ for some some $n \geq 0$, is then obtained by patching the completed cohomology for $\mathbb{G}$.

The module M_∞ satisfies several of the desiderata of (3.2.2): it is finitely generated over $R_\infty[[K_p]]$, and the modules $\operatorname{Hom}^{\mathrm{cont}}_{K_p}(M, W)^d$ (for K_p-invariant lattices W in algebraic representations) are supported on a union of components of the appropriate potentially semistable loci. Many questions about M_∞ remain open, however: whether the support of M_∞ equals the entirety of $\operatorname{Spec} R_\infty$; whether all potentially semistable points are contained in the support of $\operatorname{Hom}^{\mathrm{cont}}_{K_p}(M, W)^d$ (for an appropriate choice of W and K_p); and whether M_∞ is in fact of a purely local nature.

One further property of M_∞ is that it is projective in the category of profinite topo-

logical $\mathcal{O}[[K_p]]$-modules. In [37], we hope to show that M_∞ is in fact of full support on $\operatorname{Spec} R_{\overline{r}}[[x_1, \dots, x_n]]$ in many cases, and thus extend the method described in (3.1.3) to deduce density results for potentially semistable representations in local deformation spaces.

Acknowledgements. The author's work is partially supported by NSF grant DMS-1303450. The ideas expressed here owe much to the many discussions with my colleagues and collaborators that I've enjoyed over the years, and I would like to thank them, especially Ana Caraiani, Pierre Colmez, David Geraghty, Michael Harris, David Helm, Florian Herzig, Mark Kisin, David Savitt, and Sug Woo Shin. I am particularly indebted to Christophe Breuil, whose ideas regarding the p-adic Langlands program have been so influential and inspiring. Special thanks are owed to Frank Calegari, Toby Gee, and Vytas Paškūnas; many of the ideas described here were worked out in collaboration with them.

I am also grateful to Frank Calegari, Tianqi Fan, Toby Gee, Michael Harris, Florian Herzig, Daniel Le, David Savitt, and the Imperial College Study Group (Rebecca Bellovin, Kevin Buzzard, Toby Gee, David Helm, Judith Ludwig, James Newton, and Jack Shotton) for their careful reading of various preliminary versions of this note.

Theta correspondence: recent progress and applications

Wee Teck Gan

Abstract. We describe some recent progress in the theory of theta correspondence over both local and global fields. We also discuss applications of these recent developments to the local Langlands conjecture, the Gross-Prasad conjecture and the theory of automorphic forms for the metaplectic groups.

Mathematics Subject Classification (2010). Primary 11F67; Secondary 22E50.

Keywords. Theta correspondence, Siegel-Weil formula, local Langlands conjecture, Gross-Prasad conjecture, Shimura-Waldspurger correspondence.

1. History

In this paper, we shall report on some recent progress in the theory of theta correspondence, as well as some applications to number theory and representation theory. The use of theta correspondence has a long history, but its status as a theory was formally initiated by R. Howe in the influential paper [28] written in the 1970's but only published much later. This built upon the work of A. Weil [91] in the 1960's which provided a representation theoretic treatment of theta functions via his construction of the so-called Weil representations. In this introduction, we give a brief account of the historical development since the late 1970's; we apologise for omitting the contributions of many people.

As a theory, theta correspondence has its own share of internal problems which needed to be addressed, but from the onset, it was perceived mainly as a tool for constructing representations and automorphic forms. In particular, it gives natural constructions of certain instances of Langlands functorial lifting. In this vein, one of the first successes is Waldspurger's complete and elegant description [84, 85] of the Shimura correspondence between cuspidal representations of PGL_2 and the metaplectic double cover Mp_2. Another is Howe and Piatetski Shapiro's construction [29] of nontempered cuspidal representations on U_3 and Sp_4, contradicting the naive Ramanujan-Petersson conjecture. Such construction of nontempered cuspidal representations was later extended by J.S. Li [49–51] and C. Moeglin [61] to the general setting, resulting in the construction of many interesting examples of unitary representations and square-integrable automorphic forms.

The 1980's saw many key developments in the theory of theta correspondence. Firstly, motivated by Waldspurger's work, Rallis initiated a program [76–78] aimed at determining the cuspidality and nonvanishing of global theta liftings. This led to two important series of work. One is the work of Piatetski-Shapiro and Rallis [73] on the doubling zeta integral,

Proceedings of the International Congress of Mathematicians, Seoul, 2014

which is a Rankin-Selberg integral representing the standard L-function of classical groups. Another is the work of Kudla and Rallis [41, 42] on the Siegel-Weil formula, culminating in their paper [43]. Combining these two series of work resulted in the Rallis inner product formula in some instances. This characterises the nonvanishing of global theta liftings in terms of the analytic properties of the standard L-functions. In the course of their work, Kudla and Rallis were led to a local conjecture [44] about the nonvanishing of the local theta correspondence. They made significant progress towards this so-called conservation relation conjecture, proving it in many cases.

Secondly, starting with Kudla's paper [38], the local theta correspondence over p-adic fields was systematically investigated, culminating in Waldspurger's proof of the so-called Howe duality conjecture when $p \neq 2$ [86]. This Howe duality conjecture was shown by Howe himself [28] in the archimedean case, and for unramified groups in the nonarchimedean case [63]. Following this, significant understanding of the archimedean theta correspondence was obtained in the work of Adams-Barbasch [2–4] and Moeglin [60]. In particular, Adams-Barbasch determined the local theta correspondence over $\mathbb{C}$ completely [3], and also extended the local Shimura-Waldspurger correspondence from $\mathrm{Mp}_2(\mathbb{R})$ to $\mathrm{Mp}_{2n}(\mathbb{R})$ for general n [4]. In the p-adic case, the analogous results were conjectured but left open. In particular, Adams [1] formulated a conjecture on the functoriality of the theta correspondence in the language of A-packets, and D. Prasad [74, 75] formulated some precise conjectures describing the local theta correspondence in the (almost) equal rank case in terms of the local Langlands correspondence.

Since the mid-1990's, significant work continued to be done in classical theta correspondence, such as by Roberts [79], Moeglin [62], Muić [66–69], Muić-Savin [70], S.Y. Pan [71] and Ginzburg-Jiang-Soudry [21]. However, as many of the early pioneers turned their attention to other worthy endeavours, the field became relatively quiet compared with the flurry of activities in the 80's and early 90's and many of the problems highlighted some twenty years ago lie dormant and unresolved.

It was not until about 6 or 7 years ago that a new generation of researchers revisited these problems and it is a pleasure and privilege to report on the recent resolution of many of these problems here. This brings a certain degree of closure to the developments from 30 years ago, but we shall also highlight some exciting future directions.

2. Theta correspondence

In this section, we describe the basic setup and questions in the theory of theta correspondence.

2.1. Dual pairs. For simplicity, let F be a field of characteristic 0, and let $E = F$ or an étale quadratic F-algebra, with $\mathrm{Aut}(E/F) = \langle c \rangle$. With $\epsilon = \pm$, let V be a finite-dimensional ϵ-Hermitian space over E and W an $-\epsilon$-Hermitian space. Then $V \otimes_E W$ inherits a natural symplectic form over F and one has a natural map of isometry groups

$$\mathrm{U}(V) \times \mathrm{U}(W) \longrightarrow \mathrm{Sp}(V \otimes_E W).$$

The images of $\mathrm{U}(V)$ and $\mathrm{U}(W)$ are mutual commutants of each other, and such a pair of groups is called a *reductive dual pair*.

For ease of exposition, we shall henceforth focus on the case when E/F is a quadratic

field extension, V is Hermitian and W is skew-Hermitian, so that $\mathrm{U}(V)$ and $\mathrm{U}(W)$ are unitary groups.

2.2. Invariants of spaces. The spaces V and W have a natural invariant known as the discriminant:

$$\mathrm{disc}V \in F^\times/\mathrm{N}_{E/F}(E^\times) \quad \text{and} \quad \mathrm{discW} \in \delta^{\dim W} \cdot F^\times/\mathrm{N}_{E/F}(E^\times)$$

where δ is a fixed trace zero element in $E^\times$. When F is a local field, it is convenient to encode the discriminant in a sign $\pm$:

$$\epsilon(V) = \omega_{E/F}(\mathrm{disc}V) \quad \text{and} \quad \epsilon(W) = \omega_{E/F}(\delta^{-\dim W} \cdot \mathrm{disc}W)$$

where $\omega_{E/F}$ is the nontrivial quadratic character of $F^\times/N_{E/F}(E^\times)$. Note that $\epsilon(W)$ depends on the choice of δ. Moreover, if F is nonarchimedean, Hermitian spaces are classified by $\dim(V)$ and $\epsilon(V)$; likewise for skew-Hermitian spaces.

2.3. Weil representation. Assume that F is a local field. The symplectic group $\mathrm{Sp}(V \otimes_E W)$ has a nonlinear S^1-cover $\mathrm{Mp}(V \otimes_E W)$ known as the metaplectic group. This metaplectic group has a distinguished representation ω_ψ depending on a nontrivial additive character ψ of F. If the embedding i can be lifted to a homomorphism

$$\tilde{i} : \mathrm{U}(V) \times \mathrm{U}(W) \longrightarrow \mathrm{Mp}(V \otimes_E W),$$

then we obtain a representation $\omega_\psi \circ \tilde{i}$ of $\mathrm{U}(V) \times \mathrm{U}(W)$.

For the case of unitary groups considered here, a splitting can be specified [39] by picking two characters χ_V and χ_W of $E^\times$ such that

$$\chi_V|_{F^\times} = \omega_{E/F}^{\dim V} \quad \text{and} \quad \chi_W|_{F^\times} = \omega_{E/F}^{\dim W}.$$

Thus, $\mathrm{U}(V) \times \mathrm{U}(W)$ has a Weil representation $\omega_{V,W,\psi}$ that depends on ψ and the splitting data (χ_V, χ_W), which we shall suppress from the notation.

2.4. Local theta correspondonce. We will write $\mathrm{Irr}(\mathrm{U}(W))$ for the set of equivalence classes of irreducible smooth representations of $\mathrm{U}(W)$. For $\pi \in \mathrm{Irr}(\mathrm{U}(W))$, one considers the maximal π-isotypic quotient of $\omega_{V,W,\psi}$:

$$\omega_{V,W,\psi} \twoheadrightarrow \pi \boxtimes \Theta(\pi)$$

where $\Theta(\pi)$ is some smooth representation of $\mathrm{U}(V)$. We shall denote by $\theta(\pi)$ the maximal semisimple quotient of $\Theta(\pi)$. The goal of local theta correspondence is to determine the representations $\Theta(\pi)$ and $\theta(\pi)$ as much as possible. For example, the *Howe duality conjecture* states that if $\Theta(\pi)$ is nonzero, then it has a unique irreducible quotient, i.e. $\theta(\pi)$ is irreducible.

Note that the case when $E = F \times F$ is also necessary for global applications. In this case, the dual pair is $\mathrm{GL}_m \times \mathrm{GL}_n$. The study of this local theta correspondence is essentially completed in the paper [58] of A. Minguez. For example, the Howe duality conjecture was completely resolved. Hence we shall say no more about this case in this paper.

2.5. Theta functions. We turn now to the global setting. Thus, let k be a global field with ring of adeles $\mathbb{A}$, and let K/k be a quadratic field extension. Let V and W be a Hermitian and skew-Hermitian space over K, and fix a pair of Hecke characters χ_V and χ_W of

$\mathbb{A}_K^\times$ as before. For a nontrivial additive character $\psi = \otimes_v \psi_v$ of $k\backslash\mathbb{A}$, the adelic group $\mathrm{U}(V_\mathbb{A}) \times \mathrm{U}(W_\mathbb{A})$ possesses an abstract Weil representation $\omega_{V,W,\psi} = \otimes_v \omega_{V,W,\psi_v}$. It was shown by Weil that there is a natural equivariant map

$$\theta : \omega_{V,W,\psi} \longrightarrow \mathcal{A}(\mathrm{U}(V) \times \mathrm{U}(W)),$$

where the latter space denotes the space of automorphic forms on the dual pair. This map, called the "formation of theta functions", gives an automorphic realisation of $\omega_{V,W,\psi}$.

2.6. Global theta correspondence. One may use the functions $\theta(\phi)$ for $\phi \in \omega_{V,W,\psi}$ as kernel functions for the transfer of automorphic forms from $\mathrm{U}(W_\mathbb{A})$ to $\mathrm{U}(V_\mathbb{A})$. More precisely, if $f \in \mathcal{A}(\mathrm{U}(W))$, we set

$$\theta(\phi, f)(g) = \int_{\mathrm{U}(W_k)\backslash\mathrm{U}(W_\mathbb{A})} \theta(\phi)(gh) \cdot \overline{f(h)}\, dh,$$

where dh stands for the Tamagawa measure. This integral converges if f is a cusp form. Thus, if $\pi \subset \mathcal{A}(\mathrm{U}(W))$ is a cuspidal representation, then we obtain an equivariant map

$$\theta : \omega_{V,W,\psi} \otimes \overline{\pi} \longrightarrow \mathcal{A}(\mathrm{U}(V)).$$

The image of this map is denoted by $\Theta(\pi)$ and is called the global theta lift of π. Observe that one has, by definition, an equivariant map

$$\omega_{V,W,\psi} \twoheadrightarrow \pi \boxtimes \Theta(\pi).$$

The basic questions in global theta correspondence are whether the representation $\Theta(\pi)$ is cuspidal and whether it is nonzero. Note that if $\Theta(\pi)$ is nonzero and cuspidal, then it is semisimple, in which case $\Theta(\pi)$ is a quotient of the abstract representation $\otimes_v \Theta(\pi_v)$. Thus, if the Howe duality conjecture holds, then $\Theta(\pi) \cong \otimes_v \theta(\pi_v)$. In particular, the question of "what is $\Theta(\pi)$?" is essentially a local one.

3. Local developments

In this section, we discuss some recent developments concerning the local theta correspondence over a nonarchimedean local field F of residual characteristic $p > 0$. The following theorem, known since 1990, summarizes some basic results of Howe, Kudla, Mœglin-Vignéras-Waldspurger and Waldspurger (see [28, 38, 63, 86]).

Theorem 3.1.

(i) *For any $\pi \in \mathrm{Irr}(\mathrm{U}(W))$, the representation $\Theta(\pi)$ is either zero or of finite length.*

(ii) *If π is supercuspidal, then $\Theta(\pi)$ is either zero or irreducible (and thus is equal to $\theta(\pi)$). Moreover, for any irreducible supercuspidal π and π',*

$$\Theta(\pi) \cong \Theta(\pi') \neq 0 \Longrightarrow \pi \cong \pi'.$$

(iii) *If $p \neq 2$, the Howe duality conjecture holds.*

3.1. Local problems. The main remaining problems in local theta correspondence are thus:

(a) Establish the Howe duality conjecture when the residual characteristic of F is $p = 2$.

(b) Determine when $\Theta(\pi)$ is nonzero, in terms of some basic invariants of π.

(c) When $\Theta(\pi)$ is nonzero, understand the representation $\theta(\pi)$ as much as possible, either by computing some of its invariants or determining it precisely, such as in terms of the local Langlands correspondence.

For (a), we have the following two results. The first is due to Li-Sun-Tian [52] whereas the second is a recent result of the author and S. Takeda [19].

Theorem 3.2. *The representation $\theta(\pi)$ is multiplicity-free.*

Theorem 3.3.

(i) *If π is tempered, then $\theta(\pi)$ is either zero or irreducible. Moreover, for any irreducible tempered π and π',*
$$\theta(\pi) \cong \theta(\pi') \neq 0 \Longrightarrow \pi \cong \pi'.$$

(ii) *If $|\dim V - \dim W| \leq 1$, the Howe duality conjecture holds (for any residue characteristic p).*

In the rest of the section, we shall focus on problems (b) and (c).

3.2. Witt towers and first occurrence. Rallis observed that it is fruitful to consider theta correspondence in a family. Let V_0 be an anisotropic Hermitian space over E, and for $r \geq 0$, let
$$V_r = V_0 \oplus \mathbb{H}^r$$
where $\mathbb{H}$ is the hyperbolic plane. The collection $\{V_r \mid r \geq 0\}$ is called a Witt tower of spaces. We note that any given space V is a member of a unique Witt tower of spaces $\{V_r\}$, where V_0 is the anisotropic kernel of V.

One can then consider a family of theta correspondences associated to the tower of reductive dual pairs $(\mathrm{U}(W), \mathrm{U}(V_r))$. For $\pi \in \mathrm{Irr}(\mathrm{U}(W))$, the smallest non-negative integer r_0 such that $\Theta_{V_{r_0},W}(\pi) \neq 0$ is called the *first occurrence index* of π for the Witt tower $\{V_r\}$. By [63, p. 67], such an r_0 exists and $r_0 \leq \dim W$. Moreover, $\Theta_{V_r,W}(\pi) \neq 0$ for all $r \geq r_0$. Thus one way to rephrase problem (b) is to determine the first occurrence index of π in any given Witt tower.

3.3. Conservation relation. Harris-Kudla-Sweet [27] and Kudla-Rallis [44] discovered that the first occurrence indices of π for two different Witt towers $\{V_r\}$ and $\{V'_r\}$ are not independent of each other. More precisely, one considers two Witt towers $\{V_r\}$ and $\{V'_r\}$ such that
$$\dim V_0 \equiv \dim V'_0 \mod 2 \quad \text{but} \quad \epsilon(V_0) \neq \epsilon(V'_0).$$
Hence we may consider the first occurrence indices r_0 for the tower $\{V_r\}$ and r'_0 for the tower $\{V'_r\}$. The following is a basic theorem in the subject:

Theorem 3.4. *For any $\pi \in \mathrm{Irr}(\mathrm{U}(W))$, with first occurrence indices r_0 and r'_0 in two related Witt towers, we have*
$$\dim V_{r_0} + \dim V'_{r'_0} = 2 \dim W + 2.$$

This theorem was called the conservation relation conjecture of Kudla-Rallis. Kudla-Rallis [44] and Gong-Grenie [26] showed the inequality $\geq$ in the statement of the theorem, and also established the reverse inequality $\leq$ in many cases, for example for all supercuspidal representations. A simple and completely different proof of the theorem in the supercuspidal case was also discovered by A. Minguez [59]. Finally, a recent paper of Sun-Zhu [82] established the theorem in full. A corollary is the following dichotomy statement:

Corollary 3.5. *Let V and V' be two spaces in the Witt towers $\{V_r\}$ and $\{V'_r\}$ such that*

$$\dim V + \dim V' = 2 \cdot \dim W.$$

For any $\pi \in \mathrm{Irr}(\mathrm{U}(W))$, exactly one of the theta lifts $\Theta_{V,W}(\pi)$ and $\Theta_{V',W}(\pi)$ is nonzero.

These results place some constraints on the first occurrence indices but fall short of determining these indices. To go further, we need to introduce some basic invariants of π.

3.4. Local doubling zeta integral. The proof of Theorem 3.4 uses as a key tool the local doubling zeta integral, which was discovered by Piatetski-Shapiro and Rallis [73]. Analogous to the local zeta integral in Tate's thesis, the doubling zeta integral can be used to define the standard γ-factors for a pair (π, χ), with $\pi \in \mathrm{Irr}(\mathrm{U}(W))$ and χ a character of $E^\times$. Though this family of zeta integrals was discovered in the mid-1980's, the precise treatment and definition of the local factor $\gamma(s, \pi, \chi, \psi)$ was only carried out by Lapid-Rallis [48] in 2003. From the γ-factors, one can then define the local L-factor $L(s, \pi, \chi)$ and the local ϵ-factor $\epsilon(s, \pi, \chi, \psi)$ following a standard procedure of Shahidi.

However, there is another way to define $L(s, \pi, \chi)$ and $\epsilon(s, \pi, \chi, \psi)$ from a family of zeta integrals: one could define $L(s, \pi, \chi)$ as the GCD of the family of zeta integrals as the data varies. The two ways of defining these local L-factors have complementary strengths, and one would really like them to give the same L-factors and ϵ-factors. This is finally proved in a recent paper [95] of S. Yamana, thus bringing the theory of the doubling zeta integral to a definitive conclusion.

3.5. Epsilon dichotomy. The local factors defined by the doubling zeta integral are very useful for the study of theta correspondence. As an example, in the context of Corollary 3.5, the following result [14, 27] determines exactly which of $\Theta_{V,W}(\pi)$ and $\Theta_{V',W}(\pi)$ is nonzero in the equal rank case.

Theorem 3.6. *Assume that $\dim V = \dim W$. Let $\pi \in \mathrm{Irr}(\mathrm{U}(W))$ with central character ω_π. Then $\Theta_{V,W}(\pi) \neq 0$ if and only if*

$$\epsilon(\tfrac{1}{2}, \pi, \chi_V^{-1}, \psi) = \omega_\pi(-1) \cdot \chi_V(\delta)^{\dim W} \cdot \epsilon(V) \cdot \epsilon(W).$$

3.6. Poles of local γ-factors. As another example, the location of poles of the local γ-factors provides information on the first occurrence index.

Theorem 3.7. *Suppose that V and V' are two spaces in two related Witt towers such that $\dim V = \dim V'$. Assume that $l := \dim W - \dim V > 0$. Let π be an irreducible tempered representation of $\mathrm{U}(W)$.*

(i) *If one of $\Theta_{V,W}(\pi)$ and $\Theta_{V',W}(\pi)$ is nonzero, then $\gamma(s, \pi, \chi_V^{-1}, \psi)$ has a pole at $s = \frac{l+1}{2}$.*

(ii) *Suppose that either π is supercuspidal, or $l = 1$ and π is square integrable. Then the converse of* (i) *also holds.*

Corollary 3.8. *Let π be an irreducible tempered representation of* $\mathrm{U}(W)$. *Assume that $\gamma(s, \pi, \chi_V^{-1}, \psi)$ is holomorphic in* $\mathrm{Re}(s) \geq 1/2$. *Then we have: the first occurrence indices of π in the two Witt towers are given by:*

$$\begin{cases} \dim V_{r_0} = \dim V_{r_0'} = \dim W + 1 & \text{if } \dim W \neq \dim V_0 \mod 2, \\ \{\dim V_{r_0}, \dim V_{r_0'}\} = \{\dim W, \dim W + 2\} & \text{if } \dim W = \dim V_0 \mod 2. \end{cases}$$

Moreover, if $\dim V$ *is the smaller of the two elements in the second case, then $\epsilon(V)$ is determined by Theorem 3.6.*

Thus, one has a precise determination of the first occurrence indices in the tempered case when the relevant local γ-factor is entire in $\mathrm{Re}(s) \geq 1/2$. If π is supercuspidal, we shall see in a moment that one can determine the first occurrence indices precisely in general.

3.7. Prasad's conjecture. Consider the (almost) equal rank case when $\dim V - \dim W = 0$ or 1. For $\pi \in \mathrm{Irr}(\mathrm{U}(W))$, D. Prasad [74, 75] has given precise conjectures describing $\Theta_{V,W}(\pi)$ in terms of the local Langlands correspondence (LLC). We briefly recall the statement of the LLC.

The LLC for unitary groups postulates that each $\pi \in \mathrm{Irr}(\mathrm{U}(W))$ is classified by two invariants (ϕ, η):

(a) $\phi = WD_E \longrightarrow \mathrm{GL}_n(\mathbb{C})$ (where WD_E is the Weil-Deligne group of E and $n = \dim W$) is a conjugate-dual representation of WD_E of sign $(-1)^{n-1}$ (see [13]);

(b) η is a collection of signs. Namely, if we decompose $\phi = \oplus_i m_i \phi_i$, with ϕ_i irreducible and I_ϕ denotes the set of indices such that ϕ_i is also conjugate-dual of sign $(-1)^{n-1}$, then $\eta = (\eta_i)$ is a collection of signs indexed by I_ϕ, satisfying

$$\epsilon(W) = \prod_{i \in I_\phi} \eta_i^{m_i}. \tag{3.1}$$

The LLC for quasi-split unitary groups has been proved by C. P. Mok [65], following Arthur's book [6] for the symplectic and orthogonal groups. The case of non-quasi-split unitary groups is the ongoing work of several people.

If $\pi \in \mathrm{Irr}(\mathrm{U}(W))$ has L-parameter (ϕ, η), then Prasad's conjecture determines the L-parameter $(\theta(\phi), \theta(\eta))$ of $\theta(\pi) \in \mathrm{Irr}(\mathrm{U}(V))$ when it is nonzero.

Theorem 3.9. *Suppose that* $\dim V - \dim W = 0$ *or* 1. *Let $\pi \in \mathrm{Irr}(\mathrm{U}(W))$ and consider $\theta(\pi)$ on* $\mathrm{U}(V)$. *Then we have:*

(i) *If* $\dim V = \dim W$, *then $\theta(\pi)$ is nonzero when the condition in Theorem 3.6 holds. Moreover, $\theta(\phi) = \phi \otimes \chi_V^{-1}\chi_W$, so that $I_\phi = I_{\theta(\phi)}$ and*

$$\theta(\eta)_i / \eta_i = \epsilon(1/2, \phi_i \otimes \chi_V^{-1}, \psi(2 \cdot \mathrm{Tr}_{E/F} -)).$$

(ii) *If* $\dim V = \dim W + 1$, *then set $\theta(\phi) = (\phi \otimes \chi_V^{-1}\chi_W) \oplus \chi_W$, so that $\#I_{\theta(\phi)} = \#I_\phi$ or $\#I_\phi + 1$ depending on whether ϕ contains χ_V as a summand or not.*

(a) *if ϕ does not contain χ_V, then $\theta(\pi) \neq 0$. Its L-parameter is given by the $\theta(\phi)$ defined above, and*

$$\theta(\eta)_i = \eta_i \quad \textit{for all } i \in I_\phi.$$

The extra sign in $\theta(\eta)$ is associated to χ_V and is determined by the analog of the requirement (3.1) for the space V, so that

$$\theta(\eta)_{\chi_V} = \epsilon(W) \cdot \epsilon(V).$$

(b) *if ϕ contains χ_V (so that χ_V contributes to $I(\phi)$), then $\theta(\pi)$ is nonzero if and only if $\epsilon(V) = \epsilon(W) \cdot \eta_{\chi_V}$. Its L-parameter is given by $\theta(\phi)$ defined above and*

$$\theta(\eta)_i = \eta_i \quad \textit{for all } i \in I_\phi.$$

This resolves problem (c) completely in the (almost) equal rank case, and is shown in a recent preprint [15] of the author with Ichino.

3.8. First occurrence of supercuspidals. Putting the above results together, we can now determine the first occurrence of a supercuspidal representation $\pi \in \mathrm{Irr}(\mathrm{U}(W))$ in terms of some basic invariants of π. Set

$$\kappa = \begin{cases} 0, \text{ if } \dim W \neq \dim V_0 \mod 2; \\ 1/2, \text{ if } \dim W = \dim V_0 \mod 2, \end{cases}$$

and let l_0 be defined by:

$$\frac{l_0+1}{2} := \max\left(\{\kappa\} \cup \{s_0 : \gamma(s, \pi, \chi_V^{-1}, \psi) \text{ has a pole at } s = s_0\}\right).$$

Then it is known that l_0 is an integer of the same parity as $\dim W$–$\dim V_0$ and $-1 \leq l_0 \leq \dim W$. Moreover,

$$\{\dim V_{r_0}, \dim V'_{r_0}\} = \{\dim W - l_0, \dim W + 2 + l_0\}.$$

If $l_0 = 0$ or -1, then the first occurrence indices were already given in Corollary 3.8. If $l_0 > 0$, then $\dim W + 2 + l_0 > \dim W - l_0$, and so we need to determine which of $\dim V_{r_0}$ and $\dim V_{r'_0}$ is smaller. If $\dim V$ is the smaller of the two, we shall specify V by giving the sign $\epsilon(V)$:

- If $\dim W \equiv \dim V_0 \mod 2$, then $\epsilon(V)$ is determined by Theorem 3.6.
- If $\dim W \neq \dim V_0 \mod 2$, then $\epsilon(V)$ is determined by Theorem 3.9(ii)(b).

This resolves problem (b) for supercuspidal representations. The recent work of Moeglin [62] makes significant progress towards the general case.

4. Global developments

In this section, we survey some global developments. Hence, k is a number field with ring of adeles $\mathbb{A}$. Let K/k be a quadratic field extension, and consider a dual pair $\mathrm{U}(W) \times \mathrm{U}(V)$ of unitary groups for K/k. Write $[\mathrm{U}(W)]$ to denote the space $\mathrm{U}(W_k)\backslash\mathrm{U}(W_{\mathbb{A}})$. If π is a

cuspidal representation of $\mathrm{U}(W)$, we have its global theta lift $\Theta(\pi)$ on $\mathrm{U}(V)$. As in the local case, it is useful to consider a Witt tower $\{V_r\}$ and the associated global theta lifts $\Theta_{V_r}(\pi)$. It was shown by Rallis that there exists a minimal r_0 such that $\Theta_{V_{r_0}}(\pi) \neq 0$, in which case it is a cuspidal representation. The subsequent global theta lifts (for $r > r_0$) are noncuspidal and hence nonzero.

In view of this, the main question in global theta correspondence is to determine the nonvanishing of $\Theta_{V_r}(\pi)$ in terms of basic invariants of π. We may assume that $\Theta_{V_k}(\pi) = 0$ for $k < r$, so that $\Theta_{V_r}(\pi)$ is cuspidal. Write V for V_r henceforth.

4.1. Inner product. Rallis' approach [78] to answering this question is to compute the Petersson inner product $\langle \theta(\phi, f), \theta(\phi, f) \rangle$. The Rallis inner product formula relates this inner product to the special L-values of π. The mechanism for the Rallis inner product formula relies on the following see-saw diagram of dual pairs:

$$\begin{array}{ccc} \mathrm{U}(W \oplus W^-) & & \mathrm{U}(V) \times \mathrm{U}(V) \\ \Big| & \diagup\!\diagdown & \Big| \\ i & & \\ \mathrm{U}(W) \times \mathrm{U}(W^-) & & \mathrm{U}(V)^\Delta, \end{array}$$

where W^- denotes the skew–Hermitian space obtained from W by multiplying the form by -1, so that $\mathrm{U}(W^-) = \mathrm{U}(W)$. Then one has:

$$\begin{aligned} &\langle \theta(\phi_1, f_1), \theta(\phi_2, f_2) \rangle \\ &= \int_{[\mathrm{U}(V)]} \left(\int_{[\mathrm{U}(W)]} \theta(\phi_1)(g_1, h) \cdot \overline{f_1(g_1)}\, dg_1 \right) \cdot \left(\int_{[\mathrm{U}(W)]} \overline{\theta(\phi_2)(g_2, h)} \cdot f_2(g_2)\, dg_2 \right) dh \\ &= \int_{[\mathrm{U}(W) \times \mathrm{U}(W)]} \left(\int_{[\mathrm{U}(V)]} \theta(\phi_1)(g_1, h) \cdot \overline{\theta(\phi_2)(g_2, h)}\, dh \right) \cdot \overline{f_1(g_1)} \cdot f_2(g_2)\, dg_1\, dg_2 \quad (4.1) \end{aligned}$$

where in the last equality, we have formally exchanged the integrals. This inner integral (if it converges) can be interpreted as the global theta lift of the constant function 1 of $\mathrm{U}(V)^\Delta$ to $\mathrm{U}(W \oplus W^-)$. The inner integral converges absolutely, so that the above exchange is valid, if one is in the Weil's convergent range:

$$r = 0 \quad \text{or} \quad \dim V - r > \dim W.$$

To proceed further, one would like to give a different interpretation of the inner integral. This is the content of the so-called Siegel-Weil formula: it identifies the inner integral with an Eisenstein series. Even in Weil's convergent range, this Siegel-Weil formula was achieved in a series of papers by Weil [92], Kudla-Rallis [41, 42], Ichino [34] and Yamana [93, 94], stretching over 40 years.

4.2. The regularized theta integral. Henceforth, we shall consider life outside Weil's convergent range, so that $r > 0$ and $\dim V - r \leq \dim W$, in which case we have

$$0 < \dim V \leq 2 \dim W \quad \text{and} \quad r \leq \dim W.$$

Consider the Weil representation Ω of $\mathrm{U}(W \oplus W^-) \times \mathrm{U}(V)$. We are interested in the

theta integral

$$I(\phi)(g) = \frac{1}{\tau(\mathrm{U}(V))} \cdot \int_{[\mathrm{U}(V)]} \Theta(\phi)(g,h)\, dh.$$

for $\phi \in \Omega$ and where $\tau(\mathrm{U}(V))$ denotes the Tamagawa number. The integral diverges, but under the above conditions, Kudla-Rallis [43] discovered a regularization of this theta integral.

More precisely, one can find an element z of the Bernstein center of $\mathrm{U}(V_v)$ at some place v of k such that $\Theta(z \cdot \phi)$ is rapidly decreasing as a function on $[\mathrm{U}(V)]$ and hence the integral $I(z \cdot \phi)$ converges. One considers the (spherical) Eisenstein series $E(s)$ associated to the family of degenerate principal series representations induced from the maximal parabolic subgroup of $\mathrm{U}(V)$ stabilising a maximal isotropic subspace of V. At the point $s = \rho_V = \frac{\dim V - r}{2}$,

$$\mathrm{Res}_{s=\rho_V} E(s) = \kappa$$

is a constant function. Moreover, one has $z \cdot E(s) = P_z(s) \cdot E(s)$ for some function $P_z(s)$. Now one sets

$$B(s,\phi) = \frac{1}{\kappa \cdot P_z(s) \cdot \tau(\mathrm{U}(V))} \cdot \int_{[\mathrm{U}(V)]} \Theta(z \cdot \phi)(g,h) \cdot E(s,h)\, dh.$$

This meromorphic function is the regularised theta integral and one is interested in its analytic behaviour at the point $s = \rho_V$.

The Laurent expansion of $B(s,\phi)$ at $s = \rho_V$ has the form

$$B(s,\phi) = \frac{B_{-1}(\phi)}{s - \rho_V} + B_0(\phi) + \cdots \quad \text{when } \dim V \leq \dim W;$$

and

$$B(s,\phi) = \frac{B_{-2}(\phi)}{(s-\rho_V)^2} + \frac{B_{-1}(\phi)}{s-\rho_V} + \cdots \quad \text{when } \dim W < \dim V \leq 2 \dim W.$$

We shall refer to these two cases as the *first term range* and the *second term range* respectively. Each Laurent coefficient B_i gives a linear map

$$B_i : \omega \to \mathcal{A}(\mathrm{U}(W \oplus W^-))$$

and the one which is important for the inner product formula is the residue B_{-1}.

4.3. Siegel Eisenstein series. The purpose of the Siegel-Weil formula is to identify the automorphic forms $B_{-2}(\phi)$ and $B_{-1}(\phi)$ with the analogous Laurent coefficients of a Siegel-Eisenstein series $A(s,\phi)$ associated to ϕ.

More precisely, the diagonally embedded subspace $W^\Delta \subset W \oplus W^-$ is maximal isotropic, so that its stabiliser in $\mathrm{U}(W \oplus W^-)$ is a Siegel parabolic subgroup P, which has Levi factor $\mathrm{GL}(W^\Delta)$. Let

$$I_P(s) = \mathrm{Ind}_P^{\mathrm{U}(W \oplus W^-)} \chi_V |\det|^s.$$

be the associated Siegel principal series representation. Now the Weil representation Ω can be realised on $\mathcal{S}(W^\nabla \otimes V)$ (where W^∇ is an isotropic complement to W^Δ), and the map $\phi \mapsto f_\phi$ with

$$f_\phi(g) = (\Omega(g)\phi)(0) \quad \text{for } g \in \mathrm{U}(W_{\mathbb{A}} \oplus W_{\mathbb{A}}^-)$$

defines a $\mathrm{U}(W \oplus W^-)$-equivariant and $\mathrm{U}(V)$-invariant map

$$\Omega \longrightarrow I_P(s_{V,W}) \quad \text{with } s_{V,W} := (\dim V - \dim W)/2.$$

One then sets

$$A(s, \phi) = E(s, f_\phi).$$

Observe that in the first term range, $s_{V,W} \leq 0$, whereas in the second term range, $s_{V,W} > 0$. If $s = s_{V,W} > 0$, the Laurent expansion of the Siegel-Eisenstein series $A(s, \phi)$ there has the form

$$A(s, \phi) = \frac{A_{-1}(\phi)}{s - s_{V,W}} + A_0(\phi) + \cdots$$

As for B_i, each A_i is a linear map $A_i : \Omega \to \mathcal{A}(\mathrm{U}(W \oplus W^-))$.

4.4. First term identity. Assume that we are in the first term range, so that $s_{V,W} \leq 0$. Let V' be the space in the same Witt tower as V such that

$$\dim V + \dim V' = 2 \dim W \quad (\text{so } \dim V' \geq \dim V).$$

The space V' is called the complementary space to V with respect to W and is such that $s_{V',W} \geq 0$. We shall write A'_i and B'_i for the relevant Laurent coefficients in the context of V'. Ikeda has defined in [35] a natural $\mathrm{U}(W \oplus W^-) \times \mathrm{U}(V)$-equivariant map

$$\mathrm{Ik} : \Omega' \longrightarrow \Omega,$$

where Ω' is the Weil representation for $\mathrm{U}(V') \times \mathrm{U}(W \oplus W^-)$. Then the first term identity established in [32, 33, 35, 43, 93] is the following identity:

Theorem 4.1. *Assume that we are in the first term range. Then for all $\phi \in \Omega$,*

$$c \cdot A'_{-1}(\phi') = A_0(\phi) = 2 \cdot B_{-1}(\phi),$$

where c is an explicit constant, $\phi' \in \Omega'$ is such that $\mathrm{Ik}(\pi_K \phi') = \phi$ and π_K is the projection onto the K-fixed space (with K a maximal compact subgroup of $\mathrm{U}(V'_{\mathbb{A}})$).

4.5. Second term identity. In a recent paper [16], the regularised Siegel-Weil formula is extended to the second term range. More precisely, we have:

Theorem 4.2 (Siegel-Weil formula). *Suppose that $0 < r \leq \dim W$ and $\dim W < \dim V \leq \dim W + r$, so that we are in the second term range.*

(i) *(First term identity) For all $\phi \in \Omega$, one has*

$$A_{-1}(\phi) = B_{-2}(\phi).$$

(ii) *(Second term identity) For all $\phi \in \Omega$, one has*

$$A_0(\phi) = B_{-1}(\phi) - c \cdot \{B'_0(\mathrm{Ik}(\pi_K \phi))\} \mod \mathrm{Im} A_{-1}.$$

Here, c is some explicit constant and V' is the complementary space to V with respect to W (so $\dim V' < \dim V$ here). Finally, the term $\{...\}$ on the RHS is interpreted to be 0 if V' is anisotropic.

4.6. Rallis inner product formula. The Siegel-Weil formulas above and the theory of the doubling zeta integral, as completed by Yamana [95], enable one to establish the Rallis inner product formula. For the result in the first term range, we refer the reader to Yamana [95]. In the second term range, we have [16]:

Theorem 4.3. *Suppose that*

$$\dim W < \dim V \leq 2 \dim W \quad \textit{and} \quad r \leq \dim W$$

so that we are either in the second term range or the convergent range, depending on whether $\dim V \leq \dim W + r$ *or not. Let* π *be a cuspidal representation of* $\mathrm{U}(W)$ *and consider its global theta lift* $\Theta(\pi)$ *to* $\mathrm{U}(V)$.

(i) *Assume that* $\Theta(\pi)$ *is cuspidal. Then for* $\phi_1, \phi_2 \in \omega_{\psi,V,W}$ *and* $f_1, f_2 \in \pi$,

$$\begin{aligned}&\langle \theta(\phi_1, f_1), \theta(\phi_2, f_2) \rangle \\ =&[E:F] \cdot \mathrm{Val}_{s=s_{V,W}} \left(L(s + \frac{1}{2}, \pi \times \chi_V) \cdot Z^*(s, \phi_1 \otimes \overline{\phi_2}, f_1, f_2) \right),\end{aligned}$$

where $s_{V,W} = (\dim V - \dim W)/2 > 0$, $L(s, \pi \times \chi_V)$ *is the standard L-function of* π, *and* $Z^*(s, -)$ *denotes the normalized doubling zeta integral.*

(ii) *Assume further that for all places* v *of* F, *the local theta lift* $\Theta_{n,r}(\pi_v)$ *is nonzero. Then* $L(s + \frac{1}{2}, \pi \times \chi_V)$ *is holomorphic at* $s = s_{V,W}$, *so that*

$$\langle \theta(\phi_1, f_1), \theta(\phi_2, f_2) \rangle = [E:F] \cdot L(s_{V,W} + \frac{1}{2}, \pi \times \chi_V) \cdot Z^*(s_{V,W}, \phi_1 \otimes \overline{\phi_2}, f_1, f_2).$$

4.7. Nonvanishing of global theta lifts. As a consequence, we have the following local-global criterion for the nonvanishing of global theta lifts.

Theorem 4.4. *Assume the same conditions on* (V, W) *as in Theorem 4.3. Let* π *be a cuspidal representation of* $\mathrm{U}(W)$ *and consider its global theta lift* $\Theta(\pi)$ *to* $\mathrm{U}(V)$. *Assume that* $\Theta(\pi)$ *is cuspidal.*

(i) *If* $\Theta(\pi)$ *is nonzero, then*

  (a) *for all places* v, $\Theta(\pi_v) \neq 0$, *and*
  (b) $L(s_{V,W} + \frac{1}{2}, \pi \times \chi_V) \neq 0$ *i.e. nonzero holomorphic.*

(ii) *The converse to (i) holds if* $K_v = k_v \times k_v$ *for all archimedean places* v *of* k.

More generally, under the conditions (a) and (b) in (i), there is a Hermitian space V' *over* K *such that*

- $V' \otimes_k k_v \cong V \otimes_k k_v$ *for every finite or complex place of* k;
- *the global theta lift* $\Theta'(\pi)$ *of* π *to* $\mathrm{U}(V')$ *is nonzero.*

The reason for not having the converse to (i) in general is that, if $K_v/k_v = \mathbb{C}/\mathbb{R}$, we do not know the equivalence of the nonvanishing of the local theta correspondence and that of the normalised doubling zeta integral on an appropriate submodule of its domain.

5. Variations and extensions.

In this section, we want to mention some extensions of the theory of theta correspondence which have been pursued in the last 20 years.

5.1. Exceptional theta correspondence. There is no reason to confine oneself to dual pairs in the symplectic group. One could consider dual pairs in any connected reductive group G. For theta correspondence, however, one also needs the analog of the Weil representation. It turns out that the Weil representation is the "smallest" infinite-dimensional representation of the metaplectic group. This suggests that one should consider the analogous smallest representation of $G(F)$. Such a representation is called a minimal representation of $G(F)$.

There is a series of work devoted to the construction and classification of minimal representations of an arbitrary $G(F)$. Of these, one might mention various papers of Kazhdan, Savin and Torasso [36, 37, 80, 83]. In the global case, the automorphic realisation of the minimal representations have been constructed, largely using residues of Eisenstein series [22].

With the theory of minimal representations in place, one can start to consider theta correspondence. While the setup is the same as classical theta correspondence, one key difference is that one does not know the analog of the Howe duality conjecture for exceptional theta correspondence; in particular, one does not know the analog of Theorem 3.1. For work on exceptional theta correspondences, we may mention a series of papers by Savin and various collaborators [25, 30, 31, 57].

5.2. Singular theta lifting of Borcherds. In his 1994 ICM address [10], Borcherds described a singular theta lifting for classical dual pairs. In classical global theta correspondence, one integrates the theta kernel against cusp forms, and there is no issue with convergence. In Borcherd's context, one is trying to lift functions which blow up exponentially at the cusps, and Borcherds gave a regularisation of such a singular theta integral. An example of such a function is the classical j-function on the upper half plane. This theory is so far not representation theoretic in nature, but it allows Borcherds to construct many beautiful examples of automorphic forms which possess infinite product expansion [11], analogous to the classical η-function.

5.3. Arithmetic theta lifting of Kudla. Since the mid-1990's, Kudla [40] has pursued an arithmetic version of the theory of theta correspondence. This provides a lifting of automorphic forms to classes in the arithmetic Chow group of a Shimura variety. One goal of Kudla's program is to establish an arithmetic version of the Rallis inner product formula in the equal rank case, which involves the central derivative of the standard L-function instead of the central value. This will require an arithmetic Siegel-Weil formula. A low rank example was established in the book [45] of Kudla-Rapoport-Yang. In his PhD thesis [53, 54], Y. F. Liu formulated such a conjectural arithmetic Rallis inner product formula in the context of unitary groups of arbitrary rank.

5.4. Geometric theta lifting of Lysenko. The theory of theta correspondence was almost single-handedly extended to the framework of the Geometric Langlands Program by S. Lysenko [55, 56]. Together with V. Lafforgue [46, 47], the theory of minimal representations was also suitably geometrized.

6. Local Langlands correspondence

In the rest of this report, we will discuss a number of applications of theta correspondence. The first such application is to the local Langlands conjecture (LLC). Unlike the earlier sections, we will no longer restrict ourselves to unitary groups.

6.1. LLC for $\mathbf{GSp_4}$. In [18] and [20], the local theta correspondence was used to establish the LLC for the group $\mathrm{GSp}_4(F)$ and its non-split inner form, where F is a p-adic field. This uses an extension of the theta correspondence from the setting of isometry dual pairs to the setting of similitude dual pairs.

Let us briefly explain how theta correspondence is used in the proof. Let W be the 4-dimensional symplectic space, V the split quadratic space of dimension 6 and trivial discriminant, and V' the anisotropic quadratic space of dimension 4 and trivial discriminant. These quadratic spaces belong to the two different related Witt towers, and we consider the similitude theta correspondence for $\mathrm{GSp}(W) \times \mathrm{GO}(V)$ and $\mathrm{GSp}(W) \times \mathrm{GO}(V')$. By the dichotomy statement in Corollary 3.5, we deduce that each $\pi \in \mathrm{Irr}(\mathrm{GSp}(W))$ has nonzero theta lift to exactly one of $\mathrm{GO}(V)$ or $\mathrm{GO}(V')$. Using this, one deduces an injection

$$\mathrm{Irr}(\mathrm{GSp}(W)) \hookrightarrow \mathrm{Irr}(\mathrm{GSO}(V)) \bigsqcup \mathrm{Irr}(\mathrm{GSO}(V')).$$

Now one notes that

$$\begin{cases} \mathrm{GSO}(V') \cong (\mathrm{GL}_2(F) \times D^\times)/\{(t, t^{-1}) : t \in F^\times\} \\ \mathrm{GSO}(V) \cong (\mathrm{GL}_4(F) \times F^\times)/\{(t, t^{-2}) : t \in F^\times\}, \end{cases}$$

where D is the quaternion division F-algebra. In particular, the LLC is known for these two groups, so one may assign L-parameters to representations of $\mathrm{GSp}_4(F)$.

6.2. LLC for $\mathbf{G_2}$. We now describe an ongoing work of the author with G. Savin on the LLC for the split exceptional group of type G_2 using the exceptional theta correspondence. Quite amazingly, it turns out that a similar strategy as in the GSp_4 case can be implemented.

More precisely, one has the two dual pairs

$$\mathrm{G}_2 \times \mathrm{PB}^\times \subset \mathrm{E}_6^{\mathrm{B}} \quad \text{and} \quad \mathrm{G}_2 \times \mathrm{PGSp}_6 \subset \mathrm{E}_7$$

where B denotes a degree 3 division F-algebra, $\mathrm{E}_6^{\mathrm{B}}$ is an inner form of type E_6 and F-rank 2 and E_7 is the split group of this type. Consider the local theta correspondence for these two dual pairs, a key result is the following analog of dichotomy and the Howe duality conjecture:

Theorem 6.1. *Each $\pi \in \mathrm{Irr}(\mathrm{G}_2)$ has nonzero theta lift to exactly one of $\mathrm{PB}^\times$ or PGSp_6. Moreover, the nonzero $\theta(\pi)$ is irreducible. In particular, one has an injection*

$$\mathrm{Irr}(\mathrm{G}_2) \hookrightarrow \mathrm{Irr}(PB^\times) \sqcup \mathrm{Irr}(\mathrm{PGSp}_6).$$

By the Jacquet-Langlands correspondence and the LLC for PGL_3 and Sp_6 (due to Arthur), one may then hope to assign L-parameters to $\pi \in \mathrm{Irr}(\mathrm{G}_2)$. This theorem will play a key role in our ongoing work to establish the full LLC for G_2.

7. Gross-Prasad conjecture

One typical application of theta correspondence is that it relates certain periods on one member of a dual pair with certain periods on the other member. One such family of periods which has attracted much attention recently is the Gross-Prasad (GP) periods, which was considered by Gross and Prasad in the context of the special orthogonal groups in two papers [23, 24] some twenty years ago. They formulated precise conjectures for the nonvanishing of the GP periods. In a recent paper [13], these conjectures were extended to arbitrary classical groups. For ease of exposition, we shall consider the case of unitary groups.

7.1. GP periods. Let V_{n+1} be a Hermitian space of dimension $n+1$ over E and W_n a skew-Hermitian space of dimension n over E. Let $V_n \subset V_{n+1}$ be a nondegenerate subspace of codimension 1, so that we have a natural inclusion $\mathrm{U}(V_n) \hookrightarrow \mathrm{U}(V_{n+1})$. In particular, if we set

$$G_n = \mathrm{U}(V_n) \times \mathrm{U}(V_{n+1}) \quad \text{or} \quad \mathrm{U}(W_n) \times \mathrm{U}(W_n)$$

and

$$H_n = \mathrm{U}(V_n) \quad \text{or} \quad \mathrm{U}(W_n),$$

then we have a diagonal embedding $\Delta : H_n \hookrightarrow G_n$.

In the Hermitian case, one is interested in determining $\dim_{\mathbb{C}} \mathrm{Hom}_{\Delta H_n}(\pi, \mathbb{C})$ for $\pi \in \mathrm{Irr}(G_n)$. We shall call this the *Bessel* case of the GP conjecture. Indeed, what we have described is a special case: the general Bessel case deals with a pair of Hermitian spaces $V' \subset V$ such that $\dim V/V'$ is odd.

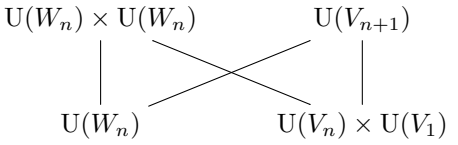
In the skew-Hermitian case, the restriction problem requires another piece of data: a Weil representation ω_{ψ,χ,W_n} of $\mathrm{U}(W_n)$, where χ is a character of $E^\times$ such that $\chi|_{F^\times} = \omega_{E/F}$. Then one is interested in determining $\dim_{\mathbb{C}} \mathrm{Hom}_{\Delta H_n}(\pi, \omega_{\psi,\chi,W_n})$. We shall call this the *Fourier-Jacobi* case (FJ) of the GP conjecture. As before, the general FJ case deals with a pair of skew-Hermitian spaces $W' \subset W$ such that $\dim W/W'$ is even. To unify notation, we shall let $\nu = \mathbb{C}$ or ω_{ψ,χ,W_n} in the respective cases.

7.2. Gross-Prasad conjecture. It was shown in [5] and [81] that the above Hom spaces have dimension at most 1. Thus the main issue is to determine when the Hom space is nonzero. The Gross-Prasad conjecture gives an answer for this issue, formulated in the framework of the local Langlands correspondence. It can be loosely stated as follows:

1. Given a generic L-parameter ϕ for G_n there is a unique η such that the representation $\pi(\phi,\eta)$ satisfies $\mathrm{Hom}_{\Delta H_n}(\pi(\phi,\eta),\nu) \neq 0$.
2. There is a precise recipe, in terms of local ϵ-factor for the distinguished character η.

In a stunning series of papers [87], [88], [89], [90], Waldspurger has established the Bessel case of the GP conjecture for special orthogonal groups in the case of tempered L-parameters; the case of general generic L-parameters is then dealt with by Mœglin-Waldspurger [64]. Beuzart-Plessis [7], [8], [9] has since extended Waldspurger's techniques to settle the Bessel case of the GP conjecture for unitary groups in the tempered case.

7.3. Theta correspondence. Now the Bessel and Fourier-Jacobi cases of the GP conjecture are related by the local theta correspondence. More precisely, there is a see-saw diagram



and the associated see-saw identity reads:

$$\mathrm{Hom}_{\mathrm{U}(W_n)}(\Theta_{\psi,\chi,V_n,W_n}(\sigma)\otimes\omega_{\psi,\chi,V_1,W_n},\pi)\cong\mathrm{Hom}_{\mathrm{U}(V_n)}(\Theta_{\psi,\chi,V_{n+1},W_n}(\pi),\sigma)$$

for $\pi\in\mathrm{Irr}(\mathrm{U}(W_n))$ and $\sigma\in\mathrm{Irr}(\mathrm{U}(V_n))$. Hence the left-hand side of the see-saw identity concerns the Fourier-Jacobi case (FJ) whereas the right-hand side concerns the Bessel case (B). It is thus apparent that precise knowledge of the local theta correspondence for unitary groups of (almost) equal rank will give the precise relation of (FJ) to (B).

In particular, as a consequence of the proof of Prasad's conjecture in Theorem 3.9, the FJ case of the GP conjecture was verified in [15] . Hence one has:

Theorem 7.1. *Assume the LLC for unitary groups. Then both the Bessel and FJ cases of the GP conjecture hold.*

8. Shimura-Waldspurger correspondence

We will conclude by returning to the Shimura-Waldspurger (SW) correspondence for Mp_2, which in some sense initiated many of the developments discussed in this paper. In particular, we will discuss its extension to Mp_{2n}.

8.1. Local SW correspondence. Let F be a nonarchimedean local field. Let W be the $2n$-dimensional symplectic vector space, and let V^+ and V^- be the two $2n+1$-dimensional quadratic spaces with trivial discriminant, with V^+ split. Then one may consider the theta correspondence for $\mathrm{Mp}(W)\times\mathrm{O}(V^\epsilon)$. As a consequence of Theorem 3.6, the following was shown in [17]:

Theorem 8.1. *Fix a nontrivial additive character ψ of F. The theta correspondence with respect to ψ gives a bijection*

$$\mathrm{Irr}_\epsilon(\mathrm{Mp}W))\longleftrightarrow\mathrm{Irr}(\mathrm{SO}(V^+))\sqcup\mathrm{Irr}(\mathrm{SO}(V^-)),$$

where we consider genuine representations of $\mathrm{Mp}(W)$ on the LHS. Assuming the LLC for $\mathrm{SO}(V^\pm)$, one then inherits an LLC for $\mathrm{Mp}(W)$. Moreover, this LLC satisfies a list of expected properties which characterise it uniquely.

When F is archimedean, the analogous theorem was obtained by Adams-Barbasch [4] some 20 years ago, and described in Adams' 1994 ICM talk [2].

8.2. Global SW correspondence. Now assume that we are working over a number field k. It is natural to attempt to use the global theta correspondence to obtain a precise description

of the automorphic discrete spectrum of $\mathrm{Mp}(W_{\mathbb{A}})$. For readers familiar with Waldspurger's work [84, 85] in the case when $\dim W = 2$, it will be apparent that there is an obstruction to this approach: the global theta lift $\Theta(\pi)$ of a cuspidal representation π of $\mathrm{Mp}(W_{\mathbb{A}})$ or $\mathrm{SO}(V_{\mathbb{A}})$ may be 0 and it is nonzero precisely when $L(1/2, \pi) \neq 0$.

This obstruction already occurs when $\dim W = 2$, and was not easy to overcome. Waldspurger had initially alluded to results of Flicker proved by the trace formula. Nowadays, one could appeal to a result of Friedberg-Hoffstein [12], stating that if $\epsilon(1/2, \pi) = 1$, then there exists a quadratic Hecke character χ such that $L(1/2, \pi \times \chi) \neq 0$. When $\dim W > 2$, however, the analogous analytic result does not seem to be forthcoming and may be very hard. We are going to suggest a new approach in the higher rank case, but before that, we would like to describe the analog of Arthur's conjecture for Mp_{2n}.

8.3. Arthur's conjecture for $\mathbf{Mp_{2n}}$. For a fixed additive automorphic character ψ, one expects that

$$L^2_{disc} = \bigoplus_{\Psi} L^2_{\Psi,\psi}$$

where

$$\Psi = \bigoplus_i \Psi_i = \bigoplus_i \Pi_i \boxtimes S_{r_i}$$

is a global discrete A-parameter for Mp_{2n}; it is also an A-parameter for SO_{2n+1}. Here, S_{r_i} is the r_i-dimensional representation of $\mathrm{SL}_2(\mathbb{C})$ and Π_i is a cuspidal representation of GL_{n_i} such that

$$\begin{cases} L(s, \Pi_i, \wedge^2) \text{ has a pole at } s = 1, \text{ if } r_i \text{ is odd;} \\ L(s, \Pi_i, \mathrm{Sym}^2) \text{ has a pole at } s = 1, \text{ if } r_i \text{ is even.} \end{cases}$$

Moreover, we have $\sum_i n_i r_i = 2n$ and the summands Ψ_i are mutually distinct.

For a given Ψ, one inherits the following additional data:

- for each v, one inherits a local A-parameter

$$\Psi_v = \bigoplus_i \Psi_{i,v} = \bigoplus_i \Pi_{i,v} \boxtimes S_{r_i}.$$

  By the LLC for GL_N, we may regard each $\Pi_{i,v}$ as an n_i-dimensional representation of the Weil-Deligne group WD_{k_v}. Hence, we may regard Ψ_v as a $2n$-dimensional representation of $WD_{k_v} \times \mathrm{SL}_2(\mathbb{C})$.

- one has a "global component group"

$$A_\Psi = \bigoplus_i \mathbb{Z}/2\mathbb{Z} \cdot a_i$$

  which is a $\mathbb{Z}/2\mathbb{Z}$-vector space equipped with a distinguished basis indexed by the Ψ_i's. Similarly, for each v, we have the local component group A_{Ψ_v} which is defined as the component group of the centralizer of the image of Ψ_v, thought of as a representation of $WD_{k_v} \times \mathrm{SL}_2(\mathbb{C})$. There is a natural diagonal map

$$\Delta : A_\Psi \longrightarrow \prod_v A_{\Psi_v}.$$

- For each v, one has a local A-packet associated to Ψ_v and ψ_v:

$$\Pi_{\Psi_v,\psi_v} = \{\sigma_{\eta_v} : \eta_v \in \mathrm{Irr}(A_{\Psi_v})\},$$

consisting of unitary representations (possibly zero, possibly reducible) of $\mathrm{Mp}_{2n}(k_v)$ indexed by the set of irreducible characters of A_{Ψ_v}. On taking tensor products of these local A-packets, we obtain a global A-packet

$$A_{\Psi,\psi} = \{\sigma_\eta : \eta = \otimes_v \eta_v \in \mathrm{Irr}(\prod_v A_{\Psi_v})\}$$

consisting of abstract unitary representations $\sigma_\eta = \otimes_v \sigma_{\eta_v}$ of $\mathrm{Mp}_{2n}(\mathbb{A})$ indexed by the irreducible characters $\eta = \otimes_v \eta_v$ of $\prod_v A_{\Psi_v}$.

- Arthur has attached to Ψ a quadratic character (possibly trivial) ϵ_Ψ of A_Ψ, This character plays an important role in the multiplicity formula for the automorphic discrete spectrum of SO_{2n+1}. For Mp_{2n}, we need to define a modification of ϵ_Ψ.

  More precisely, consider the L-parameter $\Phi_\Psi = \bigoplus_i \Phi_{\Psi_i}$ associated to Ψ, with

$$\Phi_{\Psi_i} = \bigoplus_{k=0}^{r_i-1} \Pi_i \cdot |-|^{(r_i-1-2k)/2}.$$

  Then define $\eta_\Psi \in \mathrm{Irr} A_\Psi$ by

$$\eta_\Psi(a_i) = \epsilon(1/2, \Phi_{\Psi_i}) = \begin{cases} \epsilon(1/2, \Pi_i), \text{ if } L(s, \Pi_i, \wedge^2) \text{ has a pole at } s = 1; \\ 1, \text{ if } L(s, \Pi_i, \mathrm{Sym}^2) \text{ has a pole at } s = 1. \end{cases}$$

  The modified quadratic character of A_Ψ in the metaplectic case is

$$\tilde{\epsilon}_\Psi = \epsilon_\Psi \cdot \eta_\Psi.$$

We can now state the conjecture.

Conjecture 8.2 (Arthur Conjecture for Mp_{2n}). *There is a decomposition*

$$L^2_{disc}(\mathrm{Mp}_{2n}) = \bigoplus_\Psi L^2_{\Psi,\psi}$$

where the sum runs over equivalence classes of discrete A-parameters of Mp_{2n}. *For each such* Ψ,

$$L^2_{\Psi,\psi} \cong \bigoplus_{\eta \in \mathrm{Irr}(\prod_v A_{\Psi_v}) : \Delta^*(\eta) = \tilde{\epsilon}_\Psi} \sigma_\eta$$

8.4. A new approach. In an ongoing work, we are developing a new approach for the Arthur conjecture described above. Namely, by results of Arthur [6], one now has a classification of the automorphic discrete spectrum of SO_{2r+1} for all r. Instead of trying to construct the automorphic discrete spectrum of Mp_{2n} by theta lifting from SO_{2n+1}, one could attempt to use theta liftings from SO_{2r+1} for $r \geq n$. Let us illustrate this in the case when $\dim W = 2$.

Let π be a cuspidal representation of $\mathrm{PGL}_2(\mathbb{A}) = \mathrm{SO}(V_{\mathbb{A}}^+)$. Then π gives rise to a near equivalence class in the automorphic discrete spectrum of Mp_2. If $L(1/2, \pi) \neq 0$, this near equivalence class can be exhausted by the global theta lifts of π and its Jacquet-Langlands transfer to inner forms of PGL_2. When $L(1/2, \pi) = 0$, we consider the A-parameter

$$\psi = \pi \boxtimes S_1 \oplus 1 \boxtimes S_2 \quad \text{for } \mathrm{SO}_5.$$

This is a so-called Saito-Kurokawa A-parameter. By Arthur, ψ indexes a near equivalence class in the automorphic discrete spectrum of SO_5. In a well-known paper [72], Piatetski-Shapiro gave a construction of the Saito-Kurokawa representations by theta lifting from Mp_2, using Waldspurger's results as initial data. However, *one can turn the table around*.

Namely, taking the Saito-Kurokawa near equivalence classes as given by Arthur, one can consider their theta lift back to Mp_2. By the Rallis inner product formula, such a theta lift is nonzero if the partial L-function

$$L^S(s, \Phi_\psi) = L^S(s, \pi) \cdot \zeta(s + \frac{1}{2}) \cdot \zeta(s - \frac{1}{2})$$

has a pole at $s = 3/2$, or equivalently if $L^S(3/2, \pi) \neq 0$. Now this is certainly much easier to ensure than the nonvanishing at $s = 1/2$! In this way, one can construct the desired near equivalence class for Mp_2 associated to π and by studying the local theta correspondence in detail, one can recover Waldspurger's results from 30 years ago.

Automorphic Galois representations and the cohomology of Shimura varieties

Michael Harris

Abstract. The first part of this report describes the class of representations of Galois groups of number fields that have been attached to automorphic representations. The construction is based on the program for analyzing cohomology of Shimura varieties developed by Langlands and Kottwitz. Using p-adic methods, the class of Galois representations obtainable in this way can be expanded slightly; the link to cohomology remains indispensable at present. It is often possible to characterize the set of Galois representations that can be attached to automorphic forms, using the modularity lifting methods initiated by Wiles a bit over 20 years ago. The report mentions some applications of results of this kind. The second part of the report explains some recent results on critical values of automorphic L-functions, emphasizing their relation to the motives whose ℓ-adic realizations were discussed in the first part.

Mathematics Subject Classification (2010). Primary 11F80; Secondary 11F70, 11G18, 11F67.

Keywords. Galois representation, Shimura variety, special values of L-functions.

1. Introduction

Algebraic number theory has benefited immeasurably over the past four decades from the applications of the methods and results of the Langlands program to the study of Galois representations attached to automorphic forms. Yet Galois representations do not figure prominently in Langlands's original conjectures, apart from the complex Galois representations that are the object of the Artin conjecture. There seems to be no completely precise statement in the literature of a *Langlands reciprocity conjecture* – a bijection between representations of Galois groups with values in the ℓ-adic points of reductive groups, subject to certain natural restrictions (including a version of irreducibility), and of automorphic representations of related reductive groups – although number theorists believe there should be such a conjecture and have a general idea of how it should go. The best general account of this question is still contained in the expanded version [69] of Taylor's 2002 ICM talk.

The first objective of the present survey is to describe the results in the direction of reciprocity obtained since the publication of [69]. Construction of the correspondence in one direction – from automorphic representations to Galois representations – has progressed considerably, even in directions that could not have been expected ten years ago. All of the Galois representations associated to automorphic representations have been constructed, either directly or by p-adic interpolation, using the cohomology of Shimura varieties. This source of Galois representations has been or soon will be exhausted, and new methods will

Proceedings of the International Congress of Mathematicians, Seoul, 2014

need to be invented in order to find the Galois representations attached to automorphic representations that cannot be related in any way to cohomology of Shimura varieties, notably the representations of Galois groups of number fields that are not totally real nor CM.

Little was known at the time of [69] regarding the converse direction, the problem of proving that a given Galois representation ρ is attached to automorphic forms, when $\dim \rho > 2$. Now there is a mature theory of *automorphy lifting theorems*, in the spirit of the results developed by Wiles for his proof of Fermat's Last Theorem, applying in all dimensions. The attempt to complete this theory represents one of the most active branches of algebraic number theory, and is largely responsible for the rapid growth of interest in the p-adic local Langlands program.

Let K be a number field. The Galois group $\Gamma_K := Gal(\overline{\mathbb{Q}}/K)$ acts on the p-adic étale cohomology of an algebraic variety or motive M defined over K, and this action determines the L-function $L(s, M)$. Theoretical considerations guarantee that the p-adic Galois representations on the cohomology of most algebraic varieties cannot be realized in the cohomology of Shimura varieties; for example, the cohomology of a generic hypersurface cannot be obtained in this way. Present methods, therefore, cannot prove the analytic continuation of $L(s, M)$ for most motives arising from geometry. When the Galois representation is attached to an automorphic form, on the other hand, then so is $L(s, M)$, and this implies analytic (or at least meromorphic) continuation of the latter. Moreover, the conjectures concerned with the values at integer points of $L(s, M)$ (of Deligne, Beilinson, or Bloch-Kato) can be studied with the help of automorphic forms. Everything one knows in the direction of the Birch-Swinnerton-Dyer Conjecture, for example, has been proved by means of this connection. There has been a great deal of activity in this direction as well, especially in connection with the growth of the "relative" theory of automorphic forms (the relative trace formula and conjectures of Gan-Gross-Prasad, Ichino-Ikeda, and Sakellaridis-Venkatesh). The second part of this paper reviews some of the recent results on special values of L-functions.

The conjectures on special values of complex L-functions are accompanied by conjectures on the existence of p-adic analytic functions interpolating their normalized special values. The article concludes with a few speculative remarks about automorphic p-adic L-functions.

2. Automorphic forms and Galois representations

2.1. Construction of automorphic Galois representations. Class field theory classifies abelian extensions of a number field K in terms of the the structure of the idèle class group $GL(1, K)\backslash GL(1, \mathbb{A}_K)$. In doing so it also identifies 1-dimensional representations of Γ_K with continuous characters of the idèle class group. Non-abelian class field theory can be traced back to the 1950s, when Eichler and Shimura realized that 2-dimensional ℓ-adic Galois representations could be attached to classical cusp forms that are eigenvalues of the Hecke algebra. A conjectural classification of n-dimensional ℓ-adic Galois representations, in terms of the Langlands program, was formulated in Taylor's 2002 ICM talk (cf. [69]). We review this conjecture quickly. For any finite set S of places of K, let $\Gamma_{K,S}$ be the Galois group of the maximal extension of K unramified outside S. Taylor adopts the framework of Fontaine and Mazur, who restrict their attention in [25] to continuous representations $\rho : \Gamma_K \to GL(n, \overline{\mathbb{Q}}_\ell)$ satisfying the following two axioms:

1. ρ factors through $\Gamma_{K,S}$ for some finite set S of places of K (usually containing the primes dividing ℓ);
2. For all primes v of K of residue characteristic ℓ, the restriction of ρ to a decomposition group $G_v \subset \Gamma_K$ at v is *de Rham* in the sense of Fontaine.

A ρ satisfying these two conditions is either called *geometric* or *algebraic*, depending on the context. Condition (1) guarantees that, at all but finitely many primes v of K, the restriction ρ_v of ρ to a decomposition group G_v is determined up to equivalence, and up to semisimplification, by the characteristic polynomial $P_v(\rho, T)$ of the conjugacy class $\rho(Frob_v) \in GL(n, \overline{\mathbb{Q}}_\ell)$. One of the Fontaine-Mazur conjectures implies that there is a number field E such that all $P_v(\rho, T)$ have coefficients in E; by choosing an embedding $\iota : E \hookrightarrow \mathbb{C}$ we may thus define $P_v(\rho, T)$ as a polynomial of degree n in $\mathbb{C}[T]$ with non-vanishing constant term. The set of such polynomials is in bijection with the set of (equivalence classes of) irreducible smooth representations Π_v of $GL(n, K_v)$ that are *spherical*: the space of vectors in Π_v that are invariant under the maximal compact subgroup $GL(n, \mathcal{O}_v) \subset GL(n, K_v)$, where $\mathcal{O}_v$ is the ring of integers in K_v, is non-trivial and necessarily one-dimensional. We let $\Pi_v(\rho)$ be the spherical representation corresponding to $P_v(\rho, T)$.

An irreducible representation $\Pi_v(\rho)$ of $GL(n, K_v)$ can be attached to ρ for primes $v \in S$ as well. If v is not of residue characteristic ℓ, the restriction of ρ to G_v gives rise by a simple procedure to an n-dimensional representation $WD(\rho, v)$ of the Weil-Deligne group WD_v at v. The local Langlands correspondence [41, 43] is a bijection between n-dimensional representations of WD_v and irreducible smooth representations of $GL(n, K_v)$, and we obtain $\Pi_v(\rho)$ using this bijection. If v divides ℓ, condition (2) allows us to define $WD(\rho, v)$ by means of Fontaine's D_{pst} functor. Fontaine's construction also provides a set of Hodge-Tate numbers $HT(\rho, v)$ for each archimedean prime v. This datum, together with the action of a complex conjugation c_v in a decomposition group G_v when v is a real prime, defines an n-dimensional representation ρ_v of the local Weil group W_v, and thus an irreducible $(\mathfrak{g}_v, U_v)$-module $\Pi_v(\rho)$, where $\mathfrak{g}_v$ is the (complexified) Lie algebra of $G(K_v)$ and U_v is a maximal compact subgroup of $G(K_v)$. We let $\Pi(\rho)$ denote the restricted direct product (with respect to the $GL(n, \mathcal{O}_v)$-invariant vectors at finite primes outside S) of the $\Pi_v(\rho)$, as v ranges over all places of K.

If v is an archimedean place of K, the Harish-Chandra homomorphism identifies the center $Z(\mathfrak{g}_v)$ with the symmetric algebra of a Cartan subalgebra $\mathfrak{t}_v \subset \mathfrak{g}_v$. The maximal ideals of $Z(\mathfrak{g}_v)$ are in bijection with linear maps $Hom(\mathfrak{t}, \mathbb{C})$. The *infinitesimal character* of an irreducible $(\mathfrak{g}_v, U_v)$-module Π_v is the character defining the action of $Z(\mathfrak{g}_v)$ on Π_v; its kernel is a maximal ideal of $Z(\mathfrak{g}_v)$, and thus determines a linear map $\lambda_{\Pi_v} \in Hom(\mathfrak{t}_v, \mathbb{C})$. In [17], Clozel defines an irreducible $(\mathfrak{g}_v, U_v)$-module Π_v to be *algebraic* if λ_{Π_v} belongs to the lattice in $Hom(\mathfrak{t}_v, \mathbb{C})$ spanned by the highest weights of finite-dimensional representations. Denote by $|\bullet|_v$ the v-adic absolute value, $|\bullet|_{\mathbf{A}}$ the adele norm. The following corresponds to Conjectures 3.4 and 3.5 of [69].

Conjecture 2.1.

(1) *Let $\rho : \Gamma_K \to GL(n, \overline{\mathbb{Q}}_\ell)$ be an irreducible geometric Galois representation. Then the local component*

$$\Pi_v(\rho)\left(\frac{1-n}{2}\right) := \Pi_v(\rho) \otimes |\bullet|_v^{\frac{1-n}{2}} \circ \det$$

is algebraic at each archimedean prime v of K, and the representation $\Pi_v(\rho)$ of $GL(n, \mathbf{A}_K)$ occurs in the space of cusp forms on $GL(n, K)\backslash GL(n, \mathbf{A}_K)$.

(2) *Conversely, let Π be a cuspidal automorphic representation of $GL(n, \mathbf{A}_K)$. Suppose $\Pi_v(\frac{1-n}{2})$ is algebraic for every archimedean place v of K. Then for each prime ℓ, there exists an irreducible geometric n-dimensional representation*

$$\rho_{\ell,\Pi} : \Gamma_K \ \rightarrow \ GL(n, \overline{\mathbb{Q}}_\ell)$$

such that

$$\Pi\left(\frac{1-n}{2}\right) := \Pi \otimes |\bullet|_{\mathbf{A}}^{\frac{1-n}{2}} \circ \det \ \xrightarrow{\sim} \ \Pi(\rho_{\ell,\Pi}).$$

The Galois representations $\rho_{\ell,\Pi}$ are called *automorphic*.[1] Quite a lot is known about this conjecture when K is either a CM field or a totally real field, almost exclusively in the *regular* case, when λ_Π is the infinitesimal character of an irreducible finite-dimensional representation of $G(K_v)$ for all archimedean v. Let S be a finite set of primes of K, let ρ be an n-dimensional ℓ-adic representation of Γ_K, and say that Π and ρ_ℓ correspond away from S if $\Pi_v = \Pi_v(\rho)$ for $v \notin S$. The following theorem represents the current state of knowledge regarding part (b) of Conjecture 2.1; part (a) will be treated in the next section. In its details it may already be obsolete by the time of publication.

Theorem 2.2. *Let K be a CM field or a totally real field. Let Π be a cuspidal automorphic representation of $GL(n, \mathbf{A}_K)$. Suppose Π_v is algebraic and regular for every archimedean place v of K.*

(a) *Let S be the set of finite primes at which Π is ramified. If ℓ is a rational prime, let $S(\ell)$ denote the union of S with the set of primes of K dividing ℓ. For each prime ℓ, there exists a completely reducible geometric n-dimensional representation*

$$\rho_{\ell,\Pi} : \Gamma_K \ \rightarrow \ GL(n, \overline{\mathbb{Q}}_\ell)$$

such that $\Pi(\frac{1-n}{2})$ and $\rho_{\ell,\Pi}$ correspond away from $S(\ell)$.

(b) *Suppose Π is* polarized*, in the following sense:*

(1) *If K is a CM field,*

$$\Pi^\vee \ \xrightarrow{\sim} \ \Pi^c,$$

where ^{c} denotes the action of complex conjugation acting on K

(2) *If K is totally real,*

$$\Pi^\vee \ \xrightarrow{\sim} \ \Pi \otimes \omega$$

for some Hecke character ω of $GL(1, \mathbf{A}_K)$.

Here $^\vee$ denotes contragredient. Then there is a compatible family of n-dimensional representations $\rho_{\ell,\Pi}$ satisfying (b) of 2.1. Moreover, $\rho_{\ell,\Pi}$ is de Rham, in the sense of Fontaine, at all primes v dividing ℓ.

[1] When G is a reductive algebraic group, Buzzard and Gee have conjectured a correspondence between automorphic representations of G that satisfy an algebraicity condition at archimedean places and compatible systems of ℓ-adic representations with values in the Langlands L-group of G [9]. The relation of this conjecture with Conjecture 2.1 is a bit subtle; two different algebraicity conditions are relevant to the conjecture.

2.1.1. *p*-adic approximation. To forestall certain kinds of cognitive dissonance, we switch from ℓ-adic to p-adic representations in this section. Part (b) of Theorem 2.2 has been proved over the course of several decades by a number of people. For general n-dimensional representations, the most relevant references are [17, 41, 48] for work before the proof by Laumon and Ngô of the Fundamental Lemma; and [16, 19, 20, 51, 56, 62, 64] for results based on the Fundamental Lemma. I refer the reader to the discussion in [35], and take this opportunity to insist on the centrality of Labesse's results in [51] and earlier papers, which are inexplicably omitted from some accounts.[2]

Under the polarization hypothesis of case (b), most $\rho_{p,\Pi}$ are realized in the cohomology of Shimura varieties $S(G)$ attached to appropriate unitary groups G. Some important representations are nevertheless missing when n is even. To complete the proof of (b), the missing representations are constructed by *p-adic approximation*. One needs to show that Π is in some sense the limit of a sequence of Π_i that do satisfy the strong regularity hypothesis[3] For $n = 2$ two approximation methods had been applied: Wiles used the ideas due to Hida, while Taylor obtained the most complete results by adapting ideas of Ribet. In the intervening years, the theory of *eigenvarieties*, which originated in the work of Coleman and Mazur, had been developed to define p-adic famiies of automorphic forms in a very general setting. Chenevier's thesis [14] generalized the approximation method of Wiles to attach p-adic Galois representations of dimension $n > 2$ to non-ordinary Π, using eigenvarieties. Its extension in the book [6] with Bellaïche, and the subsequent article [15] were almost sufficient to construct the missing $\rho_{p,\Pi}$ as the limit of ρ_{p,Π_i} as above. The final steps in the construction, and the proofs of most of the local properties of 2.1, were carried out in [16], using a descent argument introduced by Blasius and Ramakrishnan in [8] and extended by Sorensen in [65]. The remaining local properties – determination of local ℓ-adic and p-adic monodromy of $\rho_{p,\Pi}$ were not known when [35] was written; they were obtained in most cases in [4] and completed in [12, 13].

Part (a) of Theorem 2.2 is much more recent. The first result of this type was obtained for $GL(2)$ over imaginary quadratic fields by Taylor in [67], following his joint work [40] with Soudry and the author; this was extended to general CM fields by Mok [54]. The proof of part (a) in [38] starts with an old idea of Clozel. Let K be a CM field and let $K^+ \subset K$ be the fixed field under complex conjugation. Let G_n be the unitary group of a $2n$-dimensional hermitian space over K, and assume G_n is quasi split. Then G_n, viewed by restriction of scalars as an algebraic group over $\mathbb{Q}$, contains a maximal parabolic subgroup P_n with Levi factor isomorphic to $R_{K/\mathbb{Q}}GL(n)_K$. Let $S(n, K)$ be the locally symmetric space attached to $GL(n, \mathbf{A}_K)$. Since K is a CM field, $S(n, K)$ is not an algebraic variety, and therefore its ℓ-adic cohomology does not carry a representation of any Galois group. If Π is a cuspidal automorphic representation of $GL(n, \mathbf{A}_K)$ that is polarized, then the twisted trace formula attaches to Π a collection (an L-packet) of automorphic representations of the unitary group G mentioned above; thus Π transfers to the cohomology of the $S(G)$, and this is where the Galois representation is realized (in nearly all cases).

When Π is not polarized, one uses the theory of Eisenstein series for the parabolic group

[2]Although complete base change from unitary groups remains to be established (the quasi-split case has recently been treated in [55]), Labesse proved the basic properties in the case of cohomological representations, without which the proof of Theorem 2.2 would have been impossible.

[3]Strictly speaking, the limits discussed here are taken relative to the Zariski topology on appropriate eigenvarieties, so the term "p-adic limit" would not be quite appropriate. In many cases the missing representations can indeed be obtained as actual limits in the p-adic topology, but as far as I know these cases have not been given an intrinsic characterization.

P_n to attach a family $E(s,\Pi)$ of automorphic representations of G_n, with $s \in \mathbb{C}$. Up to twisting Π by a positive integral power of the norm, we may assume $E(s,\Pi)$ is regular at 0 and write $E(\Pi) = E(0,\Pi)$. Then $E(\Pi)$ is also cohomological and (for nearly all positive integral twists) defines a non-trivial class in the cohomology of the Shimura variety $S(G_n)$ attached to (the unitary similitude group of) G_n. The realization in p-adic étale cohomology of this Eisenstein class then defines a p-adic Galois representation. However, it is easy to see that the semisimplification of this representation is a sum of abelian characters, and therefore it cannot be used to construct the desired $\rho_{p,\Pi}$.

Some years later, Skinner (and independently Urban) revived Clozel's idea by suggesting that $E(\Pi)$ might be realized as the limit in a p-adic family of a sequence of *cuspidal* cohomological automorphic representations τ_i of G_n. One then considers the collection of $2n$-dimensional representations ρ_{p,τ_i}. The symbol $\chi_{E(\Pi)} = \lim_i tr\rho_{p,\tau_i}$ then makes sense as a $\overline{\mathbb{Q}}_p$-valued function on $\Gamma_{K,S}$ for appropriate S, and because it is the limit of traces of genuine representations it defines a $2n$-dimensional *pseudorepresentation*. The latter notion is an abstraction of the invariance properties of the character of a representation, first constructed in the 2-dimensional case by Wiles, then defined by Taylor in general using results (especially results of Procesi) from invariant theory. Taylor's theory implies that $\chi_{E(\Pi)}$ is the character of a unique $2n$-dimensional representation, and by varying Π among its abelian twists it can be shown by elementary methods that $\chi_{E(\Pi)}$ breaks up as the sum of two n-dimensional pieces, one of which is the $\rho_{p,\Pi}$ of Theorem 2.2.

The hard part is to obtain $E(\Pi)$ as the limit of cuspidal τ_i. What this means is that the eigenvalues of Hecke operators at primes at which Π is unramified are p-adic limits of the corresponding Hecke eigenvalues on τ_i. In [38] this is achieved by realizing $E(\Pi)$ in a p-adic cohomology theory that satisfies a short list of desirable properties. The most important properties are (i) the global cohomology is computed as the hypercohomology in the (rigid) Zariski topology of the de Rham complex and (ii) the cohomology has a weight filtration, characterized by the eigenvalues of an appropriate Frobenius operator. The cohomology theory chosen in [38] is a version of Berthelot's rigid cohomology (generalizing Monsky-Washnitzer cohomology). This is calculated on the complement, in the *minimal* (Baily-Borel) compactification $S(G_n)^*$ of $S(G_n)$, of the vanishing locus of lifts (modulo increasing powers of p) of the Hasse invariant. This complement is affinoid and therefore by (i) the cohomology can be computed by a complex whose terms are spaces of p-adic modular forms, in the sense of Katz. By analyzing the finiteness properties of this complex, and using the density of genuine holomorphic modular forms in the space of p-adic modular forms, [38] writes $E(\Pi)$ as the limit of cuspidal τ_i, as required.

About a year after the results of [38] were announced, Scholze discovered a more flexible construction based on a very different cohomology theory, the p-adic étale cohomology of *perfectoid spaces*. The topological constructions in [38] can in principle also lift torsion classes in the cohomology of the locally symmetric space attached to $GL(n,\mathbf{A}_K)$ to torsion classes in the cohomology of $S(G_n)$, but rigid cohomology cannot detect torsion classes. The p-adic étale cohomology of perfectoid spaces does not have this defect, and Scholze's article [61] not only gives a new and more conceptual proof of the results of [38] but applies to torsion classes as well. Thus Scholze proved a long-standing conjecture, first formulated by Ash in [2], that has greatly influenced subsequent speculation on p-adic representations of general Galois groups. The reader is referred to Scholze's article in the current proceedings for more information about his results.

Restrictions on Galois representations on the cohomology of Shimura varieties. In part (b) of 2.2 the proof of the deepest local properties of the (polarized) $\rho_{p,\Pi}$ at primes dividing p were proved by finding representations closely related to $\rho_{p,\Pi}$ (the images under tensor operations) directly in the cohomology of Shimura varieties. When Π is not polarized, the $\rho_{p,\Pi}$ are still constructed in [38] and [61] by a limiting process , starting from a family of ρ_{p,Π_i} of geometric origin, but there is every reason to believe (see below) that the $\rho_{p,\Pi}$ and its images under tensor operations will almost never be obtained in the cohomology of Shimura varieties, and although they are expected to be geometric no one has the slightest idea where they might arise in the cohomology of algebraic varieties.

Room for improvement. The infinitesimal character $\lambda_\Pi \in Hom(\mathfrak{t}_v, \mathbb{C})$ is regular provided it is orthogonal to no roots of $\mathfrak{t}_v$ in $\mathfrak{g}_v$; in other words, if it is contained in the interior of a Weyl chamber. The regularity hypothesis in Theorem 2.2 can sometimes be relaxed to allow non-degenerate limits of discrete series, whose infinitesimal characters lie on one or more walls of a Weyl chamber. The first result of this type is the Deligne-Serre theorem which attaches (Artin) representations of $\Gamma_{\mathbb{Q}}$ to holomorphic modular forms of weight 1. This has recently been generalized by Goldring [28] to representations of $GL(n)$ obtained by base change from holomorphic limits of discrete series of unitary groups.

2.2. Reciprocity. Number theorists can't complain of a shortage of Galois representations. The étale cohomology of algebraic varieties over a number field K provides an abundance of ℓ-adic representations of Γ_K satisfying the two Fontaine-Mazur axioms. One of the Fontaine-Mazur conjectures predicts that any irreducible representation of Γ_K satistying these axioms is equivalent to a constituent of ℓ-adic cohomology of some (smooth projective) variety V over K. The reciprocity Conjecture 2.1 (a) has been tested almost exclusively for ρ arising from geometry in this way. The paradigmatic case in which $K = \mathbb{Q}$ and V is an elliptic curve was discussed in the ICM talks of Wiles (in 1994) and Taylor (in 2002).[4] The Fontaine-Mazur conjecture itself has been solved in almost all 2-dimensional cases when $K = \mathbb{Q}$ for ρ that take complex conjugation to a matrix with determinant -1. Two different proofs have been given by Kisin and Emerton; both of them take as their starting point the solution by Khare and Wintenberger of Serre's conjecture on 2-dimensional modular representations of $\Gamma_{\mathbb{Q}}$. All of these results are discussed in a number of places, for example in [24, 46, 47]. I will therefore concentrate on results valid in any dimension n.

Let $\rho : \Gamma_K \to GL(n, \mathcal{O})$ be a continuous representation with coefficients in an ℓ-adic integer ring $\mathcal{O}$ with maximal ideal $\mathfrak{m}$ and residue field k; let $\bar{\rho} : \Gamma_K \to GL(n, k)$ denote the reduction of ρ modulo $\mathfrak{m}$. We say ρ is *residually automorphic* if $\bar{\rho} \xrightarrow{\sim} \bar{\rho}_{\ell,\Pi}$ for some cuspidal automorphic representation Π of $GL(n, \mathbf{A}_K)$. The method for proving reciprocity initiated by Wiles consists in proving theorems of the following kind:

Theorem 2.3 (Modularity Lifting Theorem, prototypical statement). *Suppose $\bar{\rho}$ is residually automorphic. Then every lift of $\bar{\rho}$ to characteristic zero that satisfies axioms (1) and (2) of Fontaine-Mazur, as well as*

(1) *a polarization condition;*

(2) *conditions on the size of the image of $\bar{\rho}$ (typically including the hypothesis that $\bar{\rho}$ is*

[4]The nomenclature associated with the conjecture in this particular case, which predates the Fontaine-Mazur conjecture, is a matter of considerable sociological and philosophical interest.

absolutely irreducible); and

(3) *ramification conditions at primes dividing ℓ (typically including a regularity hypothesis)*

is automorphic. In particular, if ρ itself satisfies conditions (1), (2), *and* (3), *then ρ is automorphic.*

The method for proving such theorems is called the *Taylor-Wiles method* or the *Taylor-Wiles-Kisin method*, depending on context, and is named after its inventors in the setting when $n = 2$. The first theorems of this kind for arbitrary n were proved in [21, 70]. Together with the results of [39] they imply the Sato-Tate theorem for elliptic curves over $\mathbb{Q}$ with non-integral j-invariant (see below). Subsequent improvements have allowed for less restrictive conditions in (2) and (3). The following theorem of Barnet-Lamb, Gee, Geraghty, and Taylor [3] represents the current state of the art.

Theorem 2.4 (Modularity Lifting Theorem). *Let K be a CM field with totally real subfield K^+, and let $c \in Gal(K/K^+)$ denote complex conjugation. Let ρ be as in 2.3. Suppose $\ell \geq 2(n+1)$ and K does not contain a primitive ℓ-th root of* 1. *Suppose ρ satisfies axioms (1) and (2) of Fontaine-Mazur, as well as*

(1) *$\rho^c \xrightarrow{\sim} \rho^\vee \otimes \mu$, where μ is an ℓ-adic character of Γ_{K^+} such that $\mu(c_v) = -1$ for every complex conjugation c_v;*

(2) *The restriction of $\bar{\rho}$ to $\Gamma_{K(\zeta_\ell)}$ is absolutely irreducible; and*

(3) *For any prime v of K dividing ℓ the restriction ρ_v of ρ to the decomposition group Γ_v is potentially diagonalizable and is HT-*regular*: ρ_v has n distinct Hodge-Tate weights.*

Suppose ρ is residually automorphic. Then ρ is automorphic.

Remark 2.5. This is not the most general statement – there is a version of this theorem when K is totally real, and condition (2) can be replaced by adequacy.

Remark 2.6. The first novelty is the simplification of condition (2) on the image of $\bar{\rho}$: Thorne showed in [72] that the Taylor-Wiles-Kisin method works when the image of $\bar{\rho}$ is what he called *adequate*, and this condition is implied by the irreducibility condition (2) as long as $\ell \geq 2(n+1)$. The second novelty in 2.4 is the notion of potential diagonalizability. This is roughly the requirement that, after a finite base change, ρ_v, for v dividing ℓ, is crystalline and can be deformed in a moduli space of crystalline representations to a sum of characters. It is known that ρ_v in the Fontaine-Laffaille range (the setting of [21, 70]) and ordinary ρ_v (the setting of [5, 27]) are potentially diagonalizable, but the condition is more general. In particular, it is preserved under finite ramified base change, which allows for considerable flexibility.

2.3. Potential automorphy. The need to assume residual automorphy places important restrictions on the application of theorems on the model of 2.3 to reciprocity. For some applications, however, it is enough to know that a given ρ is *potentially* residually automorphic: that ρ becomes residually automorphic after base change to an unspecified totally real or CM Galois extension K'/K. One can then often use a modularity lifting theorem to prove that $\rho \mid_{\Gamma_{K'}}$ is automorphic, in other words that ρ is *potentially automorphic*. If ρ is attached to

a motive M, then $L(s,\rho) = L(s,M)$ is given by an Euler product that converges absolutely in some right half-plane. An application of Brauer's theorem on induced characters then implies that $L(s,\rho)$ has a *meromorphic* continuation to the entire plane, and moreover (by a theorem due to Shahidi and to Jacquet-Piatetski-Shapiro-Shalika) that $L(s,\rho)$ has no zeroes down to the right-hand edge of the critical strip.

Potential automorphy was introduced by Taylor in [68] in order to prove a potential version of the Fontaine-Mazur conjecture for 2-dimensional Galois representations. The method was generalized to higher dimensions in [39] and in subsequent work of Barnet-Lamb. The idea is the following. A theorem of the form 2.3 can be applied to an ℓ-adic ρ that is residually automorphic. But it can also be applied if $\rho = \rho_\ell$ is a member of a compatible family $\{\rho_{\ell'}\}$ of ℓ'-adic representations, where ℓ' varies over all primes, provided at least one ρ_{ℓ_1} in the family is known to be residually automorphic. It thus suffices to find a motive M of rank n such that

Hypothesis 2.7. *$\bar\rho_{\ell,M} \simeq \bar\rho$ and $\bar\rho_{\ell_1,M}$ is known a priori to be residually automorphic for some $\ell_1 \neq \ell$.*

Typically one assumes $\bar\rho_{\ell',M}$ is induced from an algebraic Hecke character. The motives used in [39] are the invariants M_t, under a natural group action, in the middle-dimensional cohomology of the $n-1$-dimensional hypersurfaces X_t with equation (depending on t, with $t^{n+1} \in \mathbb{P}^1 \setminus \{0,1,\infty\}$)

$$f_t(X_0,\dots,X_n) = (X_0^{n+1} + \cdots + X_n^{n+1}) - (n+1)tX_0\dots X_n = 0 \qquad (2.1)$$

This *Dwork family* of hypersurfaces was known to physicists for their role in the calculations that led to the formulation of the mirror symmetry conjectures [11]; and they were known to number theorists because Dwork had studied their cohomology in connection with p-adic periods.

The isomorphism class of X_t depends on t^{n+1} and one sees that their cohomology defines a hypergeometric local system over $\mathbb{P}^1 \setminus \{0,1,\infty\}$. Properties of this local system proved by a number of people, are used, together with a "local-global principle" due to Moret-Bailly, to find a t over a totally real (or CM) Galois extension K'/K such that M_t satisfies Hypothesis 2.7.

Applying the method of potential automorphy is not always automatic. One has to satisfy the conditions of Moret-Bailly's theorem as well as conditions (1), (2), and (3) of 2.3. More details can be found in [35] (which was written, however, before the simplifications of [72] and [3]). Here are a few applications:

Theorem 2.8. *Let $K = \mathbb{Q}$ and let Π be a cuspidal holomorphic automorphic representation of $GL(2)_{\mathbb{Q}}$ (attached to an elliptic modular form of weight $k \geq 2$, say) to which one can associate a compatible family of 2-dimensional ℓ-adic representations $\rho_{\ell,\Pi}$. Suppose Π is not obtained by automorphic induction from a Hecke character of an imaginary quadratic field. Then $Sym^n \rho_{\ell,\Pi}$ is potentially automorphic for all $n \geq 1$.*

This theorem was proved first when $k = 2$ in [21, 39, 70], assuming Π_v is a Steinberg representation for some v. This hypothesis was dropped, and was generalized to all k in [5]. It follows from the arguments of Serre in [63] and from the non-vanishing of $L(s, Sym^n\rho)$ mentioned above, that this implies the *Sato-Tate conjecture* for elliptic modular forms [5, 21, 39, 70]:

Theorem 2.9. *Let f be an elliptic modular newform of weight k for $\Gamma_0(N)$ (for some N), and assume the ℓ-adic Galois representations $\rho_{\ell,f}$ attached to f are not dihedral. For any prime p not dividing N, let $a_p(f)$ denote the eigenvalue of the normalized Hecke operator at p on f. Let $\tilde{a}_p(f) = a_p(f)/2p^{\frac{k-1}{2}}$, which is known to be a real number in the interval $[-1,1]$. As p varies, the $\tilde{a}_p(f)$ are equidistributed in $[-1,1]$ for the measure $\sqrt{1-t^2}dt$.*

In particular, if E is an elliptic curve over $\mathbb{Q}$ without complex multiplication, and $1+p-a_p(E)$ is the number of points of E over $\mathbb{F}_p$, then the numbers $a_p(E)/2p^{\frac{1}{2}}$ are equidistributed in in $[-1,1]$ for the measure $\sqrt{1-t^2}dt$.

The hypothesis that f has trivial nebentypus (is a form for $\Gamma_0(N)$) is unnecessary and was only included to allow for a simple statement. A version of 2.8 for Hilbert modular forms was proved by Barnet-Lamb, Gee, and Geraghty, and they derived the corresponding version of Theorem 2.9. All of these results were subsumed in the following theorem of Patrikis and Taylor [59], a strengthening of one of the main theorems of [3]:

Theorem 2.10. *Let K be totally real (resp. CM) and let $\{r_\lambda\}$ be a weakly compatible family of λ-adic representations of Γ_K (where λ runs over finite places of a number field M). Assume the r_λ are pure of fixed weight w (the Frobenius eigenvalues at an unramified place of norm q are Weil $q^{\frac{w}{2}}$-numbers); that they are HT-regular; and that they satisfy an appropriate polarization condition. Then there is a finite totally real (resp. CM) Galois extension K'/K over which the family becomes automorphic.*

The Hodge-Tate multiplicities of n-dimensional ℓ-adic representations realized on the cohomology of the Dwork family are at most 1; moreover, n has to be even, and each Hodge-Tate weight between 0 and $n-1$ occurs. Griffiths transversality implies that such a condition is inevitable when Hodge structures vary in non-trivial families. This appears to restrict the applicability of the Dwork family to proving potential automorphy. However, it was observed in [34], and more generally in [5], that it suffices to prove that a given $\rho_{\ell,\Pi}$ becomes automorphic after tensoring with the Galois representation obtained by induction from an automorphic Galois character attached to a Hecke character of an appropriate cyclic CM extension K'/K. This observation was applied in the proof of 2.9 and more systematically in [3], in both cases in order to replace the given Hodge-Tate weights of ρ by the set of weights adapted to the cohomology of the Dwork family.

Remark 2.11. Let f be as in Theorem 2.9 and Π the associated automorphic representation. Theorem 2.9 is equivalent to the assertion that, as p varies over primes unramified for $\rho_{\ell,\Pi}$, the conjugacy classes of $\rho_{\ell,f}(Frob_p)$, normalized so that all eigenvalues have complex absolute value 1, are equidistributed in the space of conjugacy classes of $SU(2)$. A version of the Sato-Tate conjecture can be formulated for a general motive M; $SU(2)$ is replaced by the derived subgroup of the compact real form of the Mumford-Tate group $MT(M)$ of M. In order to prove this conjecture for more complicated $MT(M)$ one would have to be able to prove the corresponding generalization of Theorem 2.8, with the symmetric powers replaced by the full set of equivalence classes of irreducible representations σ of $MT(M)^{der}$. But even if the ℓ-adic representation $\rho_{\ell,M}$ attached to M is HT-regular, $\sigma \circ \rho_{\ell,M}$ is generally not HT-regular, and thus cannot be obtained by Theorem 2.2. Thus one has no way to start proving potential automorphy of $\sigma \circ \rho_{\ell,M}$ once $MT(M)^{0,der}$ is of rank greater than 1.

2.3.1. p-adic realization of very general Galois representations. It was mentioned above that the proof of 2.2 is completed by a p-adic approximation argument. One says more gen-

erally that a p-adic representation $\rho : \Gamma_{K,S} \to GL(n, \overline{\mathbb{Q}}_p)$ for some S is *p-adically automorphic* if $\rho = \lim_i \rho_i$ (for example, in the sense of pseudo-representations, where the limit can be in the Zariski or in the p-adic topology), where each ρ_i is an automorphic Galois representation of $\Gamma_{K,S}$. The theory of eigenvarieties shows that p-adically automorphic Galois representations vary in p-adic analytic families. The representations $\rho_{p,\Pi}$ of 2.2 are HT-regular because Π is cohomological, but analytic families of p-adically automorphic Galois representations can specialize to representations that are Hodge-Tate but not regular, and to representations that are not Hodge-Tate at all.

One can ask whether a given ρ is p-adically automorphic. There are discrete obstructions; for example the set of ramified primes is finite in any p-adic family. There are also sign obstructions. The 2-dimensional Galois representations $\rho_{\ell,f}$ attached to an elliptic modular form f are *odd*: $\det \rho_{\ell,f}(c) = -1$ when c is complex conjugation. In other words, no representation ρ for which $\det \rho_{\ell,f}(c) = 1$ can be obtained in the cohomology of a Shimura variety. The signature of complex conjugation is constant on p-adic analytic families of Galois representations, and therefore represents an obstruction to realizing such an *even* representation as a p-adically automorphic representation.

However, the direct sum of two even representations does not necessarily have such a sign obstruction. Similar discrete invariants characterize p-adically automorphic Galois representations in higher dimension, but they can be made to vanish upon taking appropriate direct sums. Say ρ is *p-adically stably automorphic* if $\rho \oplus \rho'$ is p-adically automorphic for some ρ'. One knows what this means if K is a totally real or CM field. If not, let $K_0 \subset K$ be the maximal totally real or CM subfield, and say a p-adic representation ρ is *p-adically stably automorphic* if $\rho \oplus \rho'$ is the restriction to Γ_K of a p-adically automorphic representation of Γ_{K_0}.

Question 2.12. *Is every p-adic representation of Γ_K that satisfies the Fontaine-Mazur axioms stably p-adically automorphic?*

The main theorem of [30] states, roughly, that *every* p-adic representation of Γ_K is "stably potentially residually automorphic," where the reader is invited to guess what that means.

One can often define analytic or geometric invariants of p-adic families by interpolation of their specializations to automorphic points. Thus one defines p-adic L-functions or Galois cohomology (Selmer groups) of p-adic families. Specializations to points not known to be automorphic (e.g., because they are not HT-regular) define invariants of the corresponding Galois representations.

2.3.2. Prospects for improvement.

(a) Condition (1) in Theorem 2.4 corresponds to the polarization condition in (b) of Theorem 2.2. At present no one knows how to remove this condition and thus to prove the reciprocity conjecture for all representations constructed in Theorem 2.2 (see, however, the articles [10] of Calegari and Geraghty and [31] of Hansen). Removing condition (1) is sufficient, and probably necessary, to show that the $\rho_{\ell,\Pi}$ of Theorem 2.2 are irreducible for (almost) all ℓ.

(b) Although we have seen that substitutes can be found for residual irreducibility in applications to compatible families, it remains a major obstacle for many applications. In addition to the argument applied in Skinner-Wiles for 2-dimensional representations of $\Gamma_{\mathbb{Q}}$, Thorne has recently found a new method based on level raising [73].

(c) The article [70] replaces the very deep questions regarding congruences between automorphic forms of different levels ("level-raising", which an earlier version of [21] proposed to solve by generalizing Ihara's Lemma on congruences between elliptic modular forms) by a careful study of the singularities of certain varieties of tame representations of local Galois groups. But this comes at the cost of losing control of nilpotents in the deformation rings. In particular, current methods cannot classify liftings of $\bar{\rho}$ to rings in which ℓ is nilpotent. This may be important if one wants to extend the results of this section to the torsion representations constructed by Scholze.

(d) Dieulefait has expanded on the ideas used by Khare and Wintenberger to prove the Serre conjecture and has proved some astonishing results. For example, he has proved base change of elliptic modular forms to any totally real extension [23]. The methods of [46] and of [23] do not assume residual automorphy but actually prove it in the cases they consider. It is not yet known whether or not these methods can be applied in higher dimension.

(e) The authors of [3] ask whether every potentially crystalline representation is potentially diagonalizable. An affirmative answer would expand the range of their methods. The regularity hypothesis of Condition (3) seems insuperable for the moment. At most one can hope to prove reciprocity for representations like those constructed in [28], with Hodge-Tate multiplicities at most 2. The recent proof by Pilloni and Stroh of the Artin conjecture for (totally odd) 2-dimensional complex representations of Γ_K, when K is totally real, is the strongest result known in this direction. As long as one has no method for constructing automorphic Galois representations with Hodge-Tate multiplicities 3 or greater, the reciprocity question for such representations will remain inaccessible.

3. Critical values of automorphic L-functions

3.1. Critical values and automorphic motives. Let M be a (pure) motive of rank n over a number field K, with coefficients in a number field E. By restriction of scalars we can and will regard M as a motive of rank $n[K : \mathbb{Q}]$ over $\mathbb{Q}$. The values at integer points of the L-function $L(s, M)$ are conjectured to contain deep arithmetic information about M. If, for example, $M = M(A)$ is the motive attached to the cohomology in degree 1 of an abelian variety A, then the value, or more generally the first non-vanishing derivative, of $L(s, M(A))$ at $s = 1$ is predicted by the Birch-Swinnerton-Dyer conjecture. This is the only *critical value* of $L(s, M(A))$, in the sense of Deligne (the importance of critical values had previously been noted by Shimura). Deligne formulated his conjecture on critical values in one of his contributions to the 1977 Corvallis conference. We follow Deligne in working with motives for absolute Hodge cycles; thus M is by definition a collection of compatible realizations in the cohomology of smooth projective algebraic varieties. The realization in ℓ-adic cohomology gives the Galois representation $\rho_{\ell,M}$ on an ℓ-adic vector space M_ℓ, and therefore determines $L(s, M)$. Extension of scalars from $\mathbb{Q}$ to $\mathbb{C}$ makes M a motive over $\mathbb{C}$, whose cohomology is thus a direct factor of the cohomology of a complex manifold, whose topological cohomology is a $\mathbb{Q}$-vector space called M_B (Betti realization). Complex conjugation on the points of $M(\mathbb{C})$ acts on M_B as an involution F_∞. As a motive over $\mathbb{Q}$, M also has the algebraic de Rham cohomology, a $\mathbb{Q}$-vector space M_{dR} with a decreasing

Hodge filtration $\dots F^q M_{dR} \subset F^{q-1} M_{dR} \dots$ by $\mathbb{Q}$-subspaces. For any integer m let $M(m)$ denote the Tate twist $M \otimes \mathbb{Q}(m)$. Hodge theory defines comparison isomorphisms

$$I(m)_{M,\infty} : M(m)_B \otimes \mathbb{C} \xrightarrow{\sim} M(m)_{dR} \otimes \mathbb{C}.$$

This isomorphism does not respect the rational structures on the two sides. By restricting $I(m)_{M,\infty}$ to the $+1$-eigenspace of F_∞ in $M(m)_B$ and then projecting on a certain quotient $M(m)_{dR}/F^q M(m)_{dR} \otimes \mathbb{C}$, one defines an isomorphism between two complex vector spaces of dimension roughly half that of M, provided $M(m)$ is *critical* in Deligne's sense. The determinant of this isomorphism, calculated in rational bases of the two sides, is the *Deligne period* $c^+_{\mathbb{Q}}(M(m))$. It is a determinant of a matrix of integrals of rational differentials in M_{dR} over rational homology cycles, and is well defined up to $\mathbb{Q}^\times$-multiples. More generally, if M is a *motive with coefficients in* a number field E – in other words, if there are actions of E on each of the vector spaces M_B, M_{dR}, M_ℓ, compatible with the comparison isomorphisms – then there is a Deligne period $c^+_E(M(m))$ well-defined up to $E^\times$-multiples; moreover, $L(s, M)$ then defines an element of $E \otimes \mathbb{C}$, as in [22]. In the following discussion we will drop the subscript and just write $c^+(M(m))$ for the Deligne period with coefficients.

We call $s = m$ a *critical value* of $L(s, M)$ if $M(m)$ is critical. The set of critical m can be read off from the Gamma factors in the (conjectural) functional equation of $L(s, M)$ ([22], Definition 1.3). When $M = M(A)$, $s = 1$ is the only critical value. Deligne's conjecture is the assertion that

Conjecture 3.1 ([22]). *If m is a critical value of the motive M with coefficients in E, then*

$$L(m, M)/c^+(M(m)) \in E^\times.$$

Beilinson's conjectures express the non-critical integer values of $L(s, M)$ at non-critical integers in terms of the motivic cohomology (higher algebraic K-theory) of M. Automorphic methods give very little information about non-critical values of the L-functions of motives that can be related to automorphic forms, and this survey has nothing to say about them. On the other hand, the de Rham realizations of the motives that arise in the cohomology of Shimura varieties are given explicitly in terms of automorphic forms. One can therefore state versions of Deligne's conjecture for certain of these motives entirely in the language of automorphic forms.[5] The literature on special values of L-functions is vast and a book-length survey is long overdue. Automorphic versions of Deligne's conjecture represent a relatively small segment of the literature that is still too extensive for treatment in the space of this article. The proofs are generally quite indirect, not least because one can rarely write down M_B in terms of automorphic forms. When M is realized in the cohomology (with coefficients) of a Shimura variety $S(G)$, one can occasionally define non-trivial classes in M_B by projecting onto M the cycles defined by Shimura subvarieties $S(G') \subset S(G)$. Integrating differential forms on $S(G) \times S(G)$ over the diagonal cycle $S(G)$ amounts to computing a

[5] Strictly speaking, Deligne's conjecture only makes sense in the setting of a theory of motives that is the subject of very difficult conjectures. For example, one expects that if M and M' are motives such that the triples $(M_B, M_{dR}, I(m)_{M,\infty})$ and $(M'_B, M'_{dR}, I(m)_{M',\infty})$ are isomorphic, then M and M' are isomorphic as motives. This would follow from the Hodge conjecture. Similarly, one assumes that $L(s, M) = L(s, M')$ implies that $M \simeq M'$; this would follow from the Tate conjecture.

Blasius's proof of Deligne's conjecture for L-functions of Hecke characters of CM fields is carried out within the framework of motives for absolute Hodge cycles. It is practically the only authentically motivic result known in this direction.

cohomological cup product. In this brief account we limit our attention to a class of motives whose Deligne periods can be factored as products of cup products of this kind.

Suppose K is a CM field. As explained in 2.1.1, most of the representations $\rho_{\ell,\Pi}$ of Γ_K are realized in the cohomology of a Shimura varieties $S(G)$ attached to unitary groups G. Along with the n-dimensional Galois representation this construction yields a candidate for the rank n motive $M(\Pi)$. Originally $M(\Pi)$ is defined over K; one obtains a motive $RM(\Pi) = R_{K/\mathbb{Q}}M(\Pi)$ by restriction of scalars to $\mathbb{Q}$, taking into account the theorem of Borovoi and Milne on conjugation of Shimura varieties (the Langlands conjecture). The spaces $RM(\Pi)_{dR}$ and $RM(\Pi)_B$ satisfy analogues of conditions (1) and (3) of Theorem 2.4. The regularity condition (3) implies there is a set of integers $q_1 < q_2 < \cdots < q_n$ such that $\dim_E F^q RM(\Pi)_{dR}/F^{q+1}RM(\Pi)_{dR} = 1$ if and only if $q = q_i$ for some i, and the dimension is 0 otherwise. Here $E = E(\Pi)$ is the field of coefficients of $RM(\Pi)$ (more precisely, E is a finite product of number fields). We choose a non-zero $\mathbb{Q}$-rational E-basis ω_i of $F^{q_i}RM(\Pi)_{dR}/F^{q_{i+1}}RM(\Pi)_{dR}$, view ω_i as a (vector-valued) automorphic form on $G(\mathbb{Q})\backslash G(\mathbf{A})$, and let $Q_i(\Pi) =< \omega_i, \omega_i >$ denote its appropriately normalized L_2 inner product with itself.

Conjecture 3.2. *Up to multiplication by $E^\times$, each $Q_i(\Pi)$ depends only on the automorphic representation Π of $GL(n)$ and not on the realization in the cohomology of a Shimura variety.*

This conjecture is implied by the Tate conjecture. It has been verified in many cases for the (holomorphic) period $Q_1(\Pi)$. The author has partial results for general $Q_i(\Pi)$.

Given any motive M of rank n satisfying conditions (1) and (3) of 2.4 we can define invariants $Q_i(M)$ in the same way, and a determinant factor $q(M)$ (for this and what follows, see [32, 36], and section 4 of [29]). For any integer $0 \leq r \leq n$ we write

$$P_{\leq r}(M) = q(M)^{-1} \cdot \prod_{i \leq r} Q_i(M).$$

Let M' be a second motive of rank n', satisfying conditions (1) and (3) of 2.4. Then for any integer m critical for $R_{K/\mathbb{Q}}(M \otimes M')$ there is a factorization (cf. [29] (4.11)):

$$c^+(R(M \otimes M')(m)) \sim (2\pi i)^{c(m,n,n')} \prod_{r=1}^{n} P_{\leq r}(M)^{a_r} \prod_{r'=1}^{n'} P_{\leq r'}(M')^{b_{r'}} \tag{3.1}$$

where $\sim$ means that the ratio of the two sides lies in the multiplicative group of the coefficient field, $c(m,n,n')$ is an explicit polynomial in m and the dimensions, $0 \leq a_r := a(r, M, M'), b_{r'} := b(r', M, M')$ and

$$\sum_r a_r \leq n'; \quad \sum_{r'} b_{r'} \leq n.$$

Defining Π as above, there is an (ad hoc) determinant factor $q(\Pi)$, and we let

$$P_{\leq r}(\Pi) = q(\Pi)^{-1} \cdot \prod_{i \leq r} Q_i(\Pi).$$

An automorphic version of Deligne's conjecture is

Conjecture 3.3. *Let Π and Π' be cuspidal automorphic representations of $GL(n)_K$ and $GL(n')_K$, satisfying the hypotheses of Theorem 2.2 (b). Let m be a critical value of*

$$L(s, R_{K/\mathbb{Q}}(M(\Pi) \otimes M(\Pi')) = L(s - \frac{n+n'-2}{2}, \Pi \times \Pi').$$

Then

$$L(m, R_{K/\mathbb{Q}}(M(\Pi) \otimes M(\Pi'))) \sim (2\pi i)^{c(m,n,n')} \prod_{r=1}^{n-1} P_{\leq r}(\Pi)^{a_r} \prod_{r'=1}^{n-2} P_{\leq r'}(\Pi')^{b_{r'}},$$

with a_r, $b_{r'}$ as in (3.1)*.*

The integers a_r and $b_{r'}$ of (3.1) are determined purely by the relative position of the Hodge decompositions of $M_{dR} \otimes \mathbb{C}$ and $M'_{dR} \otimes \mathbb{C}$ (and don't depend on m). Suppose $M = RM(\Pi)$, $M' = RM(\Pi')$, with Π and Π' as in (3.3). The regularity hypotheses imply that there are finite-dimensional representations $W(\Pi_\infty)$ and $W'(\Pi'_\infty)$ of $GL(n)_K$ and $GL(n')_K$, respectively, such that Π_∞ and $W(\Pi_\infty)$ (resp. Π'_∞ and $W'(\Pi'_\infty)$) have the same infinitesimal characters. The a_i and $b_{i'}$ can be computed explicitly in terms of the highest weights of $W(\Pi_\infty)$ and $W'(\Pi'_\infty)$. For example, suppose $n' = n-1$ and

$$Hom_{GL(n-1,K\otimes\mathbb{C})}(W(\Pi_\infty) \otimes W(\Pi'_\infty), \mathbb{C}) \neq 0. \tag{3.2}$$

Then $a_i = b_{i'} = 1, 1 \leq i \leq n-1; 1 \leq i' \leq n-2$; $a_n = b_{n-1} = 0$.

Theorem 3.4. *Suppose K is an imaginary quadratic field. Let Π and Π' be as in 3.3. Suppose moreover that the infinitesimal characters of Π_∞ and Π'_∞ satisfy 3.2 and are sufficiently regular. Then there are constants $c'(m, \Pi_\infty, \Pi'_\infty)$ such that*

$$L(m, R_{K/\mathbb{Q}}(M(\Pi) \otimes M(\Pi')))/[c'(m, \Pi_\infty, \Pi'_\infty) \prod_{r=1}^{n-1} P_{\leq r}(\Pi) \prod_{r'=1}^{n-2} P_{\leq r'}(\Pi')] \in \overline{\mathbb{Q}} \tag{3.3}$$

for every critical value m.

This is a reinterpretation of Theorem 1.2 of [29]. There the invariants $P_{\leq r}(\Pi)$ are replaced by complex numbers $P^{(r)}(\Pi)$, which are Petersson square norms of *holomorphic* automorphic forms on unitary Shimura varieties of different signatures (and it is shown that the quotient in (3.3) lies in a specific number field). Naturally one expects the constants $c'(m, \Pi_\infty, \Pi'_\infty)$ to be powers of $2\pi i$. The Tate conjecture implies an identity between the two kinds of invariants, and this has been proved (up to unspecified archimedean factors, and up to $\overline{\mathbb{Q}}$-multiples) in [33] (and subsequent unpublished work).

The methods of [29] are based on interpreting the Rankin-Selberg integral for $GL(n) \times GL(n-1)$ as a cohomological cup product. Such arguments have been used previously by Mahnkopf and Raghuram; see [60] for the most general results in this direction. Earlier results on this problem were conditional on the conjecture that certain archimedean zeta integrals did not vanish identically. Sun's recent proof of this conjecture [66] has revived interest in the problem and one can expect rapid progress in the next few years. For general number fields one does not have the analogues of the invariants $P_{\leq r}(\Pi)$ and the results of [60] are expressed in terms of period invariants obtained by comparing the cohomological rational structure of Π with one defined by Whittaker models. The (mild) regularity hypothesis of 3.4

is required in the comparison of these Whittaker period invariants with the motivic invariants $P_{\leq r}(\Pi)$. Similar arguments should suffice to treat the cases of Conjecture 3.3 for $n' \leq n-1$ that satisfy an analogue of (3.2), for general CM fields. (The case where $n' = 1$ was treated by the author in a series of papers, starting with [32], and is used crucially in the proof of Theorem 3.4.) The full scope of the methods of [29] is not yet clear, but it is certain that it is not limited to the situation of (3.2). The identification of $c'(m, \Pi_\infty, \Pi'_\infty)$ with the invariant $(2\pi i)^{c(m,n,n-1)}$ is likely to follow from these methods as well.[6]

3.2. How general are these results? Only a restricted class of Galois representations can be obtained using the cohomology of Shimura varieties, and only those that can be realized directly in the cohomology are associated to motives that admit an automorphic interpretation. The Rankin-Selberg L-functions described in the previous section, along with a few related constructions (symmetric and exterior squares and adjoint L-functions), seem to be the only ones whose critical values can be analyzed by automorphic methods. Raghuram's results in [60] apply only under the hypothesis (3.2). It should be straightforward to generalize his methods to pairs Π, Π' where Π is cuspidal and Π' is an essentially tempered cohomological Eisenstein series, as in [29] (or earlier work of Mahnkopf). If Raghuram's results could be extended to cases where neither Π nor Π' is cuspidal, then the hypothesis (3.2) would be superfluous (in Theorem 3.4 as well).

A motivic analysis of critical values of Rankin-Selberg L-functions, as in Theorem 3.4, has thus far only been carried out for CM fields. Bhagwat has proved an analogue of the relation (3.1) when $K = \mathbb{Q}$, following earlier work of Yoshida (see the appendix to [60]) and similar factorizations must hold for totally real fields. As far as I know, no one has proposed automorphic interpretations of the terms that occur in Bhagwat's factorization. For Π satisfying the polarization condition as in (b) of Theorem 2.2 it should be possible to interpret some of them as periods of motives realized in the cohomology of Shimura varieties attached to special orthogonal groups of signature $(2, n)$. In the absence of a polarization condition, Shimura varieties seem to be of no help.

3.3. Exact formulas for the central critical value. The conjectures of Bloch-Kato and Fontaine-Perrin-Riou give exact formulas for special values of motivic L-functions. The algebraic quotients $L(m, M)/c^+(M(m))$ and their generalizations to non-critical values are expressed explicitly as products of local and global algebraic factors defined in terms of Galois cohomology. For the central critical value these expressions generalize the Birch-Swinnerton-Dyer conjecture for the value at $s = 1$ of $L(s, M(A))$, in the notation of the previous section.

Beginning with the thesis of Waldspurger, exact formulas have also been found for certain central values of automorphic L-functions. The conjecture of Ichino-Ikeda, and its version for unitary groups formulated by N. Harris, [42, 45] give exact formulas for central values in the framework of the Gan-Gross-Prasad conjectures [26]. In what follows K is a CM field. We change notation and let Π denote a cuspidal automorphic representation of $GL(n)_K$ that descends to a (cuspidal) L-packet $P_{\Pi,V}$ of a given $G = U(V)$, viewed as group over K^+, with $\dim V = n$. Similarly, Π' is an automorphic representation of $GL(n-1)_K$ obtained by base change from a (cuspidal) L-packet $P_{\Pi',V'}$ of $G' = U(V')$. It

[6] Note added in proof. This has now been carried out, at least when the coefficients are sufficiently regular, by Lin Jie.

is assumed that V' embeds in V as a non-degenerate hermitian subspace of codimension 1. For any $\pi \in P_{\Pi,V}$ and $\pi' \in P_{\Pi',V'}$, the pairing

$$I = \pi \otimes \pi' \ \to \ \mathbb{C} : \ \ f \otimes f' \mapsto \int_{G'(K^+)\backslash G'(\mathbf{A})} f(g')f'(g')dg', \ f \in \pi, \ f' \in \pi' \qquad (3.4)$$

is invariant under the diagonal action of $G'(\mathbf{A})$. One of the Gan-Gross-Prasad conjectures asserts that the space of such invariant pairings is of dimension 1 for exactly one pair (V, V') and one pair $(\pi, \pi') \in P_{\Pi,V} \times P_{\Pi',V'}$, and that the lucky pair is identified by a complicated formula involving root numbers. The non-archimedean part of this conjecture has been proved by R. Beuzart-Plessis, following the method used by Waldspurger to solve the analogous conjecture for special orthogonal groups [7, 74]. Thus if one fixes a non-trivial pairing $B : \pi \otimes \pi' \ \to \ \mathbb{C}$, the pairing I defined in 3.4 is a multiple of B. The Ichino-Ikeda Conjecture can be seen as a determination of this multiple. In the statement of the conjecture, the superscript $^\vee$ denotes contragredient; all integrals are taken with respect to Tamagawa measure.

Conjecture 3.5 ([45]). *Let $f \in \pi$, $f' \in \pi'$, $f^\vee \in \pi^\vee$, $f'^{,\vee} \in \pi'^{,\vee}$, and suppose all four vectors are factorizable. Then*

$$\frac{I(f, f') \cdot I(f^\vee, f'^{,\vee})}{< f, f^\vee >_2 < f', f'^{,\vee} >_2} = 2^{-r} \prod_{v \in S} Z_v(f, f', f^\vee, f'^{,\vee}) \cdot \Delta \cdot \frac{L(\frac{1}{2}, \Pi \times \Pi')}{L(1, \pi, Ad)L(1, \pi', Ad)}.$$

Here $< \bullet, \bullet >_2$ are the L_2 pairings, the factor 2^{-r} is trivial when Π and Π' are cuspidal but not in general, S is the set of ramified primes for π, π', and the chosen vectors, including archimedean primes, the Z_v for $v \in S$ are normalized integrals of matrix coefficients attached to the data, Δ is a special value of a finite product of abelian L-functions (the L-function of the Gross motive), the numerator on the right-hand side is the Rankin-Selberg product for $GL(n) \times GL(n-1)$, and the factors in the denominator are the Langlands L-functions for G and G' attached to the adjoint representations of their L-groups.

Here and elsewhere, $L(s, \bullet)$ denotes the non-archimedean Euler product. The L-functions in the right-hand side are given the unitary normalization. Thus the completed L-function $\Lambda(s) = L_\infty(s, \Pi \times \Pi') \cdot L(s, \Pi \otimes \Pi')$ in the numerator of the right-hand side always satisfies $\Lambda(s) = \pm\Lambda(1-s)$. When Π and Π' satisfy (b) of 2.2, however, there is a second (motivic) normalization as well, in which the value $s = \frac{1}{2}$ is replaced by an integer value, and all the values of L-functions that occur in the right-hand side are critical.

Conjecture 3.5 is of no interest when the sign is -1, because the numerator vanishes trivially. When the L-function is motivic, there have been proposals for an arithmetic substitute for the conjecture in this case, with $L(\frac{1}{2}, \bullet)$ replaced by its derivative at $s = \frac{1}{2}$, along the lines of the Gross-Zagier conjecture and subsequent work. When the sign is $+1$, the conjecture refines the global Gan-Gross-Prasad conjecture, which asserts that $L(\frac{1}{2}, \Pi \times \Pi') = 0$ if and only if the pairing I of 3.4 is trivial.

When $L(\frac{1}{2}, \Pi \times \Pi') \neq 0$, Conjecture 3.5 gives an exact expression for its value, provided one can make good choices of the test vectors $f, f', f^\vee, f'^{,\vee}$ and can control the local zeta integrals. It is natural to speculate that these zeta integrals can be interpreted in terms of local Galois cohomological information, and that when Π and Π' are attached to motives, the expressions on the two sides of Conjecture 3.5 can be matched termwise with corresponding expressions in the Bloch-Beilinson and Bloch-Kato conjectures. The local factor

$Z_v(f, f', f^\vee, f'^{,\vee})$ is the integral of the matrix coefficient of π_v attached to the pair $(f_v, f_v^\vee)$ against the matrix coefficient of π'_v attached to $(f'_v, f'^{,\vee}_v)$. The following question is deliberately vague.

Question 3.6. *For any given pair of local (ramified) representations π_v, π'_v, is there a quadruple $f_v, f'_v, f_v^\vee, f'^{,\vee}_v$ such that the local zeta integral $Z_v(f, f', f^\vee, f'^{,\vee})$ exactly equals the local Galois-cohomological factor in the Bloch-Kato conjecture?*

As explained in [37], the expressions on the left-hand side are algebraic multiples of invariants called *Gross-Prasad periods* that depend only on Π and Π', provided the test vectors are chosen to be rationally normalized (with respect to coherent cohomology). The denominators are closely related to the $P_{\leq r}$ defined above. Combining Conjecture 3.5 with Conjecture 3.3, one gets conjectural expressions for the Gross-Prasad periods as well in terms of $P_{\leq r}(\pi)$ and $P_{\leq r'}(\pi')$; see [37], Conjecture 5.16.

In order to compare the local terms of Conjecture 3.5 with the Galois-cohomological data of the Bloch-Kato conjecture, *integral* normalizations of the test vectors are needed. It is well known, however, that even the module of elliptic modular forms with integral modular Fourier coefficients is not spanned by Hecke eigenfunctions. This is the phenomenon of *congruences* between Hecke eigenvalues for different automorphic representations, which is the subject of theorems of the form 2.3, and it is no less relevant to automorphic representations of groups other than $GL(2)$.

3.3.1. Adjoint L-functions. The denominator of the Ichino-Ikeda formula is relevant to the problem of integral normalization of test vectors. The point $s = 1$ is the only critical value of the adjoint L-functions that occur there. Suppose π has an associated motive $M(\Pi) = M(\pi)$. Then for any prime ℓ, the Bloch-Kato conjecture identifies the ℓ-adic valuation of the quotient of $L(1, \pi, Ad)$ by an (integrally normalized) Deligne period with the order of a Galois cohomology group that is supposed to count the number of ℓ-adic deformations of the residual Galois representation $\bar\rho_{\ell,\pi}$. When $n = 2$ and K is totally real, a version of this conjecture has been proved by Diamond-Flach-Guo and Dimitrov, combining the methods of Theorem 2.4 with the results of [44].

Hida's paper [44] was the starting point for his theory of families of modular forms, and was the first to establish a relation between the critical value of the adjoint L-function and congruences between modular forms. In dimension $n > 2$, the special cases of the Ichino-Ikeda conjecture proved by Wei Zhang in [75] are used in [29] to relate the Whittaker period of a Π satisfying (b) of Theorem 2.2 to $L(1, \pi, Ad)$, up to rational multiples. One hopes this provides a starting point for determining $L(1, \pi, Ad)$ up to units in number fields, as required by the Bloch-Kato conjecture.

3.4. Two speculative remarks on automorphic p-adic L-functions.

Remark 3.7. Deligne's conjecture is the starting point of the construction of p-adic L-functions. The algebraic values on the left-hand side of the identify in 3.1, suitably normalized, are predicted to extend analytically whenever M and m vary in p-adic families. The literature is vast but fragmentary, and the author's ongoing project with Eischen, Li, and Skinner will only add one (rather bulky) fragment to the collection when it is finished. Current plans are limited to *ordinary* (Hida) families, but ultimately one expects the method to extend to completely general families. In particular, such p-adic L-functions could be

specialized to the "very general" p-adic representations of 2.3.1. Moreover, using Brauer induction, one could even attach a p-adic L-functions to a motivic Galois representation $\rho_{p,M}$ that is potentially p-adically automorphic. Although such a function would have no obvious connection to the complex L-function of M, it could conceivably be related to the Galois cohomology of $\rho_{p,M}$.

Remark 3.8. One can study the behavior of the right-hand side of Conjecture 3.5 when Π and Π' vary in p-adic families. Given the right choice of data in the local zeta integrals at primes dividing p, the result should be a p-adic meromorphic function of Π and Π'. Can this function be constructed directly on the left-hand side of the identity?

Acknowledements. The research leading to these results has received funding from the European Research Council under the European Community's Seventh Framework Programme (FP7/2007-2013) / ERC Grant agreement no. 290766 (AAMOT). I thank Matt Emerton, Toby Gee, Mark Kisin, and Gaëtan Chenevier for their careful reading of earlier versions of this manuscript.

The ternary Goldbach problem

Harald Andrés Helfgott

Abstract. The ternary Goldbach conjecture, or three-primes problem, states that every odd number n greater than 5 can be written as the sum of three primes. The conjecture, posed in 1742, remained unsolved until now, in spite of great progress in the twentieth century. In 2013 – following a line of research pioneered and developed by Hardy, Littlewood and Vinogradov, among others – the author proved the conjecture. In this, as in many other additive problems, what is at issue is really the proper usage of the limited information we possess on the distribution of prime numbers. The problem serves as a test and whetting-stone for techniques in analysis and number theory – and also as an incentive to think about the relations between existing techniques with greater clarity. We will go over the main ideas of the proof. The basic approach is based on the circle method, the large sieve and exponential sums. For the purposes of this overview, we will not need to work with explicit constants; however, we will discuss what makes certain strategies and procedures not just effective, but efficient, in the sense of leading to good constants. Still, our focus will be on qualitative improvements.

Mathematics Subject Classification (2010). Primary 11P32.

Keywords. Analytic number theory, additive problems, prime numbers.

The question we will discuss, or one similar to it, seems to have been first posed by Descartes, in a manuscript published only centuries after his death [14, p. 298]. Descartes states: "Sed & omnis numerus par fit ex uno vel duobus vel tribus primis" ("But also every even number is made out of one, two or three prime numbers.") This statement comes in the middle of a discussion of sums of polygonal numbers, such as the squares.

Statements on sums of primes and sums of values of polynomials (polygonal numbers, powers n^k, etc.) have since shown themselves to be much more than mere curiosities – and not just because they are often very difficult to prove. Whereas the study of sums of powers can rely on their algebraic structure, the study of sums of primes leads to the realization that, from several perspectives, the set of primes behaves much like the set of integers – and that this is truly hard to prove.

If, instead of the primes, we had a random set of odd integers S whose density – an intuitive concept that can be made precise – equaled that of the primes, then we would expect to be able to write every odd number as a sum of three elements of S, and every even number as the sum of two elements of S. We would have to check by hand whether this is true for small odd and even numbers, but it is relatively easy to show that, after a long enough check, it would be very unlikely that there would be any exceptions left among the infinitely many cases left to check.

The question, then, is in what sense we need the primes to be like a random set of integers; in other words, we need to know what we can prove about the regularities of the

Proceedings of the International Congress of Mathematicians, Seoul, 2014

distribution of the primes. This is one of the main questions of analytic number theory; progress on it has been very slow and difficult. Thus, the real question is how to use well the limited information we do have on the distribution of the primes.

1. History and new developments

The history of the conjecture starts properly with Euler and his close friend, Christian Goldbach, both of whom lived and worked in Russia at the time of their correspondence – about a century after Descartes' isolated statement. Goldbach, a man of many interests, is usually classed as a serious amateur; he seems to have awakened Euler's passion for number theory, which would lead to the beginning of the modern era of the subject [71, Ch. 3, §IV]. In a letter dated June 7, 1742 – written partly in German, partly in Latin – Goldbach made a conjectural statement on prime numbers, and Euler rapidly reduced it to the following conjecture, which, he said, Goldbach had already posed to him: every positive integer can be written as the sum of at most three prime numbers.

We would now say "every integer greater than 1", since we no long consider 1 to be a prime number. Moreover, the conjecture is nowadays split into two:

- the *weak*, or ternary, Goldbach conjecture states that every odd integer greater than 5 can be written as the sum of three primes;
- the *strong*, or binary, Goldbach conjecture states that every even integer greater than 2 can be written as the sum of two primes.

As their names indicate, the strong conjecture implies the weak one (easily: subtract 3 from your odd number n, then express $n-3$ as the sum of two primes).

The strong conjecture remains out of reach. A short while ago – the first complete version appeared on May 13, 2013 – the present author proved the weak Goldbach conjecture.

Main Theorem. *Every odd integer greater than* 5 *can be written as the sum of three primes.*

The proof is contained in the preprints [28], [27], [29]. It builds on the great progress towards the conjecture made in the early 20th century by Hardy, Littlewood and Vinogradov. In 1937, Vinogradov proved [67] that the conjecture is true for all odd numbers n larger than some constant C. (Hardy and Littlewood had shown the same under the assumption of the Generalized Riemann Hypothesis, which we shall have the chance to discuss later.)

It is clear that a computation can verify the conjecture only for $n \leq c$, c a constant: computations have to be finite. What can make a result coming from analytic number theory be valid only for $n \geq C$?

An analytic proof, generally speaking, gives us more than just existence. In this kind of problem, it gives us more than the possibility of doing something (here, writing an integer n as the sum of three primes). It gives us a rigorous estimate for the number of ways in which this *something* is possible; that is, it shows us that this number of ways equals

$$\text{main term} + \text{error term}, \tag{1.1}$$

where the main term is a precise quantity $f(n)$, and the error term is something whose absolute value is at most another precise quantity $g(n)$. If $f(n) > g(n)$, then (1.1) is nonzero, i.e., we will have shown that the existence of a way to write our number as the sum of three primes.

(Since what we truly care about is existence, we are free to weigh different ways of writing n as the sum of three primes however we wish – that is, we can decide that some primes "count" twice or thrice as much as others, and that some do not count at all.)

Typically, after much work, we succeed in obtaining (1.1) with $f(n)$ and $g(n)$ such that $f(n) > g(n)$ asymptotically, that is, for n large enough. To give a highly simplified example: if, say, $f(n) = n^2$ and $g(n) = 100n^{3/2}$, then $f(n) > g(n)$ for $n > C$, where $C = 10^4$, and so the number of ways (1.1) is positive for $n > C$.

We want a moderate value of C, that is, a C small enough that all cases $n \leq C$ can be checked computationally. To ensure this, we must make the error term bound $g(n)$ as small as possible. This is our main task. A secondary (and sometimes neglected) possibility is to rig the weights so as to make the main term $f(n)$ larger in comparison to $g(n)$; this can generally be done only up to a certain point, but is nonetheless very helpful.

As we said, the first unconditional proof that odd numbers $n \geq C$ can be written as the sum of three primes is due to Vinogradov. Analytic bounds fall into several categories, or stages; quite often, successive versions of the same theorem will go through successive stages.

1. An *ineffective* result shows that a statement is true for some constant C, but gives no way to determine what the constant C might be. Vinogradov's first proof of his theorem (in [67]) is like this: it shows that there exists a constant C such that every odd number $n > C$ is the sum of three primes, yet gives us no hope of finding out what the constant C might be.[1] Many proofs of Vinogradov's result in textbooks are also of this type.
2. An *effective*, but not explicit, result shows that a statement is true for some unspecified constant C in a way that makes it clear that a constant C could in principle be determined following and reworking the proof with great care. Vinogradov's later proof ([68], translated in [69]) is of this nature. As Chudakov [8, §IV.2] pointed out, the improvement on [67] given by Mardzhanishvili [41] already had the effect of making the result effective.[2]
3. An *explicit* result gives a value of C. According to [8, p. 201], the first explicit version of Vinogradov's result was given by Borozdkin in his unpublished doctoral dissertation, written under the direction of Vinogradov (1939): $C = \exp(\exp(\exp(41.96)))$. Such a result is, by definition, also effective. Borodzkin later [2] gave the value $C = e^{e^{16.038}}$, though he does not seem to have published the proof. The best – that is, smallest – value of C known before the present work was that of Liu and Wang [40]: $C = 2 \cdot 10^{1346}$.
4. What we may call an *efficient* proof gives a reasonable value for C – in our case, a value small enough that checking all cases up to C is feasible.

How far were we from an efficient proof? That is, what sort of computation could ever be feasible? The number of picoseconds since the beginning of the universe is less than 10^{30}, whereas the number of protons in the observable universe is currently estimated at

[1] Here, as is often the case in ineffective results in analytic number theory, the underlying issue is that of *Siegel zeros*, which are believed not to exist, but have not been shown not to; the strongest bounds on (i.e., against the existence of) such zeros are ineffective, and so are all of the many results using such estimates.

[2] The proof in [41] combined the bounds in [67] with a more careful accounting of the effect of the single possible Siegel zero within range.

$\sim 10^{80}$. This means that even a parallel computer the size of the universe could never perform a computation requiring 10^{110} steps, even if it ran for the age of the universe. Thus, $C = 2 \cdot 10^{1346}$ is too large.

I gave a proof with $C = 10^{29}$ in May 2013. Since D. Platt and I had verified the conjecture for all odd numbers up to $n \leq 8.8 \cdot 10^{30}$ by computer [31], this established the conjecture for all odd numbers n.

(In December 2013, C was reduced to 10^{27} [29]. The verification of the ternary Goldbach conjecture up to $n \leq 10^{27}$ can be done in a home computer over a weekend. All must be said: this uses the verification of the binary Goldbach conjecture for $n \leq 4 \cdot 10^{18}$ [46], which itself required computational resources far outside the home-computing range. Checking the conjecture up to $n \leq 10^{27}$ was not even the main computational task that needed to be accomplished to establish the Main Theorem – that task was the finite verification of zeros of L-functions in [48], a general-purpose computation that should be useful elsewhere. We will discuss the procedure at the end of the article.)

What was the strategy of [27–29]? The basic framework is the one pioneered by Hardy and Littlewood for a variety of problems – namely, the *circle method*, which, as we shall see, is an application of Fourier analysis over $\mathbb{Z}$. (There are other, later routes to Vinogradov's result; see [21, 24] and especially the recent work [57], which avoids using anything about zeros of L-functions inside the critical strip.) Vinogradov's proof, like much of the later work on the subject, was based on a detailed analysis of exponential sums, i.e., Fourier transforms over $\mathbb{Z}$. So is the proof that we will sketch.

At the same time, the distance between $2 \cdot 10^{1346}$ and 10^{27} is such that we cannot hope to get to 10^{27} (or any other reasonable constant) by fine-tuning previous work. Rather, we must work from scratch, using the basic outline in Vinogradov's original proof and other, initially unrelated, developments in analysis and number theory (notably, the large sieve). Merely improving constants will not do; we must do qualitatively better than previous work (by non-constant factors) if we are to have any chance to succeed. It is on these qualitative improvements that we will focus.

* * *

It is only fair to review some of the progress made between Vinogradov's time and ours. Here we will focus on results; later, we will discuss some of the progress made in the techniques of proof. For a fuller account up to 1978, see R. Vaughan's ICM lecture notes on the ternary Goldbach problem [65].

In 1933, Schnirelmann proved [56] that every integer $n > 1$ can be written as the sum of at most K primes for some unspecified constant K. (This pioneering work is now considered to be part of the early history of additive combinatorics.) In 1969, Klimov gave an explicit value for K (namely, $K = 6 \cdot 10^9$); he later improved the constant to $K = 115$ (with G. Z. Piltay and T. A. Sheptickaja) and $K = 55$. Later, there were results by Vaughan [63] ($K = 27$), Deshouillers [15] ($K = 26$) and Riesel-Vaughan [54] ($K = 19$).

Ramaré showed in 1995 that every even number $n > 1$ can be written as the sum of at most 6 primes [51]. In 2012, Tao proved [58] that every odd number $n > 1$ is the sum of at most 5 primes.

There have been other avenues of attack towards the strong conjecture. Using ideas close to those of Vinogradov's, Chudakov [9, 10], Estermann [19] and van der Corput [62] proved (independently from each other) that almost every even number (meaning: all elements of a subset of density 1 in the even numbers) can be written as the sum of two primes. In 1973, J.-

R. Chen showed [4] that every even number n larger than a constant C can be written as the sum of a prime number and the product of at most two primes ($n = p_1+p_2$ or $n = p_1+p_2p_3$). Incidentally, J.-R. Chen himself, together with T.-Z. Wang, was responsible for the best bounds on C (for ternary Goldbach) before Lui and Wang: $C = \exp(\exp(11.503)) < 4 \cdot 10^{43000}$ [6] and $C = \exp(\exp(9.715)) < 6 \cdot 10^{7193}$ [7].

Matters are different if one assumes the Generalized Riemann Hypothesis (GRH). A careful analysis [18] of Hardy and Littlewood's work [23] gives that every odd number $n \geq 1.24 \cdot 10^{50}$ is the sum of three primes if GRH is true. According to [18], the same statement with $n \geq 10^{32}$ was proven in the unpublished doctoral dissertation of B. Lucke, a student of E. Landau's, in 1926. Zinoviev [72] improved this to $n \geq 10^{20}$. A computer check ([16]; see also [55]) showed that the conjecture is true for $n < 10^{20}$, thus completing the proof of the ternary Goldbach conjecture under the assumption of GRH. What was open until now was, of course, the problem of giving an unconditional proof.

2. The circle method: Fourier analysis on $\mathbb{Z}$

It is common for a first course on Fourier analysis to focus on functions over the reals satisfying $f(x) = f(x+1)$, or, what is the same, functions $f : \mathbb{R}/\mathbb{Z} \to \mathbb{C}$. Such a function (unless it is fairly pathological) has a Fourier series converging to it; this is just the same as saying that f has a Fourier transform $\widehat{f} : \mathbb{Z} \to \mathbb{C}$ defined by $\widehat{f}(n) = \int_{\mathbb{R}/\mathbb{Z}} f(\alpha)e(-\alpha n)d\alpha$ and satisfying $f(\alpha) = \sum_{n\in\mathbb{Z}} \widehat{f}(n)e(\alpha n)d\alpha$ (*Fourier inversion theorem*).

In number theory, we are especially interested in functions $f : \mathbb{Z} \to \mathbb{C}$. Then things are exactly the other way around: provided that f decays reasonably fast as $n \to \pm\infty$ (or becomes 0 for n large enough), f has a Fourier transform $\widehat{f} : \mathbb{R}/\mathbb{Z} \to \mathbb{C}$ defined by $\widehat{f}(\alpha) = \sum_n f(n)e(-\alpha n)$ and satisfying $f(n) = \int_{\mathbb{R}/\mathbb{Z}} \widehat{f}(\alpha)e(\alpha n)$. (Highbrow talk: we already knew that $\mathbb{Z}$ is the Fourier dual of $\mathbb{R}/\mathbb{Z}$, and so, of course, $\mathbb{R}/\mathbb{Z}$ is the Fourier dual of $\mathbb{Z}$.) "Exponential sums" (or "trigonometrical sums", as in the title of [69]) are sums of the form $\sum_n f(\alpha)e(-\alpha n)$; the "circle" in "circle method" is just a name for $\mathbb{R}/\mathbb{Z}$.

The study of the Fourier transform $\widehat{f}$ is relevant to additive problems in number theory, i.e., questions on the number of ways of writing n as a sum of k integers of a particular form. Why? One answer could be that $\widehat{f}$ gives us information about the "randomness" of f; if f were the characteristic function of a random set, then $\widehat{f}(\alpha)$ would be very small outside a sharp peak at $\alpha = 0$. We can also give a more concrete and immediate answer. Recall that, in general, the Fourier transform of a convolution equals the product of the transforms; over $\mathbb{Z}$, this means that for the additive convolution

$$(f * g)(n) = \sum_{\substack{m_1,m_2\in\mathbb{Z} \\ m_1+m_2=n}} f(m_1)g(m_2),$$

the Fourier transform satisfies the simple rule

$$\widehat{f * g}(\alpha) = \widehat{f}(\alpha) \cdot \widehat{g}(\alpha).$$

We can see right away from this that $(f * g)(n)$ can be non-zero only if n can be written as $n = m_1 + m_2$ for some m_1, m_2 such that $f(m_1)$ and $g(m_2)$ are non-zero. Similarly,

$(f * g * h)(n)$ can be non-zero only if n can be written as $n = m_1 + m_2 + m_3$ for some m_1, m_2, m_3 such that $f(m_1)$, $f_2(m_2)$ and $f_3(m_3)$ are all non-zero. This suggests that, to study the ternary Goldbach problem, we define $f_1, f_2, f_3 : \mathbb{Z} \to \mathbb{C}$ so that they take non-zero values only at the primes.

Hardy and Littlewood defined $f_1(n) = f_2(n) = f_3(n) = 0$ for n non-prime (and also for $n \leq 0$), and $f_1(n) = f_2(n) = f_3(n) = (\log n)e^{-n/x}$ for n prime (where x is a parameter to be fixed later). Here the factor $e^{-n/x}$ is there to provide "fast decay", so that everything converges; as we will see later, Hardy and Littlewood's choice of $e^{-n/x}$ (rather than some other function of fast decay) comes across in hindsight as being very clever, though not quite best-possible. (Their "choice" was, to some extent, not a choice, but an artifact of their version of the circle method.) The term $\log n$ is there for technical reasons – in essence, it makes sense to put it there because a random integer around n has a chance of about $1/(\log n)$ of being prime.

We can see that $(f_1 * f_2 * f_3)(n) \neq 0$ if and only if n can be written as the sum of three primes. Our task is then to show that $(f_1 * f_2 * f_3)(n)$ (i.e., $(f * f * f)(n)$) is non-zero for every n larger than a constant $C \sim 10^{27}$. Since the transform of a convolution equals a product of transforms,

$$(f_1 * f_2 * f_3)(n) = \int_{\mathbb{R}/\mathbb{Z}} \widehat{f_1 * f_2 * f_3}(\alpha) e(\alpha n) d\alpha = \int_{\mathbb{R}/\mathbb{Z}} (\widehat{f_1}\widehat{f_2}\widehat{f_3})(\alpha) e(\alpha n) d\alpha. \quad (2.1)$$

Our task is thus to show that the integral $\int_{\mathbb{R}/\mathbb{Z}} (\widehat{f_1}\widehat{f_2}\widehat{f_3})(\alpha) e(\alpha n) d\alpha$ is non-zero.

As it happens, $\widehat{f}(\alpha)$ is particularly large when α is close to a rational with small denominator. Moreover, for such α, it turns out we can actually give rather precise estimates for $\widehat{f}(\alpha)$. Define $\mathfrak{M}$ (called the set of *major arcs*) to be a union of narrow arcs around the rationals with small denominator:

$$\mathfrak{M} = \bigcup_{q \leq r} \bigcup_{\substack{a \bmod q \\ (a,q)=1}} \left(\frac{a}{q} - \frac{1}{qQ}, \frac{a}{q} + \frac{1}{qQ}\right),$$

where Q is a constant times x/r, and r will be set later. We can write

$$\int_{\mathbb{R}/\mathbb{Z}} (\widehat{f_1}\widehat{f_2}\widehat{f_3})(\alpha) e(\alpha n) d\alpha = \int_{\mathfrak{M}} (\widehat{f_1}\widehat{f_2}\widehat{f_3})(\alpha) e(\alpha n) d\alpha + \int_{\mathfrak{m}} (\widehat{f_1}\widehat{f_2}\widehat{f_3})(\alpha) e(\alpha n) d\alpha, \quad (2.2)$$

where $\mathfrak{m}$ is the complement $(\mathbb{R}/\mathbb{Z}) \setminus \mathfrak{M}$ (called *minor arcs*).

Now, we simply do not know how to give precise estimates for $\widehat{f}(\alpha)$ when α is in $\mathfrak{m}$. However, as Vinogradov realized, one can give reasonable upper bounds on $|\widehat{f}(\alpha)|$ for $\alpha \in \mathfrak{m}$. This suggests the following strategy: show that

$$\int_{\mathfrak{m}} |\widehat{f_1}(\alpha)||\widehat{f_2}(\alpha)||\widehat{f_3}(\alpha)| d\alpha < \int_{\mathfrak{M}} \widehat{f_1}(\alpha)\widehat{f_2}(\alpha)\widehat{f_3}(\alpha) e(\alpha n) d\alpha. \quad (2.3)$$

By (2.1) and (2.2), this will imply immediately that $(f_1 * f_2 * f_3)(n) > 0$, and so we will be done.

3. The major arcs $\mathfrak{M}$

3.1. What do we really know about L-functions and their zeros? Before we start, let us give a very brief review of basic analytic number theory (in the sense of, say, [13]). A *Dirichlet character* $\chi : \mathbb{Z} \to \mathbb{C}$ of modulus q is a character of $(\mathbb{Z}/q\mathbb{Z})^*$ lifted to $\mathbb{Z}$. (In other words, $\chi(n) = \chi(n+q)$, $\chi(ab) = \chi(a)\chi(b)$ for all a, b and $\chi(n) = 0$ for $(n,q) \neq 1$.) A *Dirichlet L-series* is defined by

$$L(s,\chi) = \sum_{n=1}^{\infty} \chi(n) n^{-s}$$

for $\Re(s) > 1$, and by analytic continuation for $\Re(s) \leq 1$. (The Riemann zeta function $\zeta(s)$ is the L-function for the trivial character, i.e., the character χ such that $\chi(n) = 1$ for all n.) Taking logarithms and then derivatives, we see that

$$-\frac{L'(s,\chi)}{L(s,\chi)} = \sum_{n=1}^{\infty} \Lambda(n) n^{-s}, \tag{3.1}$$

where Λ is the *von Mangoldt function* ($\Lambda(n) = \log p$ if n is some prime power p^α, $\alpha \geq 1$, and $\Lambda(n) = 0$ otherwise).

Dirichlet introduced his characters and L-series so as to study primes in arithmetic progressions. In general, and after some work, (3.1) allows us to restate many sums over the primes (such as our Fourier transforms $\widehat{f}(\alpha)$) as sums over the zeros of $L(s,\chi)$. A *non-trivial zero* of $L(s,\chi)$ is a zero of $L(s,\chi)$ such that $0 < \Re(s) < 1$. (The other zeros are called trivial because we know where they are, namely, at negative integers and, in some cases, also on the line $\Re(s) = 0$. In order to eliminate all zeros on $\Re(s) = 0$ outside $s = 0$, it suffices to assume that χ is *primitive*; a primitive character modulo q is one that is not induced by (i.e., not the restriction of) any character modulo $d|q$, $d < q$.)

The Generalized Riemann Hypothesis for Dirichlet L-functions is the statement that, for every Dirichlet character χ, every non-trivial zero of $L(s,\chi)$ satisfies $\Re(s) = 1/2$. Of course, the Generalized Riemann Hypothesis (GRH) – and the Riemann Hypothesis, which is the special case of χ trivial – remains unproven. Thus, if we want to prove unconditional statements, we need to make do with partial results towards GRH. Two kinds of such results have been proven:

- **Zero-free regions.** Ever since the late nineteenth century (Hadamard, de la Vallée-Poussin) we have known that there are hourglass-shaped regions (more precisely, of the shape $\frac{c}{\log t} \leq \sigma \leq 1 - \frac{c}{\log t}$, where c is a constant and where we write $s = \sigma + it$) outside which non-trivial zeros cannot lie. Explicit values for c are known [35, 36, 42]. There is also the Vinogradov-Korobov region [39, 70], which is broader asymptotically but narrower in most of the practical range (see [20], however).
- **Finite verifications of GRH.** It is possible to (ask the computer to) prove small, finite fragments of GRH, in the sense of verifying that all non-trivial zeros of a given finite set of L-functions with imaginary part less than some constant H lie on the critical line $\Re(s) = 1/2$. Such verifications go back to Riemann, who checked the first few zeros of $\zeta(s)$. Large-scale, rigorous computer-based verifications are now a possibility.

Most work in the literature follows the first alternative, though [58] did use a finite verification of RH (i.e., GRH for the trivial character). Unfortunately, zero-free regions seem

too narrow to be useful for the ternary Goldbach problem. Thus, we are left with the second alternative.

In coordination with the present work, Platt [48] verified that all zeros s of L-functions for characters χ with modulus $q \leq 300000$ satisfying $\Im(s) \leq H_q$ lie on the line $\Re(s) = 1/2$, where

- $H_q = 10^8/q$ for q odd, and
- $H_q = \max(10^8/q, 200 + 7.5 \cdot 10^7/q)$ for q even.

This was a medium-large computation, taking a few hundreds of thousands of core-hours on a parallel computer. It used *interval arithmetic* for the sake of rigor; we will later discuss what this means.

The choice to use a finite verification of GRH, rather than zero-free regions, had consequences on the manner in which the major and minor arcs had to be chosen. As we shall see, such a verification can be used to give very precise bounds on the major arcs, but also forces us to define them so that they are narrow and their number is constant. To be precise: the major arcs were defined around rationals a/q with $q \leq r$, $r = 300000$; moreover, as will become clear, the fact that H_q is finite will force their width to be bounded by $c_0 r/qx$, where c_0 is a constant (say $c_0 = 8$).

3.2. Estimates of $\widehat{f}(\alpha)$ for α in the major arcs. Recall that we want to estimate sums of the type $\widehat{f}(\alpha) = \sum f(n)e(-\alpha n)$, where $f(n)$ is something like $(\log n)\eta(n/x)$ for n equal to a prime, and 0 otherwise; here $\eta : \mathbb{R} \to \mathbb{C}$ is some function of fast decay, such as Hardy and Littlewood's choice, $\eta(t) = e^{-t}$. Let us modify this just a little – we will actually estimate

$$S_\eta(\alpha, x) = \sum \Lambda(n)e(\alpha n)\eta(n/x), \tag{3.2}$$

where Λ is the von Mangoldt function (as in (3.1)) . The use of α rather than $-\alpha$ is just a bow to tradition, as is the use of the letter S (for "sum"); however, the use of $\Lambda(n)$ rather than just plain $\log p$ does actually simplify matters.

The function η here is sometimes called a *smoothing function* or simply a *smoothing*. It will indeed be helpful for it to be smooth on $(0, \infty)$, but, in principle, it need not even be continuous. (Vinogradov's work implicitly uses, in effect, the "brutal truncation" $1_{[0,1]}(t)$, defined to be 1 when $t \in [0, 1]$ and 0 otherwise; that would be fine for the minor arcs, but, as it will become clear, it is a bad idea as far as the major arcs are concerned.)

Assume α is on a major arc, meaning that we can write $\alpha = a/q + \delta/x$ for some a/q (q small) and some δ (with $|\delta|$ small). We can write $S_\eta(\alpha, x)$ as a linear combination

$$S_\eta(\alpha, x) = \sum_\chi c_\chi S_{\eta,\chi}\left(\frac{\delta}{x}, x\right) + \text{tiny error term}, \tag{3.3}$$

where

$$S_{\eta,\chi}\left(\frac{\delta}{x}, x\right) = \sum \Lambda(n)\chi(n)e(\delta n/x)\eta(n/x). \tag{3.4}$$

In (3.3), χ runs over primitive Dirichlet characters of moduli $d|q$, and c_χ is small ($|c_\chi| \leq \sqrt{d}/\phi(q)$).

To estimate the sums $S_{\eta,\chi}$, we will use L-functions, together with one of the most common tools of analytic number theory, the Mellin transform. This transform is essentially a

Laplace transform with a change of variables, and a Laplace transform, in turn, is a Fourier transform taken on a vertical line in the complex plane. For f of fast enough decay, the Mellin transform $F = Mf$ of f is given by

$$F(s) = \int_0^\infty f(t) t^s \frac{dt}{t};$$

we can express f in terms of F by the *Mellin inversion formula*

$$f(t) = \frac{1}{2\pi i} \int_{\sigma - i\infty}^{\sigma + i\infty} F(s) t^{-s} ds$$

for any σ within an interval. We can thus express $e(\delta t)\eta(t)$ in terms of its Mellin transform F_δ and then use (3.1) to express $S_{\eta,\chi}$ in terms of F_δ and $L'(s,\chi)/L(s,\chi)$; shifting the integral in the Mellin inversion formula to the left, we obtain what is known in analytic number theory as an *explicit formula*:

$$S_{\eta,\chi}(\delta/x, x) = [\widehat{\eta}(-\delta)x] - \sum_\rho F_\delta(\rho) x^\rho + \text{tiny error term}.$$

Here the term between brackets appears only for χ trivial. In the sum, ρ goes over all non-trivial zeros of $L(s,\chi)$, and F_δ is the Mellin transform of $e(\delta t)\eta(t)$. (The tiny error term comes from a sum over the trivial zeros of $L(s,\chi)$.) We will obtain the estimate we desire if we manage to show that the sum over ρ is small.

The point is this: if we verify GRH for $L(s,\chi)$ up to imaginary part H, i.e., if we check that all zeroes ρ of $L(s,\chi)$ with $|\Im(\rho)| \le H$ satisfy $\Re(\rho) = 1/2$, we have $|x^\rho| = \sqrt{x}$. In other words, x^ρ is very small (compared to x). However, for any ρ whose imaginary part has absolute value greater than H, we know next to nothing about its real part, other than $0 \le \Re(\rho) \le 1$. (Zero-free regions are notoriously weak for $\Im(\rho)$ large; we will not use them.) Hence, our only chance is to make sure that $F_\delta(\rho)$ is very small when $|\Im(\rho)| \ge H$.

This has to be true for both δ very small (including the case $\delta = 0$) and for δ not so small ($|\delta|$ up to $c_0 r/q$, which can be large because r is a large constant). How can we choose η so that $F_\delta(\rho)$ is very small in both cases for $\tau = \Im(\rho)$ large?

The method of *stationary phase* is useful as an exploratory tool here. In brief, it suggests (and can sometimes prove) that the main contribution to the integral

$$F_\delta(t) = \int_0^\infty e(\delta t)\eta(t) t^s \frac{dt}{t} \tag{3.5}$$

can be found where the phase of the integrand has derivative 0. This happens when $t = -\tau/2\pi\delta$ (for $\operatorname{sgn}(\tau) \ne \operatorname{sgn}(\delta)$); the contribution is then a moderate factor times $\eta(-\tau/2\pi\delta)$. In other words, if $\operatorname{sgn}(\tau) \ne \operatorname{sgn}(\delta)$ and δ is not too small ($|\delta| \ge 8$, say), $F_\delta(\sigma + i\tau)$ behaves like $\eta(-\tau/2\pi\delta)$; if δ is small ($|\delta| < 8$), then F_δ behaves like F_0, which is the Mellin transform $M\eta$ of η. Here is our goal, then: the decay of $\eta(t)$ as $|t| \to \infty$ should be as fast as possible, and the decay of the transform $M\eta(\sigma + i\tau)$ should also be as fast as possible.

This is a classical dilemma, often called the *uncertainty principle* because it is the mathematical fact underlying the physical principle of the same name: you cannot have a function η that decreases extremely rapidly and whose Fourier transform (or, in this case, its Mellin transform) also decays extremely rapidly. What does "extremely rapidly" mean here? It

means (as Hardy himself proved) "faster than any exponential e^{-Ct}". Thus, Hardy and Littlewood's choice $\eta(t) = e^{-t}$ seems essentially optimal at first sight.

However, it is not optimal. We can choose η so that $M\eta$ decreases exponentially (with a constant C somewhat worse than for $\eta(t) = e^{-t}$), but η decreases faster than exponentially. This is a particularly appealing possibility because it is $t/|\delta|$, and not so much t, that risks being fairly small. (To be explicit: say we check GRH for characters of modulus q up to $H_q \sim 50 \cdot c_0 r/q \geq 50|\delta|$. Then we only know that $|\tau/2\pi\delta| \gtrsim 8$. So, for $\eta(t) = e^{-t}$, $\eta(-\tau/2\pi\delta)$ may be as large as e^{-8}, which is not negligible. Indeed, since this term will be multiplied later by other terms, e^{-8} is simply not small enough. On the other hand, we can assume that $H_q \geq 200$ (say), and so $M\eta(s) \sim e^{-(\pi/2)|\tau|}$ is completely negligible, and will remain negligible even if we replace $\pi/2$ by a somewhat smaller constant.)

We shall take $\eta(t) = e^{-t^2/2}$ (that is, the Gaussian). This is not the only possible choice, but it is in some sense natural. It is easy to show that the Mellin transform F_δ for $\eta(t) = e^{-t^2/2}$ is a multiple of what is called a *parabolic cylinder function* $U(a, z)$ with imaginary values for z. There are plenty of estimates on parabolic cylinder functions in the literature – but mostly for a and z real, in part because that is one of the cases occuring most often in applications. There are some asymptotic expansions and estimates for $U(a, z)$, a, z, general, due to Olver (see, e.g., [47]), but unfortunately they come without fully explicit error terms for a and z within our range of interest. (The same holds for [59].)

In the end, using the *saddle-point method*, I derived bounds for the Mellin transform F_δ of $\eta(t)e(\delta t)$ with $\eta(t) = e^{-t^2/2}$: for $s = \sigma + i\tau$ with $\sigma \in [0, 1]$ and $|\tau| \geq \max(100, 4\pi^2|\delta|)$,

$$|F_\delta(s)| + |F_\delta(1-s)| \leq 4.226 \cdot \begin{cases} e^{-0.1065\left(\frac{\tau}{\pi\delta}\right)^2} & \text{if } |\tau| < \frac{3}{2}(\pi\delta)^2, \\ e^{-0.1598|\tau|} & \text{if } |\tau| \geq \frac{3}{2}(\pi\delta)^2. \end{cases} \tag{3.6}$$

Similar bounds hold for σ in other ranges, thus giving us (similar) estimates for the Mellin transform F_δ for $\eta(t) = t^k e^{-t^2/2}$ and σ in the critical range $[0, 1]$.

A moment's thought shows that we can also use (3.6) to deal with the Mellin transform of $\eta(t)e(\delta t)$ for any function of the form $\eta(t) = e^{-t^2/2}g(t)$ (or, more generally, $\eta(t) = t^k e^{-t^2/2}g(t)$), where $g(t)$ is any *band-limited function*. By a band-limited function, we could mean a function whose Fourier transform is compactly supported; while that is a plausible choice, it turns out to be better to work with functions that are band-limited with respect to the Mellin transform – in the sense of being of the form

$$g(t) = \int_{-R}^{R} h(r) t^{-ir} dr,$$

where $h : \mathbb{R} \to \mathbb{C}$ is supported on a compact interval $[-R, R]$, with R not too large (say $R = 200$).

After deriving an explicit formula general enough to work with all the weights $\eta(t)$ we have discussed, and once we consider the input provided by Platt's finite verification of GRH up to H_q, we obtain simple bounds for different weights. For $\eta(t) = e^{-t^2/2}$, $x \geq 10^8$, χ a primitive character of modulus $q \leq r = 300000$, and any $\delta \in \mathbb{R}$ with $|\delta| \leq 4r/q$, we obtain

$$S_{\eta,\chi}\left(\frac{\delta}{x}, x\right) = I_{q=1} \cdot \widehat{\eta}(-\delta)x + E \cdot x, \tag{3.7}$$

where $I_{q=1} = 1$ if $q = 1$, $I_{q=1} = 0$ if $q \neq 1$, and

$$|E| \leq 5.281 \cdot 10^{-22} + \frac{1}{\sqrt{x}} \left(\frac{650400}{\sqrt{q}} + 112 \right). \tag{3.8}$$

Here $\widehat{\eta}$ stands for the Fourier transform from $\mathbb{R}$ to $\mathbb{R}$ normalized as follows:

$$\widehat{\eta}(t) = \int_{-\infty}^{\infty} e(-xt)\eta(x)dx$$

Thus, $\widehat{\eta}(-\delta)$ is just $\sqrt{2\pi}e^{-2\pi^2\delta^2}$ (self-duality of the Gaussian).

This is one of the main results of [27]. Similar bounds are also proven there for $\eta(t) = t^2e^{-t^2/2}$, as well as for a weight of type $\eta(t) = te^{-t^2/2}g(t)$, where $g(t)$ is a band-limited function, and also for a weight η defined by a multiplicative convolution. The conditions on q ($q \leq r = 300000$) and δ are what we expected from the outset.

Thus concludes our treatment of the major arcs. This is arguably the easiest part of the proof; it was actually what I left for the end, as I was fairly confident it would work out.

4. The minor arcs $\mathfrak{m}$

4.1. Qualitative goals and main ideas. What kind of bounds do we need? What is there in the literature?

We wish to obtain upper bounds on $|S_\eta(\alpha, x)|$ for some weight η and any $\alpha \in \mathbb{R}/\mathbb{Z}$ not very close to a rational with small denominator. Every α is close to some rational a/q; what we are looking for is a bound on $|S_\eta(\alpha, x)|$ that decreases rapidly when q increases.

Moreover, we want our bound to decrease rapidly when δ increases, where $\alpha = a/q + \delta/x$. In fact, the main terms in our bound will be decreasing functions of $\max(1, |\delta|/8) \cdot q$. (Let us write $\delta_0 = \max(2, |\delta|/4)$ from now on.) This will allow our bound to be good enough outside narrow major arcs, which will get narrower and narrower as q increases – that is, precisely the kind of major arcs we were presupposing in our major-arc bounds.

It would be possible to work with narrow major arcs that become narrower as q increases simply by allowing q to be very large (close to x), and assigning each angle to the fraction closest to it. This is the common procedure. However, this makes matters more difficult, in that we would have to minimize at the same time the factors in front of terms x/q, $x/\sqrt{q}$, etc., and those in front of terms q, $\sqrt{qx}$, and so on. (These terms are being compared to the trivial bound x.) Instead, we choose to strive for a direct dependence on δ throughout; this will allow us to cap q at a much lower level, thus making terms such as q and $\sqrt{qx}$ negligible.

How good must our bounds be? Since the major-arc bounds are valid only for $q \leq r = 300000$ and $|\delta| \leq 4r/q$, we cannot afford even a single factor of $\log x$ (or any other function tending to ∞ as $x \to \infty$) in front of terms such as $x/\sqrt{q|\delta_0|}$: a factor like that would make the term larger than the trivial bound x for $q|\delta_0|$ equal to a constant (r, say) and x very large. Apparently, there was no such "log-free bound" with explicit constants in the literature, even though such bounds were considered to be in principle feasible, and even though previous work ([5, 11, 12, 58]) had gradually decreased the number of factors of $\log x$. (In limited ranges for q, there were log-free bounds without explicit constants; see [11, 53]. The estimate in [69, Thm. 2a, 2b] was almost log-free, but not quite. There were

also bounds [3, 37] that used L-functions, and thus were not really useful in a truly minor-arc regime.)

It also seemed clear that a main bound proportional to $(\log q)^2 x/\sqrt{q}$ (as in [58]) was too large. At the same time, it was not really necessary to reach a bound of the best possible form that could be found through Vinogradov's basic approach, namely

$$|S_\eta(\alpha, x)| \leq C\frac{x\sqrt{q}}{\phi(q)}. \tag{4.1}$$

Such a bound had been proven by Ramaré [53] for q in a limited range and C non-explicit; later, in [50] Ramaré broadened the range to $q \leq x^{1/48}$ and gave an explicit value for C, namely, $C = 13000$. Such a bound is a notable achievement, but, unfortunately, it is not useful for our purposes. Rather, we will aim at a bound whose main term is bounded by a constant around 1 times $x(\log \delta_0 q)/\sqrt{\delta_0 \phi(q)}$; this is slightly worse asymptotically than (4.1), but it is much better in the delicate range of $\delta_0 q \sim 300000$.

* * *

We see that we have several tasks. One of them is the removal of logarithms: we cannot afford a single factor of $\log x$, and, in practice, we can afford at most one factor of $\log q$. Removing logarithms will be possible in part because of the use of efficient techniques (the large sieve for sequences with prime support) but also because we will be able to find cancellation at several places in sums coming from a combinatorial identity (namely, Vaughan's identity). The task of finding cancellation efficiently (that is, with good constants) is particularly delicate. Bounding a sum such as $\sum_n \mu(n)$ efficiently is harder than estimating a sum such as $\sum_n \Lambda(n)$ equally well, even though we are used to thinking of these problems as equivalent.

We have said that our bounds will improve as $|\delta|$ increases. This dependence on δ will be secured in different ways at different places. Sometimes δ will appear as an argument, as in $\widehat{\eta}(-\delta)$; for η piecewise continuous with $\eta' \in L_1$, we know that $|\widehat{\eta}(t)| \to 0$ as $|t| \to \infty$. Sometimes we will obtain a dependence on δ by using several different rational approximations to the same $\alpha \in \mathbb{R}$. Lastly, we will obtain a good dependence on δ in bilinear sums by supplying a scattered input to a large sieve.

If there is a main moral to the argument, it lies in the close relation between the circle method and the large sieve. The circle method rests on the estimation of an integral involving a Fourier transform $\widehat{f} : \mathbb{R}/\mathbb{Z} \to \mathbb{C}$; as we will later see, this leads naturally to estimating the ℓ_2-norm of $\widehat{f}$ on subsets (namely, unions of arcs) of the circle $\mathbb{R}/\mathbb{Z}$. The large sieve can be seen as an approximate discrete version of Plancherel's identity, which states that $|\widehat{f}|_2 = |f|_2$.

Both in this section and in §5, we shall use the large sieve in part so as to use the fact that some of the functions we work with have prime support, i.e., are non-zero only on prime numbers. There are ways to use prime support to improve the output of the large sieve. In §5, these techniques will be refined and then translated to the context of the circle method, where f has (essentially) prime support and $|\widehat{f}|^2$ must be integrated over unions of arcs. The main point is that the large sieve is not being used as a black box; rather, we can adapt ideas from (say) the large-sieve context and apply them to the circle method.

Lastly, there are the benefits of a continuous η. Hardy and Littlewood already used a continuous η; this was abandoned by Vinogradov, presumably for the sake of simplicity.

The idea that smooth weights η can be superior to sharp truncations is now commonplace. As we shall see, using a continuous η is helpful in the minor-arcs regime, but not as crucial there as for the major arcs. We will not use a smooth η; we will prove our estimates for any continuous η that is piecewise C_1, and then, towards the end, we will choose to use the same weight $\eta = \eta_2$ as in [58], in part because it has compact support, and in part for the sake of comparison. The moral here is not quite the common dictum "always smooth", but rather that different kinds of smoothing can be appropriate for different tasks; in the end, we will show how to coordinate different smoothing functions η.

4.2. Combinatorial identities. Generally, since Vinogradov, a treatment of the minor arcs starts with a combinatorial identity expressing $\Lambda(n)$ (or the characteristic function of the primes) as a sum of two or more convolutions. (In this section, by a convolution $f * g$, we will mean the *Dirichlet convolution* $(f * g)(n) = \sum_{d|n} f(d)g(n/d)$, i.e., the multiplicative convolution on the semigroup of positive integers.)

In some sense, the archetypical identity is

$$\Lambda = \mu * \log,$$

but it will not usually do: the contribution of $\mu(d)\log(n/d)$ with d close to n is too difficult to estimate precisely. There are alternatives: for example, there is Selberg's identity

$$\Lambda(n)\log n = \mu * \log^2 - \Lambda * \Lambda, \tag{4.2}$$

or the generalization of this to $\Lambda(n)(\log n)^k = \mu * \log^{k+1} - \dots$ (Bomberi-Selberg). Another useful (and very simple) identity was that used by Daboussi's [12].

The proof of Vinogradov's three-prime result was simplified substantially in [64] by the introduction of *Vaughan's identity*:

$$\Lambda(n) = \mu_{\le U} * \log - \Lambda_{\le V} * \mu_{\le U} * 1 + 1 * \mu_{>U} * \Lambda_{>V} + \Lambda_{\le V}, \tag{4.3}$$

where we are using the notation

$$f_{\le W} = \begin{cases} f(n) & \text{if } n \le W, \\ 0 & \text{if } n > W, \end{cases} \qquad f_{>W} = \begin{cases} 0 & \text{if } n \le W, \\ f(n) & \text{if } n > W. \end{cases}$$

Of the resulting sums ($\sum_n (\mu_{\le U} * \log)(n) e(\alpha n)\eta(n/x)$, etc.), the first three are said to be of *type I*, *type I* (again) and *type II*; the last sum, $\sum_{n \le V} \Lambda(n)$, is negligible.

One of the advantages of Vaughan's identity is its flexibility: we can set U and V to whatever values we wish. Its main disadvantage is that it is not "log-free", in that it seems to impose the loss of two factors of $\log x$: if we sum each side of (4.3) from 1 to x, we obtain $\sum_{n \le x} \Lambda(n) \sim x$ on the left side, whereas, if we bound the sum on the right side without the use of cancellation, we obtain a bound of $x(\log x)^2$. Of course, we will obtain some cancellation from the phase $e(\alpha n)$, but that is not enough.

As was pointed out in [58], it is possible to get a factor of $(\log q)^2$ instead of a factor of $(\log x)^2$ in the type II sums by setting U and V appropriately. A factor of $(\log q)^2$ is still too large in practice, and there are also the factors of $\log x$ in type I sums. Vinogradov had already managed to get an essentially log-free result (by a rather difficult procedure) in [69, Ch. IX]. The result in [11] is log-free. Unfortunately, the explicit result in [12] – the study of which encouraged me at the beginning of the project – is not. For a while, I worked with

the Bombieri-Selberg identity with $k = 2$. Ramaré obtained a log-free bound in [53] using the Diamond-Steinig identity, which is related to Bombieri-Selberg.

In the end, I decided to use Vaughan's identity. This posed a challenge: to obtain cancellation in Vaughan's identity at every possible step, beyond the cancellation given by the phase $e(\alpha n)$. It is clear that the presence of the Möbius function μ should give, in principle, some cancellation; we will show how to use it to obtain as much cancellation as we need.

4.3. Type I sums. There are two type I sums, namely,

$$\sum_{m\le U} \mu(m) \sum_n (\log n) e(\alpha m n) \eta\left(\frac{mn}{x}\right) \tag{4.4}$$

and

$$\sum_{v\le V} \Lambda(v) \sum_{u\le U} \mu(u) \sum_n e(\alpha v u n) \eta\left(\frac{vun}{x}\right). \tag{4.5}$$

In either case, $\alpha = a/q + \delta/x$, where q is larger than a constant r and $|\delta/x| \le 1/qQ_0$ for some $Q_0 > \max(q, \sqrt{x})$. For the purposes of this exposition, we will set it as our task to estimate the slightly simpler sum

$$\sum_{m\le D} \mu(m) \sum_n e(\alpha m n) \eta\left(\frac{mn}{x}\right), \tag{4.6}$$

where D can be U or UV or something else less than x.

Why can we consider this simpler sum without omitting anything essential? It is clear that (4.4) is of the same kind as (4.6). The inner double sum in (4.5) is just (4.6) with αv instead of α; this enables us to estimate (4.5) by means of (4.6) for q small, i.e., the more delicate case. If q is not small, then the approximation $\alpha v \sim av/q$ may not be accurate enough. In that case, we collapse the two outer sums in (4.5) into a sum $\sum_n (\Lambda_{\le V} * \mu_{\le U})(n)$, and treat all of (4.5) much as we will treat (4.6); since q is not small, we can afford to bound $(\Lambda_{\le V} * \mu_{\le U})(n)$ trivially (by $\log n$) in the less sensitive terms.

Let us first outline Vinogradov's procedure for bounding type I sums. Just by summing a geometric series, we get $\left|\sum_{n\le N} e(\alpha n)\right| \le \min(N, c/\{\alpha\})$, where c is a constant and $\{\alpha\}$ is the distance from α to the nearest integer. Vinogradov splits the outer sum in (4.6) into sums of length q. When m runs on an interval of length q, the angle am/q runs through all fractions of the form b/q; due to the error δ/x, αm could be close to 0 for two values of n, but otherwise $\{\alpha m\}$ takes values bounded below by $1/q$, $2/q$, etc. Thus

$$\left|\sum_{y<m\le y+q} \mu(m) \sum_{n\le N} e(\alpha m n)\right| \le \sum_{y<m\le y+q} \left|\sum_{n\le N} e(\alpha m n)\right| \le \frac{2N}{m} + 2cq \log eq \tag{4.7}$$

for any $y \ge 0$.

There are several ways to improve this. One is simply to estimate the inner sum more precisely; this was already done in [12]. One can also define a smoothing function η, as in (4.6); it is easy to get

$$\left|\sum_{n\le N} e(\alpha n) \eta\left(\frac{n}{x}\right)\right| \le \min\left(x|\eta|_1 + \frac{|\eta'|_1}{2}, \frac{|\eta'|_1}{2|\sin(\pi\alpha)|}, \frac{|\widehat{\eta''}|_\infty}{4x(\sin \pi\alpha)^2}\right).$$

Except for the third term, this is as in [58]. We could also choose carefully which bound to use for each m; surprisingly, this gives an improvement – in fact, an important one, for m large. However, we still get a term proportional to N/m as in (4.7), and this contributes about $(x \log x)/q$ to the sum (4.6), thus giving us an estimate that is not log-free.

What we have to do, naturally, is to take out the terms with $q|m$ for m small. We obtain a log-free bound for the sum over the terms with $m \leq M = \min(D, Q/2)$ with $q \nmid m$, since αm is then never too close to 0. For $m \leq M$ divisible by q, we can estimate the inner sum in (4.6) by the Poisson summation formula; writing $m = aq$, we get a main term

$$\frac{x\mu(q)}{q} \cdot \widehat{\eta}(-\delta) \cdot \sum_{\substack{a \leq M/q \\ (a,q)=1}} \frac{\mu(a)}{a}, \tag{4.8}$$

where (a, q) stands for the greatest common divisor of a and q. It is clear that we have to get cancellation over μ here. There is an elegant elementary argument [22] showing that the absolute value of the sum in (4.8) is at most 1. We need to gain one more log, however. This was done by Ramaré [49].

What shall we do for $m > Q/2$? We can always give a bound

$$\sum_{y < m \leq y+q} \min\left(A, \frac{C}{|\sin \pi\alpha n|^2}\right) \leq 3A + \frac{4q}{\pi}\sqrt{AC} \tag{4.9}$$

for y arbitrary; since AC will be of constant size, $(4q/\pi)\sqrt{AC}$ is pleasant enough, but the contribution of $3A \sim 3|\eta|_1 x/y$ seems lethal (it adds a multiple of $(x \log x)/q$ to the total) and at first sight unavoidable: the values of m for which αm is close to 0 no longer correspond to the congruence class $m \equiv 0 \bmod q$, and thus cannot be taken out.

The solution is to switch approximations. (The idea of using different approximations to the same α is neither new nor recent in the general context of the circle method: see [66, §2.8, Ex. 2]. What may be new is its use to clear a hurdle in type I sums.) What does this mean? If α were exactly, or almost exactly, a/q, then there would be no other very good approximations in a reasonable range. However, note that we can *define* $Q = \lfloor x/|\delta q| \rfloor$ for $\alpha = a/q + \delta/x$, and still have $|\alpha - a/q| \leq 1/qQ$. If δ is very small, Q will be larger than $2D$, and there will be no terms with $Q/2 < m \leq D$ to worry about.

What happens if δ is not very small? We know that, for any Q', there is an approximation a'/q' to α with $|\alpha - a'/q'| \leq 1/q'Q'$ and $q' \leq Q'$. However, for $Q' > Q$, we know that a'/q' cannot equal a/q: by the definition of Q, the approximation a/q is not good enough, i.e., $|\alpha - a/q| \leq 1/qQ'$ does not hold. Since $a/q \neq a'/q'$, we see that $|a/q - a'/q'| \geq 1/qq'$, and, if we take $Q' \geq (1+\epsilon)Q$, this implies that q' is relatively large ($q' \geq (\epsilon/(1+\epsilon))Q$).

Thus, for $m > Q/2$, the solution is to apply (4.9) with a'/q' instead of a/q. The contribution of A fades into insignificance: for the first sum over a range $y < m \leq y + q'$, $y \geq Q/2$, it contributes at most $x/(Q/2)$, and all the other contributions of A sum up to at most a constant times $(x \log x)/q'$.

Proceeding in this way, we obtain a total bound for (4.6) whose main terms are proportional to

$$\frac{1}{\phi(q)} \frac{x}{\log \frac{x}{q}} \min\left(1, \frac{1}{\delta^2}\right), \quad \frac{2}{\pi}\sqrt{|\widehat{\eta''}|_\infty} \cdot D \quad \text{and} \quad q \log \max\left(\frac{D}{q}, q\right), \tag{4.10}$$

with good, explicit constants. The first term – usually the largest one – is precisely what we needed: it is proportional to $(1/\phi(q))x/\log x$ for q small, and decreases rapidly as $|\delta|$ increases.

4.4. Type II, or bilinear, sums. We must now bound

$$S = \sum_m (1 * \mu_{>U})(m) \sum_{n>V} \Lambda(n) e(\alpha mn) \eta(mn/x).$$

At this point it is convenient to assume that η is the Mellin convolution of two functions. The *multiplicative* or *Mellin convolution* on $\mathbb{R}^+$ is defined by

$$(\eta_0 *_M \eta_1)(t) = \int_0^\infty \eta_0(r)\eta_1\left(\frac{t}{r}\right)\frac{dr}{r}.$$

Tao [58] takes $\eta = \eta_2 = \eta_1 *_M \eta_1$, where η_1 is a brutal truncation, viz., the function taking the value 2 on $[1/2, 1]$ and 0 elsewhere. We take the same η_2, in part for comparison purposes, and in part because this will allow us to use off-the-shelf estimates on the large sieve. (Brutal truncations are rarely optimal in principle, but, as they are very common, results for them have been carefully optimized in the literature.) Clearly

$$S = \int_V^{X/U} \sum_m \left(\sum_{\substack{d>U\\ d|m}} \mu(d)\right) \eta_1\left(\frac{m}{x/W}\right) \cdot \sum_{n\geq V} \Lambda(n) e(\alpha mn) \eta_1\left(\frac{n}{W}\right)\frac{dW}{W}. \tag{4.11}$$

By Cauchy-Schwarz, the integrand is at most $\sqrt{S_1(U,W)S_2(V,W)}$, where

$$\begin{aligned} S_1(U,W) &= \sum_{\frac{x}{2W} < m \leq \frac{x}{W}} \left|\sum_{\substack{d>U\\ d|m}} \mu(d)\right|^2, \\ S_2(V,W) &= \sum_{\frac{x}{2W} \leq m \leq \frac{x}{W}} \left|\sum_{\max\left(V, \frac{W}{2}\right) \leq n \leq W} \Lambda(n) e(\alpha mn)\right|^2. \end{aligned} \tag{4.12}$$

We must bound $S_1(U,W)$ by a constant times x/W. We are able to do this – with a good constant. (A careless bound would have given a multiple of $(x/U)\log^3(x/U)$, which is much too large.) First, we reduce $S_1(U,W)$ to an expression involving an integral of

$$\sum_{\substack{r_1\leq x\\ (r_1,r_2)=1}} \sum_{r_2\leq x} \frac{\mu(r_1)\mu(r_2)}{\sigma(r_1)\sigma(r_2)}. \tag{4.13}$$

We can bound (4.13) by the use of bounds on $\sum_{n\leq t}\mu(n)/n$, combined with the estimation of infinite products by means of approximations to $\zeta(s)$ for $s \to 1^+$. After some additional manipulations, we obtain a bound for $S_1(U,W)$ whose main term is at most $(3/\pi^2)(x/W)$ for each W, and closer to $0.22482x/W$ on average over W.

(This is as good a point as any to say that, throughout, we can use a trick in [58] that allows us to work with odd values of integer variables throughout, instead of letting m or n range over all integers. Here, for instance, if m and n are restricted to be odd, we obtain a bound of $(2/\pi^2)(x/W)$ for individual W, and $0.15107x/W$ on average over W.)

Let us now bound $S_2(V, W)$. This is traditionally done by Linnik's dispersion method. However, it should be clear that the thing to do nowadays is to use a large sieve, and, more specifically, a large sieve for primes. In order to take advantage of prime support, we use Montgomery's inequality ([33, 43]; see the expositions in [44, pp. 27–29] and [34, §7.4]) combined with Montgomery and Vaughan's large sieve with weights [45, (1.6)], following the general procedure in [45, (1.6)]. We obtain a bound of the form

$$\frac{\log W}{\log \frac{W}{2q}} \left(\frac{x}{4\phi(q)} + \frac{qW}{\phi(q)} \right) \frac{W}{2} \tag{4.14}$$

on $S_2(V, W)$, where, of course, we can also choose *not* to gain a factor of $\log W/2q$ if q is close to or greater than W.

It remains to see how to gain a factor of $|\delta|$ in the major arcs, and more specifically in $S_2(V, W)$. To explain this, let us step back and take a look at what the large sieve is. Given a civilized function $f : \mathbb{Z} \to \mathbb{C}$, Plancherel's identity tells us that

$$\int_{\mathbb{R}/\mathbb{Z}} \left| \widehat{f}\,(\alpha) \right|^2 d\alpha = \sum_n |f(n)|^2.$$

The large sieve can be seen as an approximate, or statistical, version of this: for a "sample" of points $\alpha_1, \alpha_2, \dots, \alpha_k$ satisfying $|\alpha_i - \alpha_j| \geq \beta$ for $i \neq j$, it tells us that

$$\sum_{1 \leq j \leq k} \left| \widehat{f}\,(\alpha_j) \right|^2 \leq (X + \beta^{-1}) \sum_n |f(n)|^2, \tag{4.15}$$

assuming that f is supported on an interval of length X.

Now consider $\alpha_1 = \alpha, \alpha_2 = 2\alpha, \alpha_3 = 3\alpha \dots$. If $\alpha = a/q$, then the angles $\alpha_1, \dots, \alpha_q$ are well-separated, i.e., they satisfy $|\alpha_i - \alpha_j| \geq 1/q$, and so we can apply (4.15) with $\beta = 1/q$. However, $\alpha_{q+1} = \alpha_1$. Thus, if we have an outer sum of length $L > q$ – in (4.12), we have an outer sum of length $L = x/2W$ – we need to split it into $\lceil L/q \rceil$ blocks of length q, and so the total bound given by (4.15) is $\lceil L/q \rceil (X + q) \sum_n |f(n)|^2$. Indeed, this is what gives us (4.14), which is fine, but we want to do better for $|\delta|$ larger than a constant.

Suppose, then, that $\alpha = a/q + \delta/x$, where $|\delta| > 8$, say. Then the angles α_1 and α_{q+1} are not identical: $|\alpha_1 - \alpha_{q+1}| \leq q|\delta|/x$. We also see that α_{q+1} is at a distance at least $q|\delta|/x$ from $\alpha_2, \alpha_3, \dots \alpha_q$, provided that $q|\delta|/x < 1/q$. We can go on with $\alpha_{q+2}, \alpha_{q+3}, \dots$, and stop only once there is overlap, i.e., only once we reach α_m such that $m|\delta|/x \geq 1/q$. We then give all the angles $\alpha_1, \dots, \alpha_m$ – which are separated by at least $q|\delta|/x$ from each other – to the large sieve at the same time. We do this $\lceil L/m \rceil \leq \lceil L/(x/|\delta|q) \rceil$ times, and obtain a total bound of $\lceil L/(x/|\delta|q) \rceil (X + x/|\delta|q) \sum_n |f(n)|^2$, which, for $L = x/2W$, $X = W/2$, gives us about

$$\left(\frac{x}{4Q} \frac{W}{2} + \frac{x}{4} \right) \log W$$

provided that $L \geq x/|\delta|q$ and, as usual, $|\alpha - a/q| \leq 1/qQ$. This is very small compared to the trivial bound $\lesssim xW/8$.

What happens if $L < x/|\delta q|$? Then there is never any overlap: we consider all angles α_i, and give them all together to the large sieve. The total bound is $(W^2/4 + xW/2|\delta|q) \log W$. If $L = x/2W$ is smaller than, say, $x/3|\delta q|$, then we see clearly that there are non-intersecting swarms of α_i around the rationals a/q. We can thus save a factor of $\log$ (or rather $(\phi(q)/q) \log (W/|\delta q|)$) by applying Montgomery's inequality, which operates by strewing displacements of the given angles (or, here, the swarms) around the circle to the extent possible while keeping everything well-separated. In this way, we obtain a bound of the form

$$\frac{\log W}{\log \frac{W}{|\delta|q}} \left(\frac{x}{|\delta|\phi(q)} + \frac{q}{\phi(q)} \frac{W}{2} \right) \frac{W}{2}.$$

Compare this to (4.14); we have gained a factor of $|\delta|/4$, and so we use this estimate when $|\delta| > 4$. (In [28], the criterion is $|\delta| > 8$, but, since there we have $2\alpha = a/q + \delta/x$, the value of δ there is twice what it is here; this is a consequence of working with sums over the odd integers, as in [58].)

* * *

We have succeeded in eliminating all factors of $\log$ we came across. The only factor of $\log$ that remains is $\log x/UV$, coming from the integral $\int_V^{x/U} dW/W$. Thus, we want UV to be close to x, but we cannot let it be too close, since we also have a term proportional to $D = UV$ in (4.10), and we need to keep it substantially smaller than x. We set U and V so that UV is $x/\sqrt{q \max(4, |\delta|)}$ or thereabouts.

In the end, after some work, we obtain the main result in [28]. We recall that $S_\eta(\alpha, x) = \sum_n \Lambda(n) e(\alpha n) \eta(n/x)$ and $\eta_2 = \eta_1 *_M \eta_1 = 4 \cdot 1_{[1/2,1]} * 1_{[1/2,1]}$.

Theorem 4.1. *Let $x \geq x_0$, $x_0 = 2.16 \cdot 10^{20}$. Let $2\alpha = a/q + \delta/x$, $q \leq Q$, $\gcd(a, q) = 1$, $|\delta/x| \leq 1/qQ$, where $Q = (3/4)x^{2/3}$. If $q \leq x^{1/3}/6$, then*

$$|S_\eta(\alpha, x)| \leq \frac{R_{x,\delta_0 q} \log \delta_0 q + 0.5}{\sqrt{\delta_0 \phi(q)}} \cdot x + \frac{2.5x}{\sqrt{\delta_0 q}} + \frac{2x}{\delta_0 q} \cdot L_{x,\delta_0,q} + 3.2x^{5/6}, \tag{4.16}$$

where $\delta_0 = \max(2, |\delta|/4)$,

$$\begin{aligned} R_{x,t} &= 0.27125 \log \left(1 + \frac{\log 4t}{2 \log \frac{9x^{1/3}}{2.004t}} \right) + 0.41415 \\ L_{x,\delta,q} &= \frac{\log \delta^{\frac{7}{4}} q^{\frac{13}{4}} + \frac{80}{9}}{\phi(q)/q} + \log q^{\frac{80}{9}} \delta^{\frac{16}{9}} + \frac{111}{5}. \end{aligned} \tag{4.17}$$

If $q > x^{1/3}/6$, then

$$|S_\eta(\alpha, x)| \leq 0.2727 x^{5/6} (\log x)^{3/2} + 1218 x^{2/3} \log x.$$

The factor $R_{x,t}$ is small in practice; for typical "difficult" values of x and $\delta_0 x$, it is less than 1. The crucial things to notice in (4.16) are that there is no factor of $\log x$, and that, in the main term, there is only one factor of $\log \delta_0 q$. The fact that δ_0 helps us as it grows is precisely what enables us to take major arcs that get narrower and narrower as q grows.

5. Integrals over the major and minor arcs

So far, we have sketched (§3) how to estimate $S_\eta(\alpha, x)$ for α in the major arcs and η based on the Gaussian $e^{-t^2/2}$, and also (§4) how to bound $|S_\eta(\alpha, x)|$ for α in the minor arcs and $\eta = \eta_2$, where $\eta_2 = 4 \cdot 1_{[1/2,1]} *_M 1_{[1/2,1]}$. We now must show how to use such information to estimate integrals such as the ones in (2.3).

We will use two smoothing functions η_+, η_*; in the notation of (2.2), we set $f_1 = f_2 = \Lambda(n)\eta_+(n/x)$, $f_3 = \Lambda(n)\eta_*(n/x)$, and so we must give a lower bound for

$$\int_{\mathfrak{M}} (S_{\eta_+}(\alpha, x))^2 S_{\eta_*}(\alpha, x) e(-\alpha n) d\alpha \tag{5.1}$$

and an upper bound for

$$\int_{\mathfrak{m}} \left|S_{\eta_+}(\alpha, x)\right|^2 S_{\eta_*}(\alpha, x) e(-\alpha n) d\alpha \tag{5.2}$$

so that we can verify (2.3).

The traditional approach to (5.2) is to bound

$$\begin{aligned} \int_{\mathfrak{m}} (S_{\eta_+}(\alpha, x))^2 S_{\eta_*}(\alpha, x) e(-\alpha n) d\alpha &\le \int_{\mathfrak{m}} \left|S_{\eta_+}(\alpha, x)\right|^2 d\alpha \cdot \max_{\alpha \in \mathfrak{m}} \widehat{\eta_*}(\alpha) \\ &\le \sum_n \Lambda(n)^2 \eta_+^2\left(\frac{n}{x}\right) \cdot \max_{\alpha \in \mathfrak{m}} S_{\eta_*}(\alpha, x). \end{aligned} \tag{5.3}$$

Since the sum over n is of the order of $x \log x$, this is not log-free, and so cannot be good enough; we will later see how to do better. Still, this gets the main shape right: our bound on (5.2) will be proportional to $|\eta_+|_2^2 |\eta_*|_1$. Moreover, we see that η_* has to be such that we know how to bound $|S_{\eta_*}(\alpha, x)|$ for $\alpha \in \mathfrak{m}$, while our choice of η_+ is more or less free, at least as far as the minor arcs are concerned.

What about the major arcs? In order to do anything on them, we will have to be able to estimate both $\eta_+(\alpha)$ and $\eta_*(\alpha)$ for $\alpha \in \mathfrak{M}$. Once we do this, we will obtain that the main term of (5.1) is an infinite product (independent of the smoothing functions), times x^2, times

$$\int_0^\infty \int_0^\infty \eta_+(t_1)\eta_+(t_2)\eta_*\left(\frac{n}{x} - (t_1 + t_2)\right) dt_1 dt_2. \tag{5.4}$$

In other words, we want to maximize (or nearly maximize) the expression on the right of (5.4) divided by $|\eta_+|_2^2 |\eta_*|_1$.

One way to do this is to let η_* be concentrated on a small interval $[0, \epsilon)$. Then the right side of (5.4) is approximately

$$|\eta_*|_1 \cdot \int_0^\infty \eta_+(t)\eta_+\left(\frac{n}{x} - t\right) dt. \tag{5.5}$$

To maximize this, we should make sure that $\eta_+(t) \sim \eta_+(n/x - t)$. We set $x \sim n/2$, and see that we should define η_+ so that it is supported on $[0, 2]$ and symmetric around $t = 1$, or nearly so; this will maximize the ratio of (5.5) to $|\eta_+|_2^2 |\eta_*|_1$.

We should do this while making sure that we will know how to estimate $S_{\eta_+}(\alpha, x)$ for $\alpha \in \mathfrak{M}$. We know how to estimate $S_\eta(\alpha, x)$ very precisely for functions of the form

$\eta(t) = g(t)e^{-t^2/2}$, $\eta(t) = g(t)te^{-t^2/2}$, etc., where $g(t)$ is band-limited. We will work with a function η_+ of that form, chosen so as to be very close (in ℓ_2 norm) to a function $\eta_\circ$ that is in fact supported on $[0, 2]$ and symmetric around $t = 1$.

We choose

$$\eta_\circ(t) = \begin{cases} t^2(2-t)^3 e^{-(t-1)^2/2} & \text{if } t \in [0,2], \\ 0 & \text{if } t \notin [0,2]. \end{cases}$$

This function is obviously symmetric ($\eta_\circ(t) = \eta_\circ(2-t)$) and vanishes to high order at $t = 0$, besides being supported on $[0, 2]$.

We set $\eta_+(t) = h_R(t)te^{-t^2/2}$, where $h_R(t)$ is an approximation to the function

$$h(t) = \begin{cases} t^2(2-t)^3 e^{t-\frac{1}{2}} & \text{if } t \in [0,2] \\ 0 & \text{if } t \notin [0,2]. \end{cases}$$

We just let $h_R(t)$ be the inverse Mellin transform of the truncation of Mh to an interval $[-iR, iR]$, or, what is the same,

$$h_R(t) = \int_0^\infty h(ty^{-1}) F_R(y) \frac{dy}{y},$$

where $F_R(t) = \sin(R \log y)/(\pi \log y)$ (the Dirichlet kernel with a change of variables); since the Mellin transform of $te^{-t^2/2}$ is regular at $s = 0$, the Mellin transform $M\eta_+$ will be holomorphic in a neighborhood of $\{s : 0 \le \Re(s) \le 1\}$, even though the truncation of Mh to $[-iR, iR]$ is brutal. Set $R = 200$, say. By the fast decay of $Mh(it)$ and the fact that the Mellin transform M is an isometry, $|(h_R(t) - h(t))/t|_2$ is very small, and hence so is $|\eta_+ - \eta_\circ|_2$, as we desired.

But what about the requirement that we be able to estimate $S_{\eta_*}(\alpha, x)$ for both $\alpha \in \mathfrak{m}$ and $\alpha \in \mathfrak{M}$?

Generally speaking, if we know how to estimate $S_{\eta_1}(\alpha, x)$ for some $\alpha \in \mathbb{R}/\mathbb{Z}$ and we also know how to estimate $S_{\eta_2}(\alpha, x)$ for all other $\alpha \in \mathbb{R}/\mathbb{Z}$, where η_1 and η_2 are two smoothing functions, then we know how to estimate $S_{\eta_3}(\alpha, x)$ for all $\alpha \in \mathbb{R}/\mathbb{Z}$, where $\eta_3 = \eta_1 *_M \eta_2$, or, more generally, $\eta_*(t) = (\eta_1 *_M \eta_2)(\kappa t)$, $\kappa > 0$ a constant. This is a simple exercise in exchanging the order of integration and summation:

$$\begin{aligned} S_{\eta_*}(\alpha, x) &= \sum_n \Lambda(n) e(\alpha n) (\eta_1 *_M \eta_2)\left(\kappa \frac{n}{x}\right) \\ &= \int_0^\infty \sum_n \Lambda(n) e(\alpha n) \eta_1(\kappa r) \eta_2\left(\frac{n}{rx}\right) \frac{dr}{r} = \int_0^\infty \eta_1(\kappa r) S_{\eta_2}(rx) \frac{dr}{r}, \end{aligned}$$

and similarly with η_1 and η_2 switched.

Now that we have chosen our smoothing weights η_+ and η_*, we have to estimate the major-arc integral (5.1) and the minor-arc integral (5.2). What follows can actually be done for general η_+ and η_*; we could have left our particular choice of η_+ and η_* for the end.

Estimating the major-arc integral (5.1) may sound like an easy task, since we have rather precise estimates for $S_\eta(\alpha, x)$ ($\eta = \eta_+, \eta_*$) when α is on the major arcs; we could just replace $S_\eta(\alpha, x)$ in (5.1) by the approximation given by (3.3) and (3.7). It is, however, more efficient to express (5.1) as the sum of the contribution of the trivial character (a sum of

integrals of $(\widehat{\eta}(-\delta)x)^3$, where $\widehat{\eta}(-\delta)x$ comes from (3.7)), plus a term of the form

$$(\text{maximum of } \sqrt{q}\cdot E(q) \text{ for } q\le r)\cdot \int_{\mathfrak{M}} \left|S_{\eta_+}(\alpha,x)\right|^2 d\alpha,$$

where $E(q)=E$ is as in (3.8), plus two other terms of the same form. As usual, the major arcs $\mathfrak{M}$ are the arcs around rationals a/q with $q\le r$. We will soon discuss how to bound the integral of $\left|S_{\eta_+}(\alpha,x)\right|^2$ over arcs around rationals a/q with $q\le s$, s arbitrary. Here, however, it is best to estimate the integral over $\mathfrak{M}$ using the estimate on $S_{\eta_+}(\alpha,x)$ from (3.3) and (3.7); we obtain a great deal of cancellation, with the effect that, for χ non-trivial, the error term in (3.8) appears only when it gets squared, and thus becomes negligible.

The contribution of the trivial character has an easy approximation, thanks to the fast decay of $\widehat{\eta_\circ}$. We obtain that the major-arc integral (5.1) equals a main term $C_0 C_{\eta_\circ,\eta_*} x^2$, where

$$C_0 = \prod_{p\mid n}\left(1-\frac{1}{(p-1)^2}\right)\cdot \prod_{p\nmid n}\left(1+\frac{1}{(p-1)^3}\right),$$

$$C_{\eta_\circ,\eta_*} = \int_0^\infty\int_0^\infty \eta_\circ(t_1)\eta_\circ(t_2)\eta_*\left(\frac{n}{x}-(t_1+t_2)\right)dt_1dt_2,$$

plus several small error terms. We have already chosen $\eta_\circ$, η_* and x so as to (nearly) maximize $C_{\eta_\circ,\eta_*}$.

It is time to bound the minor-arc integral (5.2). As we said in §5, we must do better than the usual bound (5.3). Since our minor-arc bound (4.16) on $|S_\eta(\alpha,x)|$, $\alpha\sim a/q$, decreases as q increases, it makes sense to use partial summation together with bounds on

$$\int_{\mathfrak{m}_s}|S_{\eta_+}(\alpha,x)|^2 = \int_{\mathfrak{M}_s}|S_{\eta_+}(\alpha,x)|^2 d\alpha - \int_{\mathfrak{M}}|S_{\eta_+}(\alpha,x)|^2 d\alpha,$$

where $\mathfrak{m}_s$ denotes the arcs around a/q, $r<q\le s$, and $\mathfrak{M}_s$ denotes the arcs around all a/q, $q\le s$. We already know how to estimate the integral on $\mathfrak{M}$. How do we bound the integral on $\mathfrak{M}_s$?

In order to do better than the trivial bound $\int_{\mathfrak{M}_s}\le\int_{\mathbb{R}/\mathbb{Z}}$, we will need to use the fact that the series (3.2) defining $S_{\eta_+}(\alpha,x)$ is essentially supported on prime numbers. Bounding the integral on $\mathfrak{M}_s$ is closely related to the problem of bounding

$$\sum_{q\le s}\sum_{\substack{a \bmod q\\(a,q)=1}}\left|\sum_{n\le x} a_n e(a/q)\right|^2 \tag{5.6}$$

efficiently for s considerably smaller than $\sqrt{x}$ and a_n supported on the primes $\sqrt{x}<p\le x$. This is a classical problem in the study of the large sieve. The usual bound on (5.6) (by, for instance, Montgomery's inequality) has a gain of a factor of $2e^\gamma(\log s)/(\log x/s^2)$ relative to the bound of $(x+s^2)\sum_n|a_n|^2$ that one would get from the large sieve without using prime support. Heath-Brown proceeded similarly to bound

$$\int_{\mathfrak{M}_s}|S_{\eta_+}(\alpha,x)|^2 d\alpha \lesssim \frac{2e^\gamma\log s}{\log x/s^2}\int_{\mathbb{R}/\mathbb{Z}}|S_{\eta_+}(\alpha,x)|^2 d\alpha. \tag{5.7}$$

This already gives us the gain of $C(\log s)/\log x$ that we absolutely need, but the constant C is suboptimal; the factor in the right side of (5.7) should really be $(\log s)/\log x$, i.e., C should be 1. We cannot reasonably hope to do better than $2(\log s)/\log x$ in the minor arcs due to what is known as the *parity problem* in sieve theory. As it turns out, Ramaré [52] had given general bounds on the large sieve that were clearly conducive to better bounds on (5.6), though they involved a ratio that was not easy to bound in general.

I used several careful estimations (including [51, Lem. 3.4]) to reduce the problem of bounding this ratio to a finite number of cases, which I then checked by rigorous computation. This approach gave a bound on (5.6) with a factor of size close to $2(\log s)/\log x$. (This solves the large-sieve problem for $s \le x^{0.3}$; it would still be worthwhile to give a computation-free proof for all $s \le x^{1/2-\epsilon}$, $\epsilon > 0$.) It was then easy to give an analogous bound for the integral over $\mathfrak{M}_s$, namely,

$$\int_{\mathfrak{M}_s} |S_{\eta_+}(\alpha, x)|^2 d\alpha \lesssim \frac{2 \log s}{\log x} \int_{\mathbb{R}/\mathbb{Z}} |S_{\eta_+}(\alpha, x)|^2 d\alpha,$$

where $\lesssim$ can easily be made precise by replacing $\log s$ by $\log s + 1.36$ and $\log x$ by $\log x + c$, where c is a small constant. Without this improvement, the main theorem would still have been proved, but the required computation time would have been multiplied by a factor of considerably more than $e^{3\gamma} = 5.6499\ldots$.

What remained then was just to compare the estimates on (5.1) and (5.2) and check that (5.2) is smaller for $n \ge 10^{27}$. This final step was just bookkeeping. As we already discussed, a check for $n < 10^{27}$ is easy. Thus ends the proof of the main theorem.

6. Some remarks on computations

There were two main computational tasks: verifying the ternary conjecture for all $n \le C$, and checking the Generalized Riemann Hypothesis for modulus $q \le r$ up to a certain height.

The first task was not very demanding. Platt and I verified in [31] that every odd integer $5 < n \le 8.8 \cdot 10^{30}$ can be written as the sum of three primes. (In the end, only a check for $5 < n \le 10^{27}$ was needed.) We proceeded as follows. Oliveira e Silva, Herzog and Pardi [46]) had already checked that the binary Goldbach conjecture is true up to $4 \cdot 10^{18}$. Given that, all we had to do was to construct a "prime ladder", that is, a list of primes from 3 up to $8.8 \cdot 10^{30}$ such that the difference between any two consecutive primes in the list is at least 4 and at most $4 \cdot 10^{18}$. (This is a known strategy: see [55].) Then, for any odd integer $5 < n \le 8.8 \cdot 10^{30}$, there is a prime p in the list such that $4 \le n - p \le 4 \cdot 10^{18} + 2$. (Choose the largest $p < n$ in the ladder, or, if n minus that prime is 2, choose the prime immediately under that.) By [46] (and the fact that $4 \cdot 10^{18} + 2$ equals $p + q$, where $p = 2000000000000001301$ and $q = 1999999999999998701$ are both prime), we can write $n - p = p_1 + p_2$ for some primes p_1, p_2, and so $n = p + p_1 + p_2$.

Building a prime ladder involves only integer arithmetic, that is, computer manipulation of integers, rather than of real numbers. Integers are something that computers can handle rapidly and reliably. We look for primes for our ladder only among a special set of integers whose primality can be tested deterministically quite quickly (Proth numbers: $k \cdot 2^m + 1$, $k < 2^m$). Thus, we can build a prime ladder by a rigorous, deterministic algorithm that can be (and was) parallelized trivially.

The second computation is more demanding. It consists in verifying that, for every L-function $L(s,\chi)$ with χ of conductor $q \le r = 300000$ (for q even) or $q \le r/2$ (for q odd), all zeroes of $L(s,\chi)$ such that $|\Im(s)| \le H_q = 10^8/q$ (for q odd) and $|\Im(s)| \le H_q = \max(10^8/q, 200 + 7.5 \cdot 10^7/q$ (for q even) lie on the critical line. This was entirely Platt's work; my sole contribution was to request computer time. In fact, he went up to conductor $q \le 200000$ (or twice that for q even); he had already gone up to conductor 100000 in his PhD thesis. The verification took, in total, about 400000 core-hours (i.e., the total number of processor cores used times the number of hours they ran equals 400000; nowadays, a top-of-the-line processor typically has eight cores). In the end, since I used only $q \le 150000$ (or twice that for q even), the number of hours actually needed was closer to 160000; since I could have made do with $q \le 120000$ (at the cost of increasing C to 10^{29} or 10^{30}), it is likely, in retrospect, that only about 80000 core-hours were needed.

Checking zeros of L-functions computationally goes back to Riemann (who did it by hand for the special case of the Riemann zeta function). It is also one of the things that were tried on digital computers in their early days (by Turing [61], for instance; see the exposition in [1]). One of the main issues to be careful about arises whenever one manipulates real numbers via a computer: generally speaking, a computer cannot store an irrational number, and so one cannot say: "computer, give me the sine of that number" and expect a precise result. What one should do is to say: "computer, I am giving you an interval $I = [a/2^k, b/2^k]$; give me an interval $I' = [c/2^\ell, d/2^\ell]$, preferably very short, such that $\sin(I) \subset I'$". This is called interval arithmetic; it is arguably the easiest way to do floating-point computations rigorously.

Processors do not do this natively, and if interval arithmetic is implemented purely on software, computations can be slowed down by a factor of about 100. Fortunately, there are ways of running interval-arithmetic computations partly on hardware, partly on software. Platt has his own library, but there are others online (e.g. PROFIL/BIAS [38]).

Lastly, there were several relatively minor computations embedded in [27–29]. A typical computation was a rigorous version of a "proof by graph" ("the maximum of a function f is clearly less than 4 because I can see it on the screen"). There is a standard way to do this (see, e.g., [60, §5.2]); essentially, the bisection method combines naturally with interval arithmetic. Yet another computation (and not a very small one) was that involved in verifying a large-sieve inequality in an intermediate range (as we discussed in §5).

It may be interesting to note that one of the inequalities used to estimate (4.13) was proven with the help of automatic quantifier elimination [32]. Proving this inequality was a very minor task, both computationally and mathematically; in all likelihood, it is feasible to give a human-generated proof. Still, it is nice to know from first-hand experience that computers can nowadays (pretend to) do something other than just perform numerical computations – and that this is true even in current mathematical practice.

Acknowledgements. Thanks are due to J. Brandes and R. Vaughan for a discussion on a possible ambiguity in the Latin word in [14, p. 298]. Descartes' statement is mentioned (with a translation much like the one given here) in Dickson's *History* [17, Ch. XVIII]. Parts of the present article are based on a previous expository note by the author. The first version of the note appeared online, in English, in an informal venue [30]; later versions were published in Spanish ([25], translated by M. A. Morales and the author, and revised with the help of J. Cilleruelo and M. Helfgott) and French ([26], translated by M. Bilu and revised by the author). Many individuals and organizations should be thanked for their

generous help towards the work summarized here; an attempt at a full list can be found in the acknowledgments sections of [27–29]. Thanks are also due to J. Brandes, K. Gong, R. Heath-Brown, Z. Silagadze, R. Vaughan and T. Wooley, for help with historical questions.

Small gaps between primes

D. A. Goldston, J. Pintz, and C. Y. Yıldırım

Abstract. This paper describes the authors' joint research on small gaps between primes in the last decade and how their methods were developed further independently by Zhang, Maynard, and Tao to prove stunning new results on primes. We now know that there are infinitely many primes differing by at most 246, and that one can find k primes a bounded distance (depending on k) apart infinitely often. These results confirm important approximations to the Hardy–Littlewood Prime Tuples Conjecture.

Mathematics Subject Classification (2010). Primary 11N05, 11N36; Secondary 11N35.

Keywords. Hardy–Littlewood prime tuples conjecture, prime numbers, sieves, gaps between primes, twin primes.

1. History

The twin prime conjecture that n and $n+2$ are both primes for infinitely many positive integers n, may have been conceived around the time of Euclid, more than two thousand years ago. Among as yet unsolved problems in mathematics it is one of the oldest. The purpose of the present article is to give an overview of the progress in the last nine years in this subject, in particular, of the results of the authors.

As a young boy Gauss observed in 1792 or 1793 that the primes around x have an average distance $\log x$ which led him to conjecture that

$$\pi(x) := \sum_{\substack{p\le x\\ p:\text{ prime}}} 1 \ \sim \mathrm{li}\ x := \int_2^x \frac{dt}{\log t} \sim \frac{x}{\log x} \qquad (x\to\infty). \tag{1.1}$$

This conjecture was proved in 1896 (independently) by Hadamard and de la Vallée Poussin, and is now called the Prime Number Theorem.

A relevant quantity in the study of small gaps between primes is

$$\Delta := \liminf_{n\to\infty} \frac{d_n}{\log n} = \liminf_{n\to\infty} \frac{p_{n+1}-p_n}{\log n}, \tag{1.2}$$

where $\{p_i\}_{i=1}^{\infty} =: \mathcal{P}$ is the set of primes sequenced in increasing order and $d_n := p_{n+1} - p_n$. The Prime Number Theorem, (1.1), immediately implies $\Delta \leqslant 1$, so the first task concerning an upper estimation of Δ was to show an estimate of the type $\Delta < 1$. During the twentieth century there were many papers on upper estimates for Δ. First, in 1926, Hardy and

Proceedings of the International Congress of Mathematicians, Seoul, 2014

Littlewood (unpublished, see [32]) succeeded in showing, assuming the Generalized Riemann Hypothesis (GRH), that

$$\Delta \leqslant 2/3. \tag{1.3}$$

The first unconditional bound

$$\Delta \leqslant 1 - c_1, \tag{1.4}$$

with an unspecified but explicitly calculable $c_1 > 0$, was shown by Erdős in 1940 [5] who used Brun's sieve. The next big step was made by Bombieri and Davenport [2] who removed the assumption of GRH in Hardy and Littlewood's method by using Bombieri's work [1] on the large sieve and showed that

$$\Delta \leqslant \left(2 + \sqrt{3}\right)/8 = 0.466\ldots. \tag{1.5}$$

Their method gave $\Delta \leqslant 1/2$ but they were also able to combine this with an explicit version of Erdős's [5] proof which led them to (1.5). After several smaller improvements (Huxley and others), Maier [23] succeeded in combining the matrix method he developed with the ideas of Bombieri–Davenport, Erdős and Huxley, making it possible to multiply the best known bound by $e^{-\gamma}$ (γ is Euler's constant) and reach

$$\Delta \leqslant 0.248\ldots. \tag{1.6}$$

In 2005 the authors proved (see [14]; or for a brief account §2, §3 below)

$$\Delta = 0. \tag{1.7}$$

2. Ideas behind the proofs of some results concerning small gaps between consecutive primes

We begin by recounting a number of conjectures related to the twin prime conjecture and more generally to small gaps between consecutive primes. Some of them have been known for a long time, some of them were introduced by us.

Conjecture 2.1 (Twin Prime Conjecture). $d_n = 2$ *infinitely often.*

A generalization of this was formulated in 1849 by de Polignac.

Conjecture 2.2 (De Polignac's Conjecture [29]). *For every given positive even integer h, $d_n = h$ infinitely often.*

For a further generalization we need the notion of *admissible k-tuples*.

Definition 2.3. $\mathcal{H} = \{h_i\}_{i=1}^k$ $(0 \leqslant h_1 < h_2 \cdots < h_k, h_k \in \mathbb{Z})$ is *admissible* if the h_i's do not cover all residue classes mod p for any prime p.

This is clearly a necessary condition that $n + h_i \in \mathcal{P}$ for all integers $1 \leq i \leq k$ holds for infinitely many numbers n.

Dickson formulated in 1904 the conjecture that this condition was also sufficient. Although his conjecture included linear forms of type $a_i n + b_i$ $(a_i, b_i \in \mathbb{Z})$ we will consider the special case $a_i = 1$ for all $i \in [1, k]$.

Conjecture 2.4 (Dickson's Conjecture [3]). *If $\mathcal{H}$ is admissible, then $n + h_i \in \mathcal{P}$ for all $i \in [1, k]$ holds for infinitely many values of n.*

About twenty years later, in 1923, Hardy and Littlewood formulated this in a quantitative form as

Conjecture 2.5 (Hardy–Littlewood Prime-Tuples Conjecture [20]). *If $\mathcal{H}$ is an admissible k-tuple, then*

$$\sum_{\substack{n\leqslant x\\ \{n+h_i\}_{i=1}^{k}\in\mathcal{P}^k}} 1 \sim \mathfrak{S}(\mathcal{H})\frac{x}{\log^k x}, \tag{2.1}$$

where

$$\mathfrak{S}(\mathcal{H}) := \prod_p \left(1 - \frac{\nu_{\mathcal{H}}(p)}{p}\right)\left(1 - \frac{1}{p}\right)^{-k} > 0, \tag{2.2}$$

and $\nu_{\mathcal{H}}(p)$ denotes the number of distinct residue classes modulo p occupied by the elements of $\mathcal{H}$.

Note that the relation $\mathfrak{S}(\mathcal{H}) > 0$ is equivalent to $\mathcal{H}$ being admissible.

Until now the conjectures were listed in increasing strength. We introduced a weaker form of Dickson's Conjecture:

Conjecture 2.6 (Conjecture DHL$(k, 2)$). *If $\mathcal{H}$ is an admissible k-tuple, then $n + \mathcal{H}$ contains at least two primes infinitely often.*

If the above conjecture is true for at least one admissible k-tuple, then it implies another conjecture which is a good approximation to the Twin Prime Conjecture. This we called the

Conjecture 2.7 (Bounded Gaps Conjecture). *There exists an absolute constant C such that $d_n = p_{n+1} - p_n \leqslant C$ for infinitely many n.*

A still weaker form of the Bounded Gap Conjecture is

Conjecture 2.8 (Small Gaps Conjecture). $\Delta = \liminf\limits_{n\to\infty} \dfrac{p_{n+1} - p_n}{\log p_n} = 0.$

Within the scope of our work the existence of small or bounded gaps between consecutive primes is intimately connected with the distribution of primes in arithmetic progressions. The following definition of an admissible level ϑ of primes was already known and used in sieve theory.

Definition 2.9. ϑ is called an *admissible level of distribution of primes* if for any $\varepsilon > 0$, $A > 0$ we have for any $X > 2$

$$\sum_{q\leqslant X^{\vartheta-\varepsilon}} \max_{\substack{a\\(a,q)=1}} \left| \sum_{\substack{p\equiv a(q)\\ p\leqslant X}} \log p - \frac{X}{\varphi(q)} \right| \leqslant \frac{C(A,\varepsilon)X}{(\log X)^A}, \tag{2.3}$$

where $C(A, \varepsilon)$ is an ineffective constant depending on A and ε.

The largest known level $\vartheta = 1/2$ is the celebrated Bombieri–Vinogradov [1, 38] Theorem. The strongest possibility, $\vartheta = 1$, is the Elliott–Halberstam [4] Conjecture, and more generally one can introduce

Conjecture 2.10 (Conjecture EH(ϑ)). (2.3) *is true for a fixed* $\vartheta \in (\frac{1}{2}, 1]$.

We succeeded in showing in 2005 the following result.

Theorem 2.11 ([14]). *If* EH(ϑ) *is true for some fixed* $\vartheta > 1/2$, *then* DHL$(k, 2)$ *is true for* $k > k_0(\vartheta)$ *and consequently the Bounded Gaps Conjecture is true, i.e.* $\liminf_{n\to\infty} d_n < \infty$.

Theorem 2.12 ([14]). *The Small Gaps Conjecture is true, i.e.* $\Delta = 0$.

We improved this somewhat later to

Theorem 2.13 ([15]). $\liminf_{n\to\infty} \dfrac{d_n}{(\log n)^{1/2}(\log\log n)^2} < \infty$.

Concerning the frequency of small gaps we showed

Theorem 2.14 ([17, 18]). *Given any fixed* $\eta > 0$ *the relation*

$$d_n = p_{n+1} - p_n < \eta \log n \tag{2.4}$$

holds for a positive proportion of all gaps.

One of the important ideas which yielded a proof of the Small Gaps Conjecture in [14] and which – along with the work of Y. Motohashi and J. Pintz [25] – represented an important step in the first proof of the Bounded Gaps Conjecture by Y. Zhang [39] was to attack, among the listed seven conjectures, particularly DHL$(k, 2)$. The idea was to find suitable non-negative weights a_n for $n \in [N, 2N)$ to be abbreviated later as $n \sim N$, such that a_n should be relatively large compared with $S = \sum_{n\sim N} a_n > 0$ if the set

$$n + \mathcal{H}_k = \{n + h_i\}_{i=1}^k \tag{2.5}$$

contains some (possibly several) primes. A good quantitative formulation is to consider (and try to maximize) the ratio

$$E_j = \frac{S_j}{S^*} := \frac{\sum_{n\sim N} a_n \chi_{\mathcal{P}}(n + h_j)\log(n + h_j)}{\sum_{n\sim N} a_n \log 3N}, \tag{2.6}$$

where $\chi_{\mathcal{P}}(m)$ denotes the characteristic function of primes, that is, $\chi_{\mathcal{P}}(m) = 1$ if m is prime and 0 otherwise.

The quantity

$$\alpha(\mathcal{H}_k) = \sum_{j=1}^k E_j \tag{2.7}$$

describes the (weighted) average number of primes in $n + \mathcal{H}_k$ if n runs between N and $2N$, i.e. $n \sim N$. If we succeed in obtaining for a k-tuple $\mathcal{H} = \mathcal{H}_k$ a lower bound greater than 1 for the quantity in (2.7), then DHL$(k, 2)$ is proved (at least for a single $\mathcal{H} = \mathcal{H}_k$), and from this the Bounded Gaps Conjecture follows immediately.

(i) If we start with the simple uniform choice $a_n \equiv 1$ we obtain

$$\alpha(\mathcal{H}_k) \sim \frac{k}{\log N} \quad \text{as} \quad N \to \infty, \tag{2.8}$$

which clearly tends to 0.

(ii) Choosing $a_n = 1$ if $\{n + h_i\}_{i=1}^k \in \mathcal{P}^k$ and 0 otherwise, we can seemingly reach the optimal value

$$\alpha(\mathcal{H}_k) = k \text{ unless } S = \sum_{n\sim N} a_n = 0. \tag{2.9}$$

Unfortunately, to exclude the possibility $S = S(N) = 0$ for $N > N_0$ is equivalent to the proof of Dickson's Conjecture, so we arrive at a tautology.

In the following $\mathcal{H} = \mathcal{H}_k$ will always be an admissible k-tuple, but to simplify notation we often write simply $\mathcal{H}$ instead of $\mathcal{H}_k$.

(iii) An essentially equivalent formulation of the above is to use the generalized von Mangoldt function

$$a_n = \Lambda_k\big(P_{\mathcal{H}}(n)\big) := \sum_{d|P_{\mathcal{H}}(n)} \mu(d) \left(\log \frac{P_{\mathcal{H}}(n)}{d}\right)^k, \quad P_{\mathcal{H}}(n) = \prod_{i=1}^k (n + h_i) \tag{2.10}$$

which vanishes if $P_{\mathcal{H}}(n)$ has more than k distinct prime factors. However, in this case a direct evaluation of S seems to be hopeless, since d can be as large as N^k.

(iv) It was an idea of Selberg to approximate (2.10) with the divisors cut at $R = N^c$ and accordingly use

$$\sum_{\substack{d|P_{\mathcal{H}}(n)\\ d\leqslant R}} \mu(d) \log^k \frac{R}{d}. \tag{2.11}$$

However, this might be negative.

(v) So the next idea is the weight used in the so-called k-dimensional Selberg sieve, i.e., simply the square of (2.11), namely,

$$a_{n,k} = \left(\sum_{d\leqslant R, d|P_{\mathcal{H}}(n)} \mu(d) \log^k \frac{R}{d}\right)^2. \tag{2.12}$$

In this case choosing $R \leqslant N^{1/2}L^{-A}$, $L = \log N$, $A > A_0(k)$, S can be readily evaluated. Assuming EH(ϑ), the unconditional case being EH(1/2) (the Bombieri–Vinogradov Theorem), the more difficult sum S_j can also be evaluated, but only under the stronger constraint

$$R \leqslant N^{(\vartheta-\varepsilon)/2}. \tag{2.13}$$

This yields for the crucial quantity $\alpha(\mathcal{H}_k)$ in (2.7)

$$\alpha(\mathcal{H}_k) = \vartheta - \varepsilon + O\left(\frac{1}{k}\right) \tag{2.14}$$

primes on average, which is unfortunately still less than 1 even under the strongest hypothesis $\vartheta = 1$, the original Elliott–Halberstam Conjecture.

(vi) The winning choice is if we are more modest and instead of Dickson's Conjecture approximate the situation when $\prod_{i=1}^k (n + h_i)$ has at most $k + \ell$ different prime factors where $\ell \geqslant 0$ is a free parameter. (The choice $\ell = 1$ was used earlier by Heath-Brown

[22], however, not to localize primes in $n+\mathcal{H}$ but to find n values where all components $n+h_i$ are almost primes). This means that we use (2.12) with $k+\ell$ instead of k, i.e. our choice in [14] was

$$a_{n,k+\ell} = \left(\sum_{d \leqslant R, d | P_{\mathcal{H}}(n)} \mu(d) \log^{k+\ell} \frac{R}{d} \right)^2. \tag{2.15}$$

This yielded under the condition (2.13) a gain of a factor 2, rather surprisingly. More precisely we got

$$\alpha(\mathcal{H}_k) = 2(\vartheta - \varepsilon) + O\left(\frac{\ell}{k}\right) + O\left(\frac{1}{\ell}\right). \tag{2.16}$$

Under the optimal choice $\ell = \left[\sqrt{k}/2\right]$ this meant

$$\alpha(\mathcal{H}_k) = 2(\vartheta - \varepsilon) + O\left(\frac{1}{\sqrt{k}}\right). \tag{2.17}$$

Consequently if EH(ϑ) is true for some $\vartheta > 1/2$ we obtain $\alpha(\mathcal{H}_k) > 1$ primes on average if $k > C/(\vartheta - 1/2)^2$.

In the unconditional case $\vartheta = 1/2$, this yielded Theorem 2.12 but missed the goal DHL$(k, 2)$ by a hairbreadth.

The way to see how this argument could lead to a proof of the Small Gaps Conjecture begins by observing that on average only $\left(2\varepsilon + \frac{c_1}{\sqrt{k}}\right)$ primes were "missing" to obtain more than one prime on average. Using all numbers of the form

$$n + h, \;\; h \in [1, H], \;\; H = \eta \log N \tag{2.18}$$

with an arbitrarily small but fixed $\eta > 0$ instead of only

$$n + h_i, \;\; h_i \in \mathcal{H}_k \tag{2.19}$$

we could pick up more primes so as to fill the missing part.

If in case of $h \in [1, H] \setminus \mathcal{H}_k$ we expect heuristically $n+h$ to be prime with a probability $1/\log N$, we can hope to collect

$$\eta > 2\varepsilon + \frac{c_1}{\sqrt{k}} + O\left(\frac{k}{\log N}\right) \tag{2.20}$$

primes among $n + h$ on average if $n \sim N$, $h \in [1, H] \setminus \mathcal{H}_k$.

The condition (2.20) is clearly satisfied if

$$\varepsilon < \frac{\eta}{3}, \;\; k > C_2 \eta^{-2}, \;\; N > N_0(k, \varepsilon, \eta). \tag{2.21}$$

In the original work [14] we used a result of Gallagher [11] and an averaging procedure over all $\mathcal{H}_k \subset [1, H]$ to show that the above sketched heuristic works in practice. In the next

section we use a simpler way, which avoids Gallagher's Theorem and uses a single, suitably chosen k-tuple $\mathcal{H}_k$ for all k.

We will not sketch the rather complicated procedure to show Theorem 2.13. We just mention here that it needs the investigation of k-tuples with

$$k \asymp \frac{(\log N)^{1/2}}{(\log\log N)^2}, \quad \ell \asymp \sqrt{k}. \tag{2.22}$$

In the work [27] it was shown that using a suitable polynomial $P(x)$ instead of the simple $x^{k+\ell}$ in (2.15) ($x = \log(R/d)$) one can improve Theorem 2.13 further to

Theorem 2.15 ([27]). $\liminf\limits_{n\to\infty} \dfrac{d_n}{(\log N)^{3/7}(\log\log N)^{4/7}} < \infty.$

One can raise the more general question of finding the optimal polynomial, or more generally the optimal function $P(x)$. B. J. Conrey calculated the optimal weight function, actually a Bessel-type function. Later in the work [10] an exact analysis confirmed the optimality of the Bessel-type function and the fact that it yielded instead of (2.17) the sharper estimate

$$\alpha(\mathcal{H}_k) = 2(\vartheta - \varepsilon) + O(k^{-2/3}). \tag{2.23}$$

This was, however, the same strength as the polynomial in [27] and [10] apart from the implicit constant in the above O symbol. Therefore the result in Theorem 2.15 can be considered as the limit of the original GPY method.

Concerning Theorem 2.14 the crucial idea is the fact, discovered by the second named author ([26]), and independently by Friedlander and Iwaniec [9] that the weights a_n are strongly concentrated on numbers n where all components $n + h_i$ are almost prime, more precisely for numbers n with

$$P^-\left(\prod_{i=1}^{k}(n+h_i)\right) > N^\delta, \ \ n \sim N, \tag{2.24}$$

where δ is an arbitrarily small fixed positive constant and $P^-(m)$ denotes the smallest prime factor of n. In fact, it was proved in [26] that

$$\sum_{\substack{n\sim N\\ P^-(P_{\mathcal{H}}(n))\leqslant N^\delta}} a_n \leqslant C\delta \sum_{n\sim N} a_n \tag{2.25}$$

with a constant $C = C(k)$. (The factor $C(k)\delta$ was improved to $C'k^3\delta^2$ with an absolute constant C' in [17]).

3. Sketch of the proof of Theorems 2.11 and 2.12

In the following we consider a general sieve situation when the number of residues sieved out mod p satisfies

$$\Omega_{\mathcal{H}}(p) = \Omega(p) = k \ \text{ for } \ p \nmid \Delta(\mathcal{H}) := \prod_{i>j}(h_i - h_j), \ k \text{ fixed} \tag{3.1}$$

and let $\Omega(n)$ be extended multiplicatively for all squarefree values of n. Actually we have $\Omega(p) = \Omega_{\mathcal{H}}(p) = \nu_{\mathcal{H}}(p)$. There are three possibilities:

(i) to work analytically with two complex variables (cf. [14]);

(ii) to work elementarily (cf. [13] using pure sieve methods beyond (2.3));

(iii) to work partially elementarily and partially analytically with one complex variable.

Here we will pursue the third possibility, worked out in an unpublished note of K. Soundararajan [37].

We use a somewhat more general weight function: a polynomial $P(y)$ but note that the argument would work the same for a function $P(y)$ analytic on $[0,1]$, if $P(y)$ has at least a kth order zero at 0.

First we evaluate the sum of the weights a_n, where in the following we will define

$$a_n = \left(\sum_{d\leqslant R} \mu(d) P\left(\frac{\log(R/d)}{\log R}\right)\right)^2, \tag{3.2}$$

$$S = \sum_{n\sim N} a_n \sim N \sum_{d,e\leqslant R}{}' \mu(d)\mu(e)\frac{\Omega([d,e])}{[d,e]} P\left(\frac{\log(R/d)}{\log R}\right) P\left(\frac{\log(R/e)}{\log R}\right) \tag{3.3}$$

(we ignored a negligible error of size $O(R^{2+\varepsilon})$) and $\sum'$ will always denote summation over squarefree variables).

Introducing the notation $(d,e) = u$, $d = um$, $e = un$, $(m,n) = 1$ we obtain

$$S \sim N \sum_{u\leqslant R}{}' \sum_{\substack{m,n\leqslant R/u\\(m,n)=1\\(m,u)=(n,u)=1}}{}' \frac{\mu(m)\mu(n)\Omega(u)\Omega(m)\Omega(n)}{umn} P\left(\frac{\log(R/um)}{\log R}\right) P\left(\frac{\log R/un}{\log R}\right). \tag{3.4}$$

We can rewrite the condition $(m,n) = 1$ using the relation

$$\sum_{\beta|m,\beta|n} \mu(\beta) = \begin{cases} 1 & \text{if } (m,n) = 1,\\ 0 & \text{otherwise} \end{cases} \tag{3.5}$$

as

$$S \sim N \sum_{u\leqslant R}{}' \sum_{\beta\leqslant R/u}{}' \mu(\beta)\frac{\Omega(u)\Omega^2(\beta)}{u\beta^2} \left(\sum_{\substack{m'\leqslant R/u\beta\\(m',u)=1}}{}' \frac{\mu(\beta m')\Omega(m')}{m'} P\left(\frac{\log(R/u\beta m')}{\log R}\right)\right)^2. \tag{3.6}$$

Grouping terms with the same value of $u\beta =: \gamma$ with notation $m = m'$ we have

$$S \sim N \sum_{\gamma\leqslant R}{}' \frac{\Omega(\gamma)}{\gamma} \left(\sum_{\beta|\gamma}{}' \frac{\mu(\beta)\Omega(\beta)}{\beta}\right) \left(\sum_{\substack{m\leqslant R/\gamma\\(m,\gamma)=1}}{}' \frac{\mu(m)\Omega(m)}{m} P\left(\frac{\log(R/\gamma m)}{\log R}\right)\right)^2. \tag{3.7}$$

Let us denote the inner sum by $J\left(\gamma, \frac{R}{\gamma}\right)$ where the first variable refers to the condition $(m,\gamma)=1$, the second to $m \leqslant R/\gamma$. Further let for a squarefree γ

$$G(s+1,\gamma) := \sum_{\substack{m \\ (m,\gamma)=1}}{}' \frac{\mu(m)\Omega(m)}{m^{s+1}} =: \zeta(s+1)^{-k}F(s+1,\gamma). \tag{3.8}$$

Here we have for Re $s>0$

$$F(s+1,\gamma) = \prod_p \left(1-\frac{\Omega(p)}{p^{s+1}}\right)\left(1-\frac{1}{p^{s+1}}\right)^{-k}\prod_{p|\gamma}\left(1-\frac{\Omega(p)}{p^{s+1}}\right)^{-1}. \tag{3.9}$$

Using the Taylor expansion

$$P(x) = \sum_{j=k}^{\infty} \frac{P^{(j)}(0)x^j}{j!} \tag{3.10}$$

and Perron's formula ($c>0$, arbitrary)

$$\frac{1}{2\pi i}\int_{(c)} \frac{x^s}{s^{j+1}}ds = \begin{cases} \frac{(\log x)^j}{j!} & \text{if } x \geqslant 1, \\ 0 & \text{if } 0 \leqslant x \leqslant 1 \end{cases} \qquad (j \in \mathbb{Z}^+) \tag{3.11}$$

we can rewrite $J\left(\gamma, \frac{R}{\gamma}\right)$ as

$$\begin{aligned} J\left(\gamma,\frac{R}{\gamma}\right) &= \sum_{j=k}^{\infty}\frac{P^{(j)}(0)}{(\log R)^j}\sum_{\substack{m\leqslant R/\gamma \\ (m,\gamma)=1}}{}'\frac{\mu(m)\Omega(m)}{m}\frac{1}{j!}\left(\log\frac{R/\gamma}{m}\right)^j \\ &= \sum_{j=k}^{\infty}\frac{P^{(j)}(0)}{(\log R)^j}\cdot\frac{1}{2\pi i}\int_{(c)}\sum_{\substack{m=1 \\ (m,\gamma)=1}}^{\infty}\frac{\mu(m)\Omega(m)}{m^{s+1}}\left(\frac{R}{\gamma}\right)^s\frac{ds}{s^{j+1}} \\ &= \sum_{j=k}^{\infty}\frac{P^{(j)}(0)}{(\log R)^j}\cdot\frac{1}{2\pi i}\int_{(c)}F(s+1,\gamma)\zeta(s+1)^{-k}\left(\frac{R}{\gamma}\right)^s\frac{ds}{s^{j+1}}. \end{aligned} \tag{3.12}$$

Since $F(s+1,\gamma)$ is regular for $\sigma > -\frac{1}{2}$ we can transform the line inside the zero-free region of $\zeta(s+1)$, that is, to $\sigma > 1-c/(\log(|t|+2))$, $|t| \leqslant \exp\left(\sqrt{\log R}\right)$. The integral is negligible on the new contour and so we obtain by the residue at $s=0$

$$\begin{aligned} J\left(\gamma,\frac{R}{\gamma}\right) &\sim \sum_{j=k}^{\infty}\frac{P^{(j)}(0)}{(\log R)^j}F(1,\gamma)\frac{(\log R/\gamma)^{j-k}}{(j-k)!} \\ &= \frac{F(1,\gamma)}{(\log R)^k}\sum_{\nu=0}^{\infty}\frac{P^{(\nu+k)}(0)}{\nu!}\left(\frac{\log(R/\gamma)}{\log R}\right)^{\nu} \\ &= \frac{F(1,\gamma)}{(\log R)^k}P^{(k)}\left(\frac{\log R/\gamma}{\log R}\right). \end{aligned} \tag{3.13}$$

We remark that although this argument does not work if R/γ is not large enough, that part can be shown to be negligible directly from (3.7). So we obtain

$$S \sim \frac{N}{(\log R)^{2k}} \sideset{}{'}\sum_{\gamma \leqslant R} \frac{\Omega(\gamma)}{\gamma} \prod_{p|\gamma} \left(1 - \frac{\Omega(p)}{p}\right) \cdot F(1,\gamma)^2 \left(P^{(k)}\left(\frac{\log R/\gamma}{\log R}\right)\right)^2 \tag{3.14}$$
$$\sim \frac{N}{(\log R)^{2k}} \mathfrak{S}^2(\mathcal{H}) \sideset{}{'}\sum_{\gamma \leqslant R} \frac{\Omega(\gamma)}{\gamma} \prod_{p|\gamma} \left(1 - \frac{\Omega(p)}{p}\right)^{-1} \left(P^{(k)}\left(\frac{\log R/\gamma}{\log R}\right)\right)^2.$$

Since apart from finitely many primes, for which

$$p \mid \Delta(\mathcal{H}) := \prod_{i>j} (h_i - h_j) \tag{3.15}$$

we have $\Omega(p) = k$, the behaviour of $\Omega(n)$ is similar to that of the generalized divisor function

$$\tau_k(n) = \sum_{n_1 n_2 \dots n_k = n} 1. \tag{3.16}$$

This implies (for the details see Lemma 11 of [13])

$$\sideset{}{'}\sum_{\gamma \leqslant x} \frac{\Omega(\gamma)}{\gamma} \prod_{p|\gamma} \left(1 - \frac{\Omega(p)}{p}\right)^{-1} \sim \mathfrak{S}(\mathcal{H})^{-1} \frac{(\log x)^k}{k!}. \tag{3.17}$$

The sum in (3.14) can be evaluated from (3.17) by partial summation, and we obtain

$$S \sim \frac{\mathfrak{S}(\mathcal{H}) N}{(\log R)^k (k-1)!} \int_0^1 y^{k-1} \left(P^{(k)}(1-y)\right)^2 dy. \tag{3.18}$$

Let us consider now the quantity

$$S_j = \sideset{}{'}\sum_{n \sim N} a_n \chi_{\mathcal{P}}(n + h_j) \log n, \quad h_j \in \mathcal{H}. \tag{3.19}$$

In this case (if $R < N$) the two conditions

$$n + h_j \in \mathcal{P}, \quad d \mid \prod_{i=1}^{k} (n + h_i), \quad d \leqslant R \tag{3.20}$$

and

$$n + h_j \in \mathcal{P}, \quad d \mid \prod_{\substack{i=1 \\ i \neq j}}^{k} (n + h_i), \quad d \leqslant R \tag{3.21}$$

are equivalent. So the situation is similar to (3.3) if

$$R \leqslant N^{(\vartheta - \varepsilon)/2} \tag{3.22}$$

since it is easy to see that by the condition (2.3) (which is unconditionally true with $\vartheta = 1/2$ by the Bombieri–Vinogradov Theorem) we can substitute $\chi_{\mathcal{P}}(n+h_j)\log n$ by 1. Thus we have

$$S_j \sim \sum_{d,e\leqslant R}{}' \mu(d)\mu(e)\frac{\Omega_j([d,e])}{[d,e]}P\left(\frac{\log(R/d)}{\log R}\right)P\left(\frac{\log(R/e)}{\log R}\right) \tag{3.23}$$

with the only difference that we have now $\Omega_j(p) = \Omega(p) - 1 = k-1$ if $p \nmid \Delta$. The singular series $\mathfrak{S}_j(\mathcal{H})$ is accordingly

$$\begin{aligned}\mathfrak{S}_j(\mathcal{H}) &= \prod_p \left(1 - \frac{\nu_{\mathcal{H}}(p)-1}{p-1}\right)\left(1-\frac{1}{p}\right)^{-(k-1)} \\ &= \prod_p \left(1-\frac{\nu_p(\mathcal{H})}{p}\right)\left(1-\frac{1}{p}\right)^{-k} = \mathfrak{S}(\mathcal{H}).\end{aligned} \tag{3.24}$$

So we obtain for all $j \in [1,k]$ under the stronger condition (3.22) now analogously to (3.18)

$$S_j \sim \frac{\mathfrak{S}(\mathcal{H})N}{(\log R)^{k-1}(k-2)!}\int_0^1 y^{k-2}\left(P^{(k-1)}(1-y)\right)^2 dy \tag{3.25}$$

and this gives in total for $R = N^{(\vartheta-\varepsilon)/2}$, $P^{(k-1)}(x) = Q(x)$

$$\frac{\sum_{j=1}^k S_j}{S\log 3N} \sim \frac{\log R}{\log N}k(k-1)M(Q) \sim \frac{k(k-1)(\vartheta-\varepsilon)}{2}M(Q) \tag{3.26}$$

primes on average in $\{n+h_i\}_{i=1}^k$ if n runs between N and $2N$ and the numbers n are weighted by $a_n \log n$, where

$$M(Q) = \frac{\int_0^1 y^{k-2}\big(Q(1-y)\big)^2 dy}{\int_0^1 y^{k-1}\big(Q'(1-y)\big)^2 dy}. \tag{3.27}$$

In case of the simple choice

$$P(x) = x^{k+\ell},\ \ \ell = \left[\sqrt{k}/2\right] \Leftrightarrow Q(x) = C(k,\ell)x^{\ell+1} \tag{3.28}$$

we obtain

$$\begin{aligned}M(Q) &= \frac{\int_0^1 y^{k-2}(1-y)^{2\ell+2}dy}{(\ell+1)^2\int_0^1 y^{k-1}(1-y)^{2\ell}dy} = \frac{(k-2)!(2\ell+2)!/(k+2\ell+1)!}{(\ell+1)^2(k-1)!(2\ell)!/(k+2\ell)!} \\ &= \frac{4\left(1-\frac{1}{2(\ell+1)}\right)}{(k+2\ell+1)(k-1)} \sim \frac{4\left(1-O\left(\frac{1}{\sqrt{k}}\right)\right)}{k^2}.\end{aligned} \tag{3.29}$$

By (3.26) this yields on the weighted average

$$2(\vartheta-\varepsilon)\left(1-O\left(\frac{1}{\sqrt{k}}\right)\right) \tag{3.30}$$

primes in $\{n+\mathcal{H}\}$ if $n\sim N$.

The quantity above is clearly greater than 1 if

$$\vartheta>1/2,\quad k>k_0(\vartheta), \tag{3.31}$$

which proves Theorem 2.11.

Suppose now $h_0\notin\mathcal{H}$, let $\mathcal{H}_0=\mathcal{H}\cup\{h_0\}$, and $\Omega_0(p)=\Omega_{\mathcal{H}_0}(p)$ is defined as in (3.1) with $k+1$ in place of k,

$$S_0=\sum_{n\sim N}a_n\chi_{\mathcal{P}}(n+h_0)\log n. \tag{3.32}$$

In case of $\nu_{\mathcal{H}_0}(p)=\nu_{\mathcal{H}}(p)$ we have $\Omega_0(p)=\nu_{\mathcal{H}}(p)-1$ residue classes in the sieve mod p (Ω_0 is defined as in (3.1)); if $\nu_{\mathcal{H}_0}(p)=\nu_{\mathcal{H}}(p)+1$, then $\Omega_0(p)=\nu_{\mathcal{H}}(p)$. So we have in both cases $\Omega_0(p)=\nu_{\mathcal{H}_0}(p)-1$ and $\Omega_0(p)=k$ if $p\nmid\Delta(\mathcal{H}_0)$.

This yields an analogous asymptotic to (3.18) for S_0, with $\mathcal{H}$ replaced by $\mathcal{H}_0$:

$$S_0\sim\frac{\mathfrak{S}(\mathcal{H}_0)N}{(\log R)^k(k-1)!}\int\limits_0^1 y^{k-1}\left(P^{(k)}(1-y)\right)^2dy \tag{3.33}$$

and consequently

$$\frac{S_0}{S}\sim\frac{\mathfrak{S}\left(\mathcal{H}\cup\{h_0\}\right)}{\mathfrak{S}(\mathcal{H})}\quad(\text{as } N\to\infty). \tag{3.34}$$

This relation helps us to obtain Theorem 2.12 unconditionally. Let us consider an interval of length

$$H=\eta\log N, \tag{3.35}$$

where η is an arbitrarily small fixed positive constant. Let us suppose that we can find for any k an admissible k-tuple $\mathcal{H}=\mathcal{H}_k$ such that with a fixed absolute constant $c_0>0$

$$\mathfrak{S}\left(\mathcal{H}_k\cup h_0\right)>c_0\mathfrak{S}(\mathcal{H})\ \text{ for any even } h_0. \tag{3.36}$$

In this case using only $\vartheta=1/2$, that is, the Bombieri–Vinogradov Theorem, we obtain on average

$$\frac{\sum\limits_{h=1}^{H}\sum\limits_{n\sim N}a_n\chi_{\mathcal{P}}(n+h)\log n}{\sum\limits_{n\sim N}a_n\log 3N}\geqslant(1-2\varepsilon)\left(1-O\left(\frac{1}{\sqrt{k}}\right)\right)+\frac{c_0\eta}{2}-\frac{k}{\log 3N}>1 \tag{3.37}$$

primes between n and $n+H$ if

$$k>k_0(\eta),\ \ \varepsilon<\varepsilon_0(\eta),\ \ N>N_0(\eta,k,\varepsilon). \tag{3.38}$$

In order to show the existence of $\mathcal{H}_k$ with (3.36) we can just choose

$$\mathcal{H}=\mathcal{H}_k=\left\{i\prod_{p\leqslant 2k}p\right\}_{i=1}^{k}. \tag{3.39}$$

Then we have for any even h with $\nu_p = \nu_{\mathcal{H}}(p)$

$$\begin{aligned}\frac{\mathfrak{S}(\mathcal{H}\cup h)}{\mathfrak{S}(\mathcal{H})} &\geqslant 2\prod_{2<p\leqslant 2k}\frac{1-2/p}{(1-1/p)^2}\prod_{p>2k}\frac{1-(\nu_p+1)/p}{1-(\nu_p+1)/p+\nu_p/p^2} \\ &\geqslant c_1\prod_{p>2k}\left(1+O\left(\frac{k}{p^2}\right)\right)\geqslant c_0.\end{aligned} \tag{3.40}$$

In such a way we obtain Theorem 2.12. We remark that the above proof avoids Gallagher's Theorem [11]. Another proof, also avoiding Gallagher's Theorem is given in [16] which yields some other results, like small gaps between consecutive primes in arithmetic progressions and improved upper estimates for the quantity

$$\Delta_r = \liminf_{n\to\infty}\frac{p_{n+r}-p_n}{\log p_n}. \tag{3.41}$$

4. Sketch of the proof of Theorem 2.14

The most crucial idea in the proof of Theorem 2.14 is that we will change the weights and instead of the original normalized weights (cf. (2.15)).

$$a_n = \left(\sum_{d\leq R, d\mid P_{\mathcal{H}}(n)}\mu(d)\left(\frac{\log(R/d)}{\log R}\right)^{k+\ell}\right)^2,\ P_{\mathcal{H}}(n)=\prod_{i=1}^{k}(n+h_i),\ \ell=\left[\frac{\sqrt{k}}{2}\right] \tag{4.1}$$

we will work with the new weight ($n\sim N$)

$$a'_n = \begin{cases} a_n & \text{if } P^-\big(P_{\mathcal{H}}(n)\big) > N^{\delta}, \\ 0 & \text{otherwise,}\end{cases} \tag{4.2}$$

where δ will be a fixed small positive constant with $\varepsilon<\varepsilon_0(\eta)$, $k>k_0(\eta,\varepsilon)$, $\delta<\delta_0(k,\eta,\varepsilon)$, $R=N^{(\vartheta-\varepsilon)/2}$ and we consider primes in intervals of length

$$H=\eta\log N \tag{4.3}$$

as indicated in (2.2).

As mentioned at the end of Section 2 the sum of weights $a^*_{n,\mathcal{H}}$ with $\mathcal{P}_{\mathcal{H}}(n)$ having at least one small prime divisor not exceeding N^{δ} is negligible and we have (2.25) with a constant $C=C(k)$, i.e.

$$\begin{aligned}0\leq\sum_{n\sim N}(a_n-a'_n) &= \sum_{\substack{n\sim N\\ P^-(P_{\mathcal{H}}(n))\leq N^{\delta}}} a_n \leq C\delta\sum_{n\sim N}a_n, \\ \sum_{\substack{n\sim N\\ P^-(P_{\mathcal{H}}(n))\leq N^{\delta}}} a_n\chi_{\mathcal{P}}(n+h)\log(n+h) &\leq C\delta\sum_{n\sim N}a_n\chi_{\mathcal{P}}(n+h)\log(n+h).\end{aligned} \tag{4.4}$$

These are Lemmas 4 and 5 of [26].

The other tool is Gallagher's Theorem [11], according to which for k fixed, $H \to \infty$

$$\sum_{\substack{\mathcal{H}\subset[1,H]\\ |\mathcal{H}|=k}} \mathfrak{S}(\mathcal{H}) \sim \frac{H^k}{k!}. \tag{4.5}$$

Let further (for a more detailed proof see [17] and [18])

$$\pi(n,H) := \pi(n+H) - \pi(N), \quad \Theta(n) := \begin{cases} \log n & \text{if } n \in \mathcal{P}, \\ 0 & \text{otherwise,} \end{cases} \tag{4.6}$$

$$\Theta(n,H) := \sum_{h=1}^{H} \Theta(n+h)$$

$$M := \sum_{\substack{p_j\sim N\\ p_{j+1}-p_j\le H}} 1, \quad Q(N,H) := \sum_{\substack{n\sim N\\ \pi(n,H)>1}} 1 \le HM + O\left(Ne^{-c\sqrt{\log N}}\right), \tag{4.7}$$

and consider now instead of (3.19) the modified quantity

$$S'(h,\mathcal{H}) = \sum_{n\sim N} a'_n \Theta(n+h). \tag{4.8}$$

The substitution of a_n by a'_n will just slightly change the corresponding value of $S'(\mathcal{H})$ and $S'(h,\mathcal{H})$ respectively, to

$$S'(\mathcal{H}) = \sum_{n\sim N} a'_n = (1+O(\delta))S(\mathcal{H}), \tag{4.9}$$

$$S'(h,\mathcal{H}) = \sum_{n\sim N} a'_n \Theta(n+h) = (1+O(\delta))S(h,\mathcal{H}) \tag{4.10}$$

compared with

$$S(h,\mathcal{H}) := \sum_{n\sim N} a_n \Theta(n+h), \tag{4.11}$$

where the asymptotics for the quantity (4.11) are given in (3.25) and (3.33) respectively, and $P(x) = x^{k+\ell}$ in this section.

The crucial change is that in case of $a'_{n,\mathcal{H}} > 0$ all the prime divisors of $\mathcal{P}_{\mathcal{H}}(n)$ are at least N^δ with a fixed small δ, so by (4.1) we have a trivial estimate for it:

$$a'_n \leqslant 2^{\omega(P_{\mathcal{H}}(n))} \leqslant 2^{2k^2/\delta} \ll_{k,\delta} 1. \tag{4.12}$$

On the other hand, in this case we cannot use the simplification of Section 3, that is, to work with a suitably chosen single $\mathcal{H}_k$. Averaging over all $\mathcal{H} \subseteq [1,H]$, $|\mathcal{H}| = k$, with the abbreviations (we take the unconditional case $\vartheta = 1/2$ from now on)

$$\frac{H}{\log R} = \frac{\eta}{\left(\frac12 - \varepsilon\right)/2} = \eta', \quad \sum_{\mathcal{H}}^{(k)} = \sum_{\substack{\mathcal{H}\subset[1,H]\\ |\mathcal{H}|=k}} \tag{4.13}$$

we obtain from (3.18), using (3.28)–(3.29) and (4.5)

$$\sum_{\mathcal{H}}^{(k)} S'(\mathcal{H}) \sim (1+O(\delta))\frac{(\eta')^k NC(k,\ell)(2\ell)!}{k!(\ell+1)^2(k+2\ell)!} =: (1+O(\delta))B. \tag{4.14}$$

On the other hand, we have by (3.33) and (4.5)

$$\begin{aligned}&\sum_{\mathcal{H}}^{(k)} \sum_{\substack{n\sim N\\ h\in[1,H]\setminus\mathcal{H}}} a'_n\Theta(n+h) \qquad (4.15)\\ &\sim (k+1)\sum_{\mathcal{H}}^{(k+1)} \mathfrak{S}(\mathcal{H})\frac{NC(k,\ell)(2\ell)!(1+O(\delta))}{(\log R)^k(\ell+1)^2(k+2\ell)!} := (1+O(\delta))B\eta\log N.\end{aligned}$$

Finally, we have by (3.25) and (4.5) with $\ell = \left[\sqrt{k}/2\right]$, $\vartheta = 1/2$

$$\begin{aligned}&\sum_{\mathcal{H}}^{(k)} \sum_{h\in\mathcal{H}} \sum_{n\sim N} a'_n\Theta(n+h) \qquad (4.16)\\ &\sim (1+O(\delta))\frac{k\eta'^k NC(k,\ell)(2\ell+2)!}{k!(k+2\ell+1)!}\log R\\ &\sim (1+O(\delta))B\left(1-\frac{1}{2(\ell+1)}\right)\left(1-\frac{2\ell+1}{k+2\ell+1}\right)(1-2\varepsilon)\log N.\end{aligned}$$

Adding (4.15), (4.16) and subtracting from it (4.14) multiplied by $\log 3N$ we obtain

$$\begin{aligned}&\sum_{\mathcal{H}}^{(k)} \sum_{n\sim N} a'_n\big(\Theta(n,H)-\log 3N\big) \qquad (4.17)\\ &> B\log N\left\{(1-2\varepsilon)\left(1-\frac{C}{\sqrt{k}}\right)+\eta-1+O(\delta)\right\} > \frac{\eta}{2}B\log N\end{aligned}$$

if, as stated in the introduction of Section 4 (between (4.2) and (4.3)) we fix ε, k, δ with

$$\varepsilon < \varepsilon_0(\eta),\ \ k > k_0(\eta,\varepsilon),\ \ \delta < \delta_0(k,\eta,\varepsilon). \tag{4.18}$$

Consequently, if (4.18) holds, which we will always assume in the following, then

$$\frac{\eta}{2}B\log N < (1+o(1))\log N \sum_{\substack{n\sim N\\ \pi(n,H)>1}} \pi(n,\mathcal{H})\sum_{\mathcal{H}}^{(k)} a'_n. \tag{4.19}$$

Introducing the notation

$$T(n,H) := \sum_{\substack{\mathcal{H}\\ P^-\left(P_{\mathcal{H}}(n)\right)>N^\delta}}^{(k)} 1 \tag{4.20}$$

we have by (4.6)–(4.7), (4.12) and Cauchy's inequality

$$\eta B \ll \Big(\sum_{\substack{n\sim N\\ \pi(n,\mathcal{H})>1}} 1\Big)^{1/2}\Big(\sum_{n\sim N}\pi^2(n,H)T(n,H)^2\Big)^{1/2} \tag{4.21}$$

$$\ll \left((HM)^{1/2} + O\left(N^{1/2}e^{-c\sqrt{\log N}/2}\right)\right)\left(\sum_{n\sim N}\pi^2(n,H)T(n,H)^2\right)^{1/2}.$$

Further, we have by Selberg's sieve (Theorem 5.1 of [21] or Theorem 2 in § 2.2.2 of [19]) for any set $\mathcal{H}$ and $\delta < 1/2$

$$\sum_{\substack{n\sim N\\ P^-\left(P_{\mathcal{H}}(n)\right)>R^\delta}} 1 \leqslant \frac{|\mathcal{H}|!\mathfrak{S}(\mathcal{H})}{(\log R^\delta)^{|\mathcal{H}|}}N(1+o(1)) \quad (R,N\to\infty). \tag{4.22}$$

This implies by Gallagher's Theorem (4.5)

$$\sum_{n\sim N}\pi(n,H)^2T(n,H)^2 \ll \sum_{1\le h,h'\le H}\sum_{\mathcal{H}_1}^{(k)}\sum_{\mathcal{H}_2}^{(k)}\sum_{\substack{n\sim N\\ P^-\left(\mathcal{H}_1\cup\mathcal{H}_2\cup\{h\}\cup\{h'\}\right)>N^\delta}} 1 \tag{4.23}$$

$$\ll_k N\sum_{r=k}^{2k+2}\sum_{\mathcal{H}_0}^{(r)}\frac{\mathfrak{S}(\mathcal{H}_0)}{(\log R^\delta)^r} \ll_{k,\delta} N\sum_{r=k}^{2k+2}\left(\frac{H}{\log R}\right)^r \ll_{k,\delta} (\eta')^k N.$$

Taking into account the definition of B in (4.14) we obtain from (4.21) and (4.23)

$$\eta(\eta')^{k/2} \ll_{k,\delta} \left(\left(\frac{HM}{N}\right)^{1/2} + e^{-c\sqrt{\log N}/2}\right). \tag{4.24}$$

Consequently,

$$\frac{HM}{N} \gg_{k,\delta,\eta} 1. \tag{4.25}$$

Hence,

$$M \gg_{k,\delta,\eta} \frac{N}{\log N} \gg_{k,\delta,\eta} \pi(2N), \tag{4.26}$$

which proves Theorem 2.14.

It may be shown (see Theorem 2 of [18]) that this is sharp in the sense that the assertion does not remain true if $H = o(\log N)$. The proof uses the Selberg sieve upper bound for prime tuples and Gallagher's result (4.5).

5. Bounded gaps between primes. Zhang's theorem

We recall that in our original work (Theorem 2.11 in Section 2) we showed that EH(ϑ) for any $\vartheta > 1/2$ implies DHL$(k,2)$ for $k > k_0(\vartheta)$, consequently the Bounded Gaps Conjecture. From the proof it is trivial that the condition

$$\max_{a,(a,q)=1} \tag{5.1}$$

in (2.3) can be weakened to

$$\max_{a,(a,q)=1,P_{\mathcal{H}}(a)\equiv 0(q)} \tag{5.2}$$

if we want to show for a specific $\mathcal{H}$ that $n + \mathcal{H}$ contains at least two primes infinitely often. However, in 2008 in a joint work of Y. Motohashi and J. Pintz the following stronger form of Theorem 2.11 was proved, in which the summation in (2.3) can be reduced to smooth moduli. $P^+(n)$ will denote the largest prime factor of n.

Theorem 5.1 ([25]). *If there exist $\delta > 0$, $\vartheta > 1/2$ and an admissible k-tuple $\mathcal{H}$ with $k > k_0(\delta, \vartheta)$ such that for any $\varepsilon > 0$, $A > 0$*

$$\sum_{\substack{q \leq N^{\vartheta-\varepsilon} \\ P^+(q) \leq N^\delta}} \max_{a \atop (a,q)=1, q \mid P_{\mathcal{H}}(a)} \left| \sum_{\substack{p \equiv a(q) \\ p \sim N}} \log p - \frac{N}{\varphi(q)} \right| \leq \frac{C(A,\varepsilon)N}{\log^A N} \tag{5.3}$$

holds for $N > N_0(\mathcal{H}, \vartheta, \delta)$, then $n + \mathcal{H}$ contains at least two primes for some $n \sim N$.

Remark 5.2. Zhang proved a version of this result, and it appeared with a different proof in his work [39]. Zhang proved condition (5.3) with the explicit values

$$\vartheta = \frac{1}{2} + \frac{1}{584}, \quad \delta = \frac{1}{1168}, \tag{5.4}$$

which finally led to

Theorem 5.3 ([39]). DHL$(k, 2)$ *is true for $k \geqslant 3.5 \cdot 10^6$ and consequently*

$$\liminf_{n \to \infty} (p_{n+1} - p_n) \leqslant C = 7 \cdot 10^7.$$

His proof of (5.4) uses several deep works of Fouvry, Fouvry–Iwaniec, Bombieri–Friedlander–Iwaniec, Friedlander–Iwaniec, Heath-Brown, which are based on ideas and works of Linnik, Weil, Deligne and Birch–Bombieri concerning the estimate of Kloostermann sums.

The Polymath 8a project of T. Tao [30] introduced many improvements into this procedure (for example to apply instead of the simple weight function $P(x) = x^{k+\ell}$ the optimal Bessel function first used by Conrey, later analyzed in details in [10] together with many improvements in both the Motohashi–Pintz Theorem and in the estimation of Kloostermann sums) and obtained distribution estimates up to level $1/2 + 7/300$, and thus reached

Theorem 5.4 (Polymath 8a). DHL$(k, 2)$ *is true for $k \geqslant 632$ and consequently*

$$\liminf_{n \to \infty} (p_{n+1} - p_n) \leqslant 4680.$$

6. Bounded gaps between primes: The Maynard–Tao theorem

About half a year after the manuscript of Zhang [39], simultaneously and independently, J. Maynard [24] and in his Polymath blogs T. Tao [31] introduced another idea which led to a new, more efficient proof of the Bounded Gaps Conjecture. The main results of Maynard [24] were the following.

Theorem 6.1 (Maynard [24]). DHL$(k, 2)$ *is true for $k \geq 105$, consequently*

$$\liminf_{n \to \infty} (p_{n+1} - p_n) \leqslant 600.$$

Theorem 6.2 (Maynard [24]). *Assuming the Elliott–Halberstam Conjecture,* DHL$(k,2)$ *is true for* $k \geq 5$*, consequently*

$$\liminf_{n\to\infty}(p_{n+1}-p_n) \leqslant 12.$$

The two surprising aspects of the Maynard–Tao method were that it produced not only pairs but arbitrarily long (finite) blocks of primes in bounded intervals, and for this knowing that (2.3) holds with any fixed $\vartheta > 0$ (however small) would suffice.

The earlier known strongest result of somewhat similar nature was the much weaker one in our work [16]. It asserted for any $r > 0$

$$\Delta_r := \liminf_{n\to\infty} \frac{p_{n+r}-p_n}{\log p_n} \leq e^{-\gamma}\left(\sqrt{r}-1\right)^2. \tag{6.1}$$

Further, under the very deep Elliott–Halberstam Conjecture (see (2.3) with $\vartheta = 1$) we could show [14]

$$\Delta_2 = 0. \tag{6.2}$$

Theorem 6.3 (Maynard–Tao [24]). *We have for any* r

$$\liminf_{n\to\infty}(p_{n+r}-p_n) \ll r^3 e^{4r}. \tag{6.3}$$

The main idea of Maynard and Tao is that the weights are defined instead of

$$a_n = \left(\sum_{\substack{d\leqslant R\\ d|P_{\mathcal{H}}(n)}} \mu(d) P\left(\frac{\log R/d}{\log R}\right)\right)^2, \quad \mathcal{P}_{\mathcal{H}}(n) = \prod_{i=1}^{k}(n+h_i) \tag{6.4}$$

in the more general form

$$a_n = \left(\sum_{\substack{d_1\dots d_k\leqslant R\\ d_i|n+h_i}} \mu(d) P\left(\frac{\log d_1}{\log R},\dots,\frac{\log d_k}{\log R}\right)\right)^2, \tag{6.5}$$

where $P(t_1,\dots,t_k) := \mathbb{R}^k \to \mathbb{R}$ is a fixed piecewise differentiable function with support on $t_1+t_2+\cdots+t_k \leqslant 1$. The idea of the use of these more general weights goes back to Selberg ([36], p. 245). Similar type of weights were used by Goldston and Yıldırım [12], but due to the special choice of $P(t_1,\dots,t_k) = \prod_{i=1}^{k}(1-kt_i),\ t_i \leqslant 1/k$, this led only to the result

$$\Delta = \liminf_{n\to\infty} \frac{p_{n+1}-p_n}{\log p_n} \leqslant \frac{1}{4}. \tag{6.6}$$

We remark here that the general choice of $P\left(\frac{\log R/d}{\log R}\right)$ in Section 3 corresponds to the special case of the above with

$$P(t_1,t_2,\dots,,t_k) = \widetilde{P}(t_1+t_2+\cdots+t_k). \tag{6.7}$$

Another very interesting remark is that in order to show bounded intervals with arbitrarily long finite blocks of primes (with a bound $e^{2r/\vartheta}$ in place of e^{4r}) we do not need the value

$\vartheta = 1/2$, that is, the Bombieri–Vinogradov Theorem, just any value $\vartheta > 0$. So we obtain a numerically slightly weaker form of the existence of arbitrarily long (finite) blocks of primes in bounded invervals even by the use of the first theorem establishing a positive admissible level ϑ for the distribution of primes, due to A. Rényi [33, 34] reached in 1947–48, by the large sieve of Linnik.

Upon further work on the Maynard–Tao method in the Polymath 8b project of Tao, Theorem 6.1 has been improved to

Theorem 6.4 (Polymath 8b project). DHL$(k, 2)$ *is true for* $k \geqslant 50$*, consequently*

$$\liminf_{n\to\infty}(p_{n+1} - p_n) \leq 246.$$

7. De Polignac numbers and some conjectures of Erdős on gaps between consecutive primes

There are various 60–70 years old conjectures of Erdős on which a sharpened version of Zhang's Theorem (or that of Maynard and Tao) combined with other arguments of the second named author can give an answer. Below we give a list of them without proofs which can be found in [28]. The numerical values reflect the stage at the end of Polymath 8A.

Using an argument of the second named author (Lemma 4 in [26]) together with a more general form of the arguments of Theorem 3 of Zhang and its improvement by Tao's project, the following strengthening of Theorem 3 of Zhang can be shown. (Let $P^-(n)$ be the smallest prime factor of n.)

Theorem 7.1 ([28]). *Let* $k \geq 632$*,* $\mathcal{H}$ *an admissible* k*-tuple,* $h_i \ll \log N$*,* $N > N_0(k)$*. Then there are at least*

$$c_1(k, \mathcal{H})\frac{N}{\log^k N}$$

numbers $n \in [N, 2N)$ *such that* $n + \mathcal{H}$ *contains at least two primes and almost primes in all other components satisfying* $P^-(n + h_i) > N^{c_2(k)}$ *for* $i = 1, 2, \ldots, k$*.*

Remark 7.2. A similar version to the above-mentioned crucial Lemma 4 of [26] appears in the book Opera de Cribro of Friedlander–Iwaniec [9] published also in 2010.

Whereas the original Theorem 3 of Zhang yields only one de Polignac number, by the aid of Theorem 7.1 we can show

Theorem 7.3 ([28]). *There are infinitely many de Polignac numbers. In fact, they have a positive lower density* $> 10^{-7}$*.*

Theorem 7.4 ([28]). *There exists an ineffective* C *such that we have always at least one de Polignac number between* X *and* $X + C$ *for any* X*. (All gaps between consecutive de Polignac numbers are uniformly bounded.)*

Erdős [6] proved in 1948 the inequality

$$\liminf_{n\to\infty}\frac{d_{n+1}}{d_n} \leq 1 - c_0 < 1 + c_0 \leq \limsup\frac{d_{n+1}}{d_n} \tag{7.1}$$

with a very small positive value c_0 and conjectured that the $\liminf = 0$ and the $\limsup = \infty$.

Theorem 7.5 ([28]). $\liminf_{n\to\infty} \frac{d_{n+1}}{d_n} = 0$, $\limsup \frac{d_{n+1}}{d_n} = \infty$.

Further, we have even

$$\liminf_{n\to\infty} \frac{d_{n+1}\log n}{d_n} < \infty, \qquad \limsup_{n\to\infty} \frac{d_{n+1}}{d_n \log n} > 0. \tag{7.2}$$

In general it is difficult to show anything for three consecutive differences. However, we can show

Theorem 7.6 ([28]). $\limsup_{n\to\infty} \frac{\min(d_{n-1}, d_{n+1})}{d_n (\log n)^c} = \infty$ *with* $c = 1/632$.

Since the Prime Number Theorem implies

$$\frac{1}{N}\sum_{n=1}^{N} \frac{d_n}{\log n} = 1, \tag{7.3}$$

it is interesting to investigate the normalized distribution of the sequence d_n, $d_n/\log n$. Erdős conjectured 60 years ago that the set of limit points,

$$J = \left\{\frac{d_n}{\log n}\right\}' = [0, \infty], \tag{7.4}$$

but no finite limit point was known until 2005, when we showed $0 \in J$. (We denote by G' the set of limit points of the set G.) This was rather strange since in 1955 Erdős [7] and simultaneously Ricci [35] proved that J has positive Lebesgue measure. A partial answer to the conjecture of Erdős is

Theorem 7.7 ([28]). *There is an (ineffective) constant* c^* *such that*

$$[0, c^*] \subset J. \tag{7.5}$$

The above result raises the question whether considering a finer distribution $d_n/f(n)$ with a monotonically increasing function $f(n) \le \log n$, $f(n) \to \infty$ the same phenomenon is still true. The answer is yes.

Theorem 7.8 ([28]). *Let* $f(n) \le \log n$, $f(n) \to \infty$ *be an increasing function,*

$$J_f = \left\{\frac{d_n}{f(n)}\right\}'. \tag{7.6}$$

Then there is an (ineffective) constant c_f^* *such that*

$$[0, c_f^*] \subset J_f. \tag{7.7}$$

Zhang's theorem shows the existence of infinitely many generalized twin prime pairs with a difference at most $7 \cdot 10^7$, while the theorem of Green and Tao shows the existence of arbitrarily long (finite) arithmetic progressions in the sequence of primes. A common generalization of these two results is given below. (Let p' denote the prime following p.)

Theorem 7.9 ([28]). *There exists an even* $d \le 4680$ *with the following property. For any* k *there is a* k*-term arithmetic progression of primes such that* $p' = p + d$ *for all elements of the progression.*

Some problems in analytic number theory for polynomials over a finite field

Zeev Rudnick

Abstract. The lecture explores several problems of analytic number theory in the context of function fields over a finite field, where they can be approached by methods different than those of traditional analytic number theory. The resulting theorems can be used to check existing conjectures over the integers, and to generate new ones. Among the problems discussed are: Counting primes in short intervals and in arithmetic progressions; Chowla's conjecture on the autocorrelation of the Möbius function; and the additive divisor problem.

Mathematics Subject Classification (2010). Primary 11T55; Secondary 11N05, 11N13.

Keywords. Function fields over a finite field, Chowla's conjecture, the additive divisor problem, primes in short intervals.

1. Introduction

The goal of this lecture is to explore traditional problems of analytic number theory in the context of function fields over a finite field. Several such problems which are currently viewed as intractable over the integers, have recently been addressed in the function field context with vastly different tools than those of traditional analytic number theory, and the resulting theorems can be used to check existing conjectures over the integers, and to generate new ones. The problems that I will address concern

- Counting primes in short intervals and in arithmetic progressions
- Chowla's conjecture on the autocorrelation of the Möbius function
- The twin prime conjecture
- The additive divisor problem
- The variance of sums of arithmetic functions in short intervals and arithmetic progressions.

Before describing the problems, I will briefly survey some quantitative aspects of the arithmetic of the ring of polynomials over a finite field.

Proceedings of the International Congress of Mathematicians, Seoul, 2014

2. Background on arithmetic in $\mathbb{F}_q[x]$

2.1. The prime polynomial theorem. Let $\mathbb{F}_q$ be a finite field of q elements, and $\mathbb{F}_q[x]$ the ring of polynomials with coefficients in $\mathbb{F}_q$. The polynomial ring $\mathbb{F}_q[x]$ shares several qualitative properties with the ring of integers $\mathbb{Z}$, for instance having a Euclidean algorithm, hence unique factorization into irreducibles. There are also several common quantitative aspects. To set these up, I review some basics.

The units of the ring of integers are ± 1, and every nonzero integer is a multiple by a unit of a positive integer. Analogously, the units of $\mathbb{F}_q[x]$ are the nonzero scalars $\mathbb{F}_q^\times$, and every nonzero polynomial is is a multiple by a unit of a monic polynomial. The analogue of a (positive) prime is a monic irreducible polynomial. To investigate arithmetic properties of "typical" integers, one samples them uniformly in the dyadic interval $[X, 2X]$ with $X \to \infty$; likewise to investigate arithmetic properties of "typical" polynomials, one samples them uniformly from the monic polynomials $\mathcal{M}_n$ of degree n, with $\#\mathcal{M}_n = q^n \to \infty$.

The Prime Number Theorem (PNT) states that the number $\pi(x)$ of primes $p \leq x$ is asymptotically equal to

$$\pi(x) \sim \mathrm{Li}(x) := \int_2^x \frac{dt}{\log t} \sim \frac{x}{\log x}\ , \quad x \to \infty\ . \tag{2.1}$$

The Riemann Hypothesis is equivalent to the assertion that

$$\pi(x) = \mathrm{Li}(x) + O\Big(x^{1/2+o(1)}\Big)\ . \tag{2.2}$$

The Prime Polynomial Theorem asserts that the number $\pi_q(n)$ of monic irreducible polynomials of degree n is

$$\pi_q(n) = \frac{q^n}{n} + O\Big(\frac{q^{n/2}}{n}\Big)\ , \tag{2.3}$$

the implied constant absolute. This corresponds to the PNT (and to the Riemann Hypothesis) if we map $x \leftrightarrow q^n$, recalling that x is the number of positive integers up to x and q^n is the number of monic polynomials of degree n. Note that (2.3) gives an asymptotic result whenever $q^n \to \infty$; in comparison, the results described below will usually be valid only in the large finite field limit, that is n fixed and $q \to \infty$.

2.2. Cycle structure. For $f \in \mathbb{F}_q[x]$ of positive degree n, we say its cycle structure is $\lambda(f) = (\lambda_1, \dots, \lambda_n)$ if in the prime decomposition $f = \prod_\alpha P_\alpha$ (we allow repetition), we have $\#\{\alpha : \deg P_\alpha = j\} = \lambda_j$. In particular $\deg f = \sum_j j\lambda_j$. Thus we get a partition of $\deg f$, which we denote by $\lambda(f)$. For instance, $\lambda_1(f)$ is the number of roots of f in $\mathbb{F}_q$, and f is totally split in $\mathbb{F}_q[x]$ - that is $f(x) = \prod_{j=1}^n (x - a_j)$, $a_j \in \mathbb{F}_q$- if and only if $\lambda(f) = (n, 0, \dots, 0)$. Moreover f is prime if and only if $\lambda(f) = (0, 0, \dots, 0, 1)$.

The cycle structure of a permutation σ of n letters is $\lambda(\sigma) = (\lambda_1, \dots, \lambda_n)$ if in the decomposition of σ as a product of disjoint cycles, there are λ_j cycles of length j. For instance, $\lambda_1(\sigma)$ is the number of fixed points of σ, and $\sigma = I$ is the identity if and only if $\lambda(\sigma) = (n, 0, \dots)$. Moreover $\sigma \in S_n$ is an n-cycle if and only if $\lambda(\sigma) = (0, 0, \dots, 0, 1)$.

For each partition $\lambda \vdash n$, denote by $p(\lambda)$ the probability that a random permutation on n letters has cycle structure λ:

$$p(\lambda) = \frac{\#\{\sigma \in S_n : \lambda(\sigma) = \lambda\}}{\#S_n}\ . \tag{2.4}$$

Cauchy's formula for $p(\lambda)$ is

$$p(\lambda) = \prod_{j=1}^{n} \frac{1}{j^{\lambda_j} \cdot \lambda_j!} \tag{2.5}$$

In particular, the proportion of n-cycles in the symmetric group S_n is $1/n$.

The connection between cycle structures of polynomials and of permutations is by means of the following observation, a straight-forward consequence of the Prime Polynomial Theorem (2.3): Given a partition $\lambda \vdash n$, the probability that a random monic polynomial f of degree n has cycle structure λ is asymptotic, as $q \to \infty$, to the probability $p(\lambda)$ that a random permutation of n letters has that cycle structure:

$$\frac{1}{q^n} \#\{f \text{ monic}, \deg f = n : \lambda(f) = \lambda\} = p(\lambda) + O\Big(\frac{1}{q}\Big) . \tag{2.6}$$

Note that unlike the Prime Polynomial Theorem (2.3), this result (2.6) gives an asymptotic only in the large finite field limit $q \to \infty$, n fixed.

Having set up the preliminaries, I turn to discussing new results on quantitative aspects of arithmetic in $\mathbb{F}_q[x]$.

3. Asymptotics in short intervals and arithmetic progressions

3.1. Primes in short intervals. Some of the most important problems in prime number theory concern the distribution of primes in short intervals and in arithmetic progressions. According to the Prime Number Theorem, the density of primes near x is $1/\log x$. Thus one wants to know what is the number $\pi(x, H)$ of primes in an interval of length $H = H(x) \ll x$ around x:

$$\pi(x, H) := \#\{x < p \le x + H : p \text{ prime}\} . \tag{3.1}$$

We expect that for H sufficiently large,

$$\pi(x, H) \sim \frac{H}{\log x} . \tag{3.2}$$

The PNT implies that (3.2) holds for $H \approx x$, and the Riemann Hypothesis gives (3.2) for all $H > x^{1/2+o(1)}$. In 1930, Hoheisel gave an unconditional proof that (3.2) holds for all $H > x^{1-\delta}$ for any positive $\delta < 1/33,000$; this has since been improved, currently to $H > x^{7/12-o(1)}$ (Heath Brown 1988). It is believed that the result should hold for all $H > x^{\epsilon}$, for any $\epsilon > 0$, though Maier [30] showed that it does not hold for $H = (\log x)^N$ for any N; see Granville and Soundararajan [15] for a general framework for such results on irregularities of distribution and for sharper results. Selberg (1943) showed, assuming the Riemann Hypothesis, that (3.2) holds for *almost all* x provided $H/(\log x)^2 \to \infty$.

To set up an analogous problem for the polynomial ring $\mathbb{F}_q[x]$, we first need to define short intervals. For a nonzero polynomial $f \in \mathbb{F}_q[x]$, we define its norm by

$$|f| = \#\mathbb{F}_q[x]/(f) = q^{\deg f} ,$$

in analogy with the norm of a nonzero integer $0 \ne n \in \mathbb{Z}$, which is $|n| = \#\mathbb{Z}/n\mathbb{Z}$. Given a monic polynomial $A \in \mathcal{M}_n$ of degree n, and $h < n$, the "short interval" around A of diameter q^h is the set

$$I(A; h) := \{f \in \mathcal{M}_n : |f - A| \le q^h\} . \tag{3.3}$$

The number of polynomials in this "interval" is

$$H := \#I(A;h) = q^{h+1} \ . \tag{3.4}$$

We wish to count the number of prime polynomials in the interval $I(A;h)$. In the limit $q \to \infty$, Bank, Bary-Soroker and Rosenzweig [4] give an essentially optimal short interval result:

Theorem 3.1. *Fix $3 \le h < n$. Then for every monic polynomial A of degree n, the number of prime polynomials P in the interval $I(A;h) = \{f : |f - A| \le q^h\}$ about A satisfies*

$$\#\{P \text{ prime}, P \in I(A;h)\} = \frac{H}{n}\left(1 + O_n(q^{-1/2})\right) \ ,$$

the implied constant depending only on n.

For irregularities of distribution analogous to Maier's theorem in the large degree limit $n \to \infty$ (q fixed), see [36].

For other applications, we will need a version which takes into account the cycle structure:

Theorem 3.2 ([4]). *Fix $n > 1$, $3 \le h < n$ and a partition $\lambda \vdash n$. Then for any sequence of finite fields $\mathbb{F}_q$, and every monic polynomial A of degree n,*

$$\#\{f \in I(A;h) : \lambda(f) = \lambda\} = p(\lambda)H\left(1 + O_n(q^{-1/2})\right) \ ,$$

with $p(\lambda)$ as in (2.4)*,* (2.5)*, the implied constant depending only on n.*

3.2. Primes in arithmetic progressions. Dirichlet's theorem states that any arithmetic progression $n = A \bmod Q$ contains infinitely many primes provided that A and Q are coprime, and the prime number theorem in arithmetic progressions states that for fixed modulus Q, the number of such primes $p \le x$ is

$$\pi(x;Q,A) \sim \frac{\mathrm{Li}(x)}{\phi(Q)}, \quad x \to \infty \ , \tag{3.5}$$

where $\phi(Q)$ is Euler's totient function, the number of residues coprime to Q. The Generalized Riemann Hypothesis (GRH) asserts that (3.5) continues to hold for moduli as large as $Q < X^{1/2-o(1)}$. An unconditional version, for almost all $Q < x^{1/2-o(1)}$, and all $A \bmod Q$, is given by the Bombieri-Vinogradov theorem. Going beyond the GRH, the Elliott-Halberstam conjecture gives a similar statement for Q as large as $x^{1-\epsilon}$.

For $\mathbb{F}_q[x]$, it is a consequence of the Riemann Hypothesis for curves over a finite field (Weil's theorem) that given a modulus $Q \in \mathbb{F}_q[x]$ of positive degree, and a polynomial A coprime to Q, the number $\pi_q(n;Q,A)$ of primes $P = A \bmod Q$, $P \in \mathcal{M}_n$ satisfies

$$\pi_q(n;Q,A) = \frac{\pi_q(n)}{\Phi(Q)} + O(\deg Q \cdot q^{n/2}) \ ,$$

where $\Phi(Q)$ is the number of coprime residues modulo Q. For $q \to \infty$, the main term is dominant as long as $\deg Q < n/2$.

Going beyond the Riemann Hypothesis for curves, Bank, Bary-Soroker and Rosenzweig [4] show an individual asymptotic continues to hold for even larger moduli in the limit $q \to \infty$:

Theorem 3.3 ([4]). *If* $1 \le \deg Q \le n-3$ *then*

$$\pi_q(n; Q, A) = \frac{\pi_q(n)}{\Phi(Q)} \left(1 + O_n(q^{-\frac{1}{2}})\right) .$$

This should be considered as an individual version of the Elliot-Halberstam conjecture. As in the short interval case, they have a stronger result which takes into account the cycle structure.

4. Autocorrelations and twisted convolution

In this section we describe results on the autocorrelation of various classical arithmetic functions in the function field context.

4.1. Autocorrelations of the Möbius function and Chowla's conjecture. Equivalent formulations of the PNT and the Riemann Hypothesis can be given in terms of growth of partial sums of the Möbius function, defined by $\mu(n) = (-1)^k$ if n is a product of k distinct primes, and $\mu(n) = 0$ otherwise: The PNT is equivalent to nontrivial cancellation $\sum_{n \le x} \mu(n) = o(x)$, and the RH is equivalent to square-root cancellation: $\sum_{n \le x} \mu(n) = O(x^{1/2+o(1)})$.

A conjecture of Chowla on the auto-correlation of the Möbius function, asserts that given an r-tuple of distinct integers $\alpha_1, \dots, \alpha_r$ and $\epsilon_i \in \{1, 2\}$, not all even, then

$$\lim_{N \to \infty} \frac{1}{N} \sum_{n \le N} \mu(n + \alpha_1)^{\epsilon_1} \cdot \dots \cdot \mu(n + \alpha_r)^{\epsilon_r} = 0 . \tag{4.1}$$

Note that the number of nonzero summands here, that is the number of $n \le N$ for which $n + \alpha_1, \dots, n + \alpha_r$ are all square-free, is asymptotically $\mathfrak{S}(\alpha)N$, where $\mathfrak{S}(\alpha) > 0$ if the numbers $\alpha_1, \dots, \alpha_r$ do not contain a complete system of residues modulo p^2 for every prime p, so that Chowla's conjecture (4.1) addresses non-trivial cancellation in the sum. At this time, the only known case of Chowla's conjecture (4.1) is $r = 1$ where it is equivalent with the Prime Number Theorem.

Sarnak [35] showed that Chowla's conjecture implies that $\mu(n)$ does not correlate with any "deterministic" (i. e., zero entropy) sequence. For recent studies on the correlation between $\mu(n)$ and several sequences of arithmetic functions, see [5, 8, 16, 29].

In joint work with Dan Carmon [6], we have resolved a version of Chowla's conjecture for $\mathbb{F}_q[x]$ in the limit $q \to \infty$. To formulate it, one defines the Möbius function of a nonzero polynomial $F \in \mathbb{F}_q[x]$ to be $\mu(F) = (-1)^r$ if $F = cP_1 \dots P_r$ with $0 \ne c \in \mathbb{F}_q$ and $P_1, \dots, P_r$ are distinct monic irreducible polynomials, and $\mu(F) = 0$ otherwise.

Theorem 4.1. *Fix* $r > 1$ *and assume that* $n > 1$ *and* q *is odd. Then for any choice of distinct polynomials* $\alpha_1, \dots, \alpha_r \in \mathbb{F}_q[x]$, *with* $\max \deg \alpha_j < n$, *and* $\epsilon_i \in \{1, 2\}$, *not all even,*

$$\left| \sum_{F \in \mathcal{M}_n} \mu(F + \alpha_1)^{\epsilon_1} \dots \mu(F + \alpha_r)^{\epsilon_r} \right| \ll_{r,n} q^{n - \frac{1}{2}} . \tag{4.2}$$

Thus for fixed $r, n > 1$,

$$\lim_{q\to\infty} \frac{1}{\#\mathcal{M}_n} \sum_{F\in\mathcal{M}_n} \mu(F+\alpha_1)^{\epsilon_1} \dots \mu(F+\alpha_r)^{\epsilon_r} = 0 \tag{4.3}$$

under the assumption of Theorem 4.1, giving an analogue of Chowla's conjecture (4.1).

Note that the number of square-free monic polynomials of degree n is, for $n > 1$, equal to $q^n - q^{n-1}$. Hence, given r distinct polynomials $\alpha_1, \dots, \alpha_r \in \mathbb{F}_q[x]$, with $\deg \alpha_j < n$, the number of $F \in \mathcal{M}_n$ for which all of $F(x) + \alpha_j(x)$ are square-free is $q^n + O(rq^{n-1})$ as $q \to \infty$. Thus indeed we display cancellation.

The starting point in our argument is Pellet's formula, which asserts that for the polynomial ring $\mathbb{F}_q[x]$ with q odd, the Möbius function $\mu(F)$ can be computed in terms of the discriminant $\mathrm{disc}(F)$ of $F(x)$ as

$$\mu(F) = (-1)^{\deg F} \chi_2(\mathrm{disc}(F)) \ , \tag{4.4}$$

where χ_2 is the quadratic character of $\mathbb{F}_q$. That allows us to express the LHS of (4.2) as an n-variable character sum and to estimate it by freezing all but one of the variables, and then using the Riemann Hypothesis for curves (Weil's theorem) to bound the one-variable sum. A key point is to bound the number of times when there is no cancellation in the one-variable sum.

4.2. Twin primes. It is an ancient conjecture that there are infinitely many twin primes, and a refined quantitative form, due to Hardy and Littlewood, asserts that given distinct integers $a_1, \dots, a_r$, the number $\pi(x; a_1, \dots, a_r)$ of integers $n \le x$ for which $n + a_1, \dots, n + a_r$ are simultaneously prime is asymptotically

$$\pi(x; a_1, \dots, a_r) \sim \mathfrak{S}(a_1, \dots, a_r) \frac{x}{(\log x)^r}, \quad x \to \infty \ , \tag{4.5}$$

for a certain constant $\mathfrak{S}(a_1, \dots, a_r)$, which is positive whenever there are no local congruence obstructions. Despite the striking recent breakthroughs by Zhang [37] and Maynard [31], this conjecture is still open even for $r = 2$ (twin primes).

Recently the function field version of the problem was solved. Bary-Soroker [3] proved that for given n, r then for any sequence of finite fields $\mathbb{F}_q$ of odd cardinality q, and distinct polynomials $a_1, \dots, a_r \in \mathbb{F}_q[x]$ of degree less than n, the number $\pi_q(n; a_1, \dots, a_r)$ of monic polynomials $f \in \mathbb{F}_q[x]$ of degree n such that $f + a_1, \dots, f + a_r$ are simultaneously irreducible satisfies

$$\pi_q(n; a_1, \dots, a_r) \sim \frac{q^n}{n^r}, \quad q \to \infty \ . \tag{4.6}$$

This improves on earlier results by Pollack [33] and by Bary-Soroker [2].

4.3. The additive divisor problem. The divisor function $d_r(n)$ is the number of ways of writing a positive integer n as a product of r positive integers. In particular for $r = 2$ we recover the classical divisor function $d_2(n) = \sum_{d|n} 1$. The mean value of d_r is

$$\frac{1}{x} \sum_{n\le x} d_r(n) \sim \frac{(\log x)^{r-1}}{(r-1)!}, \quad x \to \infty \ . \tag{4.7}$$

Likewise, the divisor function $d_r(f)$ for a monic polynomial $f \in \mathbb{F}_q[x]$ is defined as the number of r-tuples of monic polynomials $(a_1, \dots, a_r)$ so that $f = a_1 \cdot \dots \cdot a_r$. The mean value of d_r, when averaged over all monic polynomials of degree n, is

$$\frac{1}{q^n} \sum_{f \in \mathcal{M}_n} d_r(f) = \binom{n+r-1}{r-1} = \frac{n^{r-1}}{(r-1)!} + \dots , \tag{4.8}$$

which is a polynomial of degree $r-1$ in n.

The "additive divisor problem" (other names are "shifted divisor" and "shifted convolution") is to understand the autocorrelation of the divisor function, that is the sum (where $h \neq 0$ is fixed for this discussion)

$$D_r(X; h) := \sum_{n \leq X} d_r(n) d_r(n+h) . \tag{4.9}$$

These sums are of importance in studying the moments of the Riemann ζ-function on the critical line, see [7, 19].

For $r = 2$ (the ordinary divisor function), Ingham [18] and Estermann [10] showed that

$$\sum_{n \leq X} d_2(n) d_2(n+h) \sim X P_2(\log X; h), \quad X \to \infty \tag{4.10}$$

where $P_2(u; h)$ is a quadratic polynomial in u.

For $r \geq 3$ it is conjectured that

$$D_r(X; h) \sim X P_{2(r-1)}(\log X; h), \quad X \to \infty \tag{4.11}$$

where $P_{2(r-1)}(u; h)$ is a polynomial in u of degree $2(r-1)$, whose coefficients depend on h (and r). However, even a conjectural description of the polynomials $P_{2(r-1)}(u; h)$ is difficult to obtain, see [7, 19].

In joint work with Andrade and Bary-Soroker [1], we study a version of the additive divisor problem for $\mathbb{F}_q[x]$. We show:

Theorem 4.2. *Let $0 \neq h \in \mathbb{F}_q[x]$, and $n > \deg h$. Then for q odd,*

$$\frac{1}{q^n} \sum_{f \in \mathcal{M}_n} d_r(f) d_r(f+h) = \binom{n+r-1}{r-1}^2 + O_n(q^{-1/2}) , \tag{4.12}$$

the implied constant depending only on n.

Note that $\binom{n+r-1}{r-1}^2$ is a polynomial in n of degree $2(r-1)$ with leading coefficient $1/[(r-1)!]^2$.

4.4. About proofs. The results of this section can all be deduced from one principle (though this was not the original proof of most), namely that for a random monic polynomial $f \in \mathcal{M}_n$ of degree n, the cycle structure of f and its shift $f + \alpha$ are *independent* as $q \to \infty$. Precisely, in [1] we show that for for fixed $n > 1$, and two partitions $\lambda', \lambda'' \vdash n$, given any sequence of finite fields $\mathbb{F}_q$ of odd cardinality q, and nonzero $\alpha \in \mathbb{F}_q[x]$ of degree less than n, then

$$\lim_{q \to \infty} \frac{1}{q^n} \#\{f \in \mathcal{M}_n : \lambda(f) = \lambda', \lambda(f+\alpha) = \lambda''\} = p(\lambda') \times p(\lambda'') \tag{4.13}$$

where $p(\lambda)$, as in (2.4), (2.5), is the probability that a random permutation on n letters has cycle structure λ. This result is an elaboration of earlier work by Bary-Soroker [3] which dealt with the case of n-cycles, where $\lambda = \tilde{\lambda} = (0, \dots, 0, n)$. There is also a version allowing several distinct shifts.

To prove (4.13) we need to compute a certain Galois group: Let $\mathbb{F}$ be an algebraic closure of $\mathbb{F}_q$, $\mathbf{A} = (A_0, \dots, A_{n-1})$ be indeterminates, and

$$\mathcal{F}(\mathbf{A}, x) = x^n + A_{n-1}x^{n-1} + \cdots + A_0 \tag{4.14}$$

the generic polynomial of degree n, whose Galois group over $\mathbb{F}(\mathbf{A})$ is well-known to be the full symmetric group S_n. For nonzero $\alpha \in \mathbb{F}_q[x]$ of degree less than n, let

$$\mathcal{G}(\mathbf{A}, x) = \mathcal{F}(\mathbf{A}, x)\Big(\mathcal{F}(\mathbf{A}, x) + \alpha(x)\Big) . \tag{4.15}$$

Bary-Soroker [3] shows that for odd q, the Galois group of $\mathcal{G}$ over $\mathbb{F}(\mathbf{A})$ is the product $S_n \times S_n$, the maximal possible group. The proof requires an ingredient from the proof of Chowla's conjecture [6] discussed above.

Once we know the Galois group of $\mathcal{G}(\mathbf{A}, x)$, we apply an explicit version of Chebotarev's theorem for function fields to prove (4.13), see [1] for the details.

5. The variance of sums of arithmetic functions and matrix integrals

I now describe some results concerning the variance of sums of several arithmetic functions. A common feature is that the variance is expressed as a matrix integral.

5.1. Variance of primes in short intervals. The von Mangoldt function is defined as $\Lambda(n) = \log p$ if $n = p^k$ is a prime power, and 0 otherwise. A form of the Prime Number Theorem (PNT) is the assertion that

$$\psi(x) := \sum_{n \le x} \Lambda(n) \sim x \quad \text{as } x \to \infty . \tag{5.1}$$

To study the distribution of primes in short intervals, we define for $1 \le H \le x$,

$$\psi(x; H) := \sum_{n \in [x - \frac{H}{2}, x + \frac{H}{2}]} \Lambda(n) . \tag{5.2}$$

The Riemann Hypothesis guarantees an asymptotic formula $\psi(X; H) \sim H$ as long as $H > X^{\frac{1}{2}+o(1)}$. Goldston and Montgomery [13] studied the variance of $\psi(x; H)$, relating it to the pair correlation function of the zeros of the Riemann zeta function. The conjecture of Goldston and Montgomery, as refined by Montgomery and Soundararajan[1] [32] is that in the range $X^\epsilon < H < X^{1-\epsilon}$, as $X \to \infty$:

$$\frac{1}{X}\int_1^X |\psi(x; H) - H|^2 \, dx \sim H\Big(\log X - \log H - (\gamma + \log 2\pi)\Big) \tag{5.3}$$

with γ being Euler's constant.

With J. Keating, we prove a function field analogue of Conjecture 5.3:

[1] based on Hardy-Littlewood type heuristics

Theorem 5.1 ([26]). *For $h \le n-5$, as $q \to \infty$,*

$$\frac{1}{q^n} \sum_{A \in \mathcal{M}_n} \left| \sum_{|f-A| \le q^h} \Lambda(f) - H \right|^2 \sim H \int_{U(n-h-2)} |\operatorname{tr} U^n|^2 \, dU = H(n-h-2) \, .$$

Recall $H := \#\{f : |f-A| \le q^h\} = q^{h+1}$. Here the matrix integral is over the unitary group $U(n-h-2)$, equipped with its Haar probability measure.

5.2. Variance of primes in arithmetic progressions. A form of the Prime Number Theorem for arithmetic progression states that for a modulus Q and A coprime to Q,

$$\psi(X; Q, A) := \sum_{\substack{n \le X \\ n = A \bmod Q}} \Lambda(n) \sim \frac{X}{\phi(Q)}, \quad \text{as } X \to \infty \, . \tag{5.4}$$

In most arithmetic applications it is crucial to allow the modulus to grow with X. For very large moduli $Q > X$, there can be at most one prime in the arithmetic progression $P = A \mod Q$ so that the interesting range is $Q < X$. To study the fluctuations of $\psi(X; Q, A)$, define

$$G(X, Q) = \sum_{\substack{A \bmod Q \\ \gcd(A,Q)=1}} \left| \psi(X; Q, A) - \frac{X}{\phi(Q)} \right|^2 \, . \tag{5.5}$$

Hooley, in his ICM article [17], conjectured that under some (unspecified) conditions,

$$G(X, Q) \sim X \log Q \, . \tag{5.6}$$

Friedlander and Goldston [12] conjecture that (5.6) holds if $X^{1/2+\epsilon} < Q < X$, and further conjecture that if $X^{1/2+\epsilon} < Q < X^{1-\epsilon}$ then

$$G(X, Q) = X \left(\log Q - \left(\gamma + \log 2\pi + \sum_{p | Q} \frac{\log p}{p-1} \right) \right) + o(X) \, . \tag{5.7}$$

They show that both (5.6) (in the range $X^{1/2+\epsilon} < Q < X$) and (5.7) (in the range $X^{1/2+\epsilon} < Q < X^{1-\epsilon}$) hold assuming GRH and a strong version of the Hardy-Littlewood conjecture (4.5) on prime pairs. For $Q < X^{1/2}$ little is known. In any case, Hooley's conjecture (5.6) has not been proved in any range.

With J. Keating [26] we resolve the function-field version of Conjecture (5.6):

Theorem 5.2. *Fix $n \ge 2$. Given a sequence of finite fields $\mathbb{F}_q$ and square-free polynomials $Q(x) \in \mathbb{F}_q[x]$ with $2 \le \deg Q \le n-1$, then as $q \to \infty$,*

$$G(n; Q) \sim q^n \int_{U(\deg Q - 1)} |\operatorname{tr} U|^n dU = q^n (\deg Q - 1) \, . \tag{5.8}$$

We can compare our result (5.8) to the conjectures (5.6) and (5.7): The range $X^{1/2} < Q < X$ corresponds to $\deg Q < n < 2 \deg Q$, so that we recover the function field version of conjecture (5.6); note that (5.8) holds for all n, not just in that range. Thus we believe that Hooley's conjecture (5.6) should hold for all $Q > X^{\epsilon}$. We refer to Fiorilli's recent work [11] for a more refined conjecture in this direction.

5.3. Almost-primes. A variation on this theme was proposed by B. Rodgers [34]. Instead of primes, he considered "almost primes", that is products of two prime powers. A useful weight function for these is the generalized von Mangoldt function

$$\Lambda_2 = \Lambda * \Lambda + \deg \cdot \Lambda = \mu * \deg^2 \tag{5.9}$$

which is supported on products of two prime powers ($*$ means Dirichlet convolution). The mean value of Λ_2 over the set $\mathcal{M}_n$ of monic polynomials of degree n is

$$\frac{1}{q^n} \sum_{f \in \mathcal{M}_n} \Lambda_2(f) = n^2 - (n-1)^2 = 2n - 1 \, . \tag{5.10}$$

To count almost primes in the short intervals, set for $A \in \mathcal{M}_n$, and $1 \leq h < n$

$$\Psi_2(A; h) = \sum_{f \in I(A;h)} \Lambda_2(f) \, . \tag{5.11}$$

Rodgers showed [34] that the variance of $\Psi_2(A; h)$ is given as $q \to \infty$, for fixed n and $h \leq n - 5$, by the matrix integral

$$\operatorname{Var} \Psi_2(\bullet; h) \sim H \int_{U(n-h-2)} \left| \sum_{j=1}^{n-1} \operatorname{tr} U^j \operatorname{tr} U^{n-j} - n \operatorname{tr} U^n \right|^2 dU, \quad q \to \infty \, . \tag{5.12}$$

He shows the matrix integral to be equal to $(4(n-h-2)^3 - (n-h-2))/3$, in fact that

$$\int_{U(N)} \left| \sum_{j=1}^{n-1} \operatorname{tr} U^j \operatorname{tr} U^{n-j} - n \operatorname{tr} U^n \right|^2 dU = \sum_{d=1}^{\min(n,N)} (d^2 - (d-1)^2))^2 \, . \tag{5.13}$$

5.4. Sums of the Möbius function and the Good-Churchhouse conjecture. It is a standard heuristic to assume that the Möbius function behaves like a random variable taking values ± 1 with equal probability, and supported on the square-free integers (which have density $1/\zeta(2) = 6/\pi^2$). In particular if we consider the sums of $\mu(n)$ in blocks of length H,

$$M(x; H) := \sum_{|n-x| < H/2} \mu(n) \tag{5.14}$$

then when averaged over x, $M(x, H)$ has mean zero, and it was conjectured by Good and Churchhouse [14] in 1968 that $M(x; H)$ has variance

$$\frac{1}{X} \int_X^{2X} |M(x; H)|^2 \sim \frac{H}{\zeta(2)} \tag{5.15}$$

for $X^\epsilon < H = H(X) < X^{1-\epsilon}$. Moreover they conjectured that the normalized sums $M(x; H)/\sqrt{H/\zeta(2)}$ have asymptotically a normal distribution.

We can apply our method to evaluate the variance of sums of the Möbius function in short intervals for $\mathbb{F}_q[x]$. Set

$$\mathcal{N}_\mu(A; h) := \sum_{f \in I(A;h)} \mu(f) \, . \tag{5.16}$$

The mean value of $\mathcal{N}_\mu(A; h)$ is 0, and the variance is

Theorem 5.3 (Keating-Rudnick [27]). *If $h \le n-5$ then as $q \to \infty$,*

$$\operatorname{Var} \mathcal{N}_\mu(\bullet; h) \sim H \int_{U(n-h-2)} |\operatorname{tr} \operatorname{Sym}^n U|^2 dU = H$$

where Sym^n is the representation of the unitary group $U(N)$ on polynomials of degree n in N variables.

Theorem 5.3 is consistent with Conjecture (5.15) if we replace H by $H/\zeta_q(2)$ where $\zeta_q(2) = \sum_f 1/|f|^2$ (the sum over all monic f), which tends to 1 as $q \to \infty$.

5.5. The divisor function in short intervals. Dirichlet's divisor problem addresses the size of the remainder term $\Delta_2(x)$ in partial sums of the divisor function:

$$\Delta_2(x) := \sum_{n \le x} d_2(n) - x\Big(\log x + (2\gamma - 1)\Big) \tag{5.17}$$

where γ is the Euler-Mascheroni constant. For the higher divisor functions one defines a remainder term $\Delta_k(x)$ similarly as the difference between the partial sums $\sum_{n \le x} d_k(n)$ and a smooth term $xP_{k-1}(\log x)$ where $P_{k-1}(u)$ is a certain polynomial of degree $k-1$.

Let

$$\Delta_k(x; H) = \Delta_k(x+H) - \Delta_k(x) \tag{5.18}$$

be the remainder term for sums of d_k over short intervals $[x, x+H]$. Jutila [22], Coppola and Salerno [8], and Ivić [20, 21] show that, for $X^\epsilon < H < X^{1/2-\epsilon}$, the mean square of $\Delta_2(x, H)$ is asymptotically equal to

$$\frac{1}{X} \int_X^{2X} \Big(\Delta_2(x, H)\Big)^2 dx \sim H P_3(\log X - 2 \log H) \tag{5.19}$$

for a certain cubic polynomial P_3.

Lester and Yesha [28] showed that $\Delta_2(x, H)$, normalized to have unit mean-square using (5.19), has a Gaussian value distribution at least for a narrow range of H below $X^{1/2}$: $H = \sqrt{X}/L$, where $L = L(X) \to \infty$ with X, but $L \ll X^{o(1)}$, (see [28] for the precise statement), the conjecture being that this should hold for $X^\epsilon < H < X^{1/2-\epsilon}$ for any $\epsilon > 0$.

In joint work with J. Keating and E. Roditty-Gershon [25], we study the corresponding problem of the sum of $d_k(f)$ over short intervals for $\mathbb{F}_q[x]$. Set

$$\mathcal{N}_{d_k}(A; h) := \sum_{f \in I(A;h)} d_k(f)\,. \tag{5.20}$$

The mean value is

$$\frac{1}{q^n} \sum_{A \in \mathcal{M}_n} \mathcal{N}_{d_k}(A; h) = q^{h+1} \binom{n+k-1}{k-1}\,. \tag{5.21}$$

In analogy with (5.17), (5.18) we set

$$\Delta_k(A; h) := \mathcal{N}_{d_k}(A; h) - q^{h+1} \binom{n+k-1}{k-1}\,. \tag{5.22}$$

It can be shown that $\Delta_k(A;h) \equiv 0$ vanishes identically for $h > (1-\frac{1}{k})n - 1$. Using Theorem 3.2 [4], we can show that for all $3 \le h < n$

$$\Delta_k(A;h) \ll_{n,k} q^{h+\frac{1}{2}} \tag{5.23}$$

is smaller than the main term.

We express the mean square of $\Delta_k(A,h)$ (which is the variance of $\mathcal{N}_{d_k}(A;h)$) in terms of a matrix integral. Let $\Lambda^j : U(N) \to GL(\Lambda^j \mathbb{C}^N)$ be the exterior j-th power representation ($0 \le j \le N$). Define the matrix integrals over the group $U(N)$ of $N \times N$ unitary matrices

$$I_k(m;N) := \int_{U(N)} \Big| \sum_{\substack{j_1+\cdots+j_k=m \\ 0\le j_1,\ldots,j_k\le N}} \operatorname{tr}\Lambda^{j_1}(U)\ldots\operatorname{tr}\Lambda^{j_k}(U)\Big|^2 dU \ , \tag{5.24}$$

the integral with respect to the Haar probability measure.

By definition, $I_k(m;N) = 0$ for $m > kN$. We have a functional equation $I_k(m;N) = I_k(kN-m;N)$ and

$$I_k(m;N) = \binom{m+k^2-1}{k^2-1}, \quad m \le N \ . \tag{5.25}$$

The identity (5.25) can be proved by various means, for instance using the work of Diaconis and Gamburd [9] relating matrix integrals to counting magic squares.

Theorem 5.4 ([25]). *Let $n \ge 5$, and $h \le \min(n-5, (1-\frac{1}{k})n - 2)$. Then as $q \to \infty$,*

$$\frac{1}{q^n} \sum_{A \in \mathcal{M}_n} |\Delta_k(A;h)|^2 \sim H \cdot I_k(n; n-h-2) \ .$$

In particular for the standard divisor function ($k=2$), if $h \le n/2 - 2$ and $n \ge 8$ then

$$\frac{1}{q^n} \sum_{A \in \mathcal{M}_n} |\Delta_2(A;h)|^2 \sim H \frac{(n-2h+5)(n-2h+6)(n-2h+7)}{6} \ . \tag{5.26}$$

This is consistent with (5.19), which leads us to expect a cubic polynomial in $(n-2h)$.

6. How to compute the variance

Our results on variance described in § 5 depend on expressing the variance in terms of zeros of Dirichlet L-functions for $\mathbb{F}_q[x]$, and using recent equidistribution results of Katz [23], [24], tailor-made for this purpose. To describe how this is done, we give some background on L-functions.

6.1. Dirichlet L-functions. Let $Q(x) \in \mathbb{F}_q[x]$ be a polynomial of positive degree. A Dirichlet character modulo Q is a homomorphism $\chi : (\mathbb{F}_q[x]/(Q))^\times \to \mathbb{C}^\times$. A Dirichlet character χ is "even" if $\chi(cF) = \chi(F)$ for all $0 \ne c \in \mathbb{F}_q$, and χ is *primitive* if there is no proper divisor $Q' \mid Q$ so that $\chi(F) = 1$ whenever F is coprime to Q and $F = 1 \mod Q'$. The number of Dirichlet characters modulo Q is $\Phi(Q)$, and the number of even characters modulo Q is $\Phi^{ev}(Q) = \Phi(Q)/(q-1)$.

The L-function $\mathcal{L}(u,\chi)$ attached to χ is defined as

$$\mathcal{L}(u,\chi) = \sum_{\substack{f \text{ monic} \\ (f,Q)=1}} \chi(f) u^{\deg f} = \prod_{P \nmid Q} (1 - \chi(P) u^{\deg P})^{-1} \tag{6.1}$$

where the product, over all monic irreducible polynomials in $\mathbb{F}_q[x]$, is absolutely convergent for $|u| < 1/q$.

If $Q \in \mathbb{F}_q[x]$ is a polynomial of degree $\deg Q \geq 2$, and $\chi \neq \chi_0$ is a nontrivial character mod Q, then the L-function $\mathcal{L}(u,\chi)$ is a polynomial in u of degree at most $\deg Q - 1$. Moreover, if χ is an even character there is a "trivial" zero at $u = 1$.

For a primitive even character modulo Q, we can write

$$\mathcal{L}(u,\chi) = (1-u)\det(I - uq^{1/2}\Theta_\chi) \tag{6.2}$$

where the matrix $\Theta_\chi \in U(\deg Q - 2)$ is unitary (as follows from the Riemann Hypothesis for curves), uniquely defined up to conjugacy. It is called the unitarized Frobenius matrix of χ. Likewise, if χ is odd and primitive then $\mathcal{L}(u,\chi) = \det(I - uq^{1/2}\Theta_\chi)$ where $\Theta_\chi \in U(\deg Q - 1)$ is unitary.

Katz [24] showed that as χ varies over all primitive even characters modulo x^{N+2}, the unitarized Frobenii Θ_χ become uniformly distributed in the projectivized unitary group $PU(N)$ for $N \geq 3$ as $q \to \infty$ (and also for $N = 2$ if q is coprime to 2 and 5). Thus for any nice class function F on $U(N)$, which is invariant under the center ($F(zU) = F(u)$, z on the unit circle), we have

$$\lim_{q\to\infty} \frac{1}{\Phi_{ev}(x^{N+2})} \sum_{\substack{\chi \bmod x^{N+2} \\ \text{even primitive}}} F(\Theta_\chi) = \int_{PU(N)} F(U) dU \ . \tag{6.3}$$

6.2. Short intervals as arithmetic progressions. Our method to handle sums over short intervals $I(A;h) = \{f : |f - A| \leq q^h\}$ is to relate them to arithmetic progressions modulo x^{n-h}.

Denote by $\mathcal{P}_{\leq n}$ the set of all polynomials of degree at most n. We define a map $\theta_n : \mathcal{P}_{\leq n} \to \mathcal{P}_{\leq n}$ by

$$\theta_n(f) = x^n f(\frac{1}{x}) \tag{6.4}$$

which takes $f(x) = f_0 + f_1 x + \cdots + f_n x^n$, $n = \deg f$ to the "reversed" polynomial

$$\theta_n(f)(x) = f_0 x^n + f_1 x^{n-1} + \cdots + f_n \ . \tag{6.5}$$

Then for $B \in \mathcal{M}_{n-h-1}$, the map θ_n takes the "interval" $I(T^{h+1}B;h)$ bijectively onto the arithmetic progression $\{g \in \mathcal{P}_{\leq n} : g \equiv \theta_{n-h-1}(B) \mod x^{n-h}\}$.

6.3. A formula for the variance. The identification of short intervals with arithmetic progressions allows us to express sums of several arithmetic functions in terms of even Dirichlet characters. For the case of the von Mangoldt function, this is done in [26]. I illustrate this identification in the case of the Möbius function (Theorem 5.3): We denoted by

$\mathcal{N}_\mu(A;h) = \sum_{f\in I(A;h)} \mu(f)$. Then for $B \in \mathcal{M}_{m-h-1}$,

$$\mathcal{N}_\mu(T^{h+1}B;h) = \frac{1}{\Phi_{ev}(x^{n-h})} \sum_{\substack{\chi \bmod x^{n-h}\\ \chi\neq\chi_0 \text{ even}}} \bar\chi(\theta_{n-h-1}(B))(\mathcal{M}(n;\mu\chi) - \mathcal{M}(n-1;\mu\chi)) \tag{6.6}$$

where

$$\mathcal{M}(n;\mu\chi) = \sum_{f\in\mathcal{M}_n} \mu(f)\chi(f)\ . \tag{6.7}$$

We next express the sums $\mathcal{M}(n;\mu\chi)$ in terms of zeros of the L-function $\mathcal{L}(u,\chi)$; for χ primitive this means in terms of the unitarized Frobenius matrix Θ_χ. The connection is made by writing the generating function identity

$$\sum_{n=0}^{\infty} \mathcal{M}(n;\mu\chi)u^n = \frac{1}{\mathcal{L}(u,\chi)}\ . \tag{6.8}$$

Therefore we find that for χ primitive and even,

$$\mathcal{M}(n;\mu\chi) = \sum_{k=0}^{n} q^{k/2}\,\mathrm{tr}\,\mathrm{Sym}^k\,\Theta_\chi \tag{6.9}$$

where for $N > 1$, $\mathrm{Sym}^n : GL(N,\mathbb{C}) \to GL(\mathrm{Sym}^n\,\mathbb{C}^N)$ is the symmetric n-th power representation. Consequently we obtain

$$\mathrm{Var}\,\mathcal{N}_\mu(\bullet;h) = \frac{q^{h+1}}{\Phi_{\mathrm{ev}}(x^{n-h})} \sum_{\substack{\chi \bmod x^{n-h}\\ \chi \text{ even and primitive}}} |\,\mathrm{tr}\,\mathrm{Sym}^n\,\Theta_\chi|^2 + O(q^h)\ . \tag{6.10}$$

Using Katz's equidistribution theorem (6.3) we get

$$\lim_{q\to\infty} \frac{\mathrm{Var}(\mathcal{N}_\mu(\bullet;h))}{q^{h+1}} = \int_{PU(n-h-2)} |\mathrm{tr}\,\mathrm{Sym}^n\,U|^2\,dU\ . \tag{6.11}$$

The matrix integrals equals 1, hence we conclude that $\mathrm{Var}(\mathcal{N}_\mu(;h)) \sim q^{h+1} = H$, which is Theorem 5.3.

Acknowledgements. The research leading to these results has received funding from the European Research Council under the European Union's Seventh Framework Programme (FP7/2007-2013) / ERC grant agreement n° 320755. I am grateful to J. Andrade, L. Bary-Soroker, J. Keating, E. Kowalski, S. Lester, E. Roditty-Gershon and K. Soundararajan for their comments on earlier versions of this survey.

Perfectoid spaces and their applications

Peter Scholze

Abstract. We survey the theory of perfectoid spaces and its applications.

Mathematics Subject Classification (2010). Primary 14G22, 11F80; Secondary 14G20, 14C30, 14L05, 14G35, 11F03.

Keywords. Perfectoid spaces, rigid-analytic geometry, almost mathematics, p-adic Hodge theory, Shimura varieties, Langlands program.

1. Introduction

In algebraic geometry, one of the most important dichotomies is the one between characteristic 0 and positive characteristic p. Our intuition is formed from the study of complex manifolds, which are manifestly of characteristic 0, but in number theory, the most important questions are in positive or mixed characteristic. Algebraic geometry gives a framework to transport intuition from characteristic 0 to positive characteristics. However, there are also several new phenomena in characteristic p, such as the presence of the Frobenius map, which acts naturally on all spaces of characteristic p. Using the Frobenius, one can formulate the Weil conjectures, and more generally the theory of weights. This makes many results accessible over fields such as $\mathbb{F}_p((t))$, which are wide open over fields of arithmetic interest such as $\mathbb{Q}_p$. The theory of perfectoid spaces was initially designed as a means of transporting information available over $\mathbb{F}_p((t))$ to $\mathbb{Q}_p$, but has since found a number of independent applications. The purpose of this report is to give an overview of the developments in the field since perfectoid spaces were introduced in early 2011.

To study the transition between characteristic 0 and characteristic p, it is useful to look at the corresponding local fields $\mathbb{Q}_p$ and $\mathbb{F}_p((t))$:

$$\mathbb{Q}_p = \{ \sum_{n \gg -\infty} a_n p^n \mid a_n \in \{0, 1, \dots, p-1\} \} ,$$
$$\mathbb{F}_p((t)) = \{ \sum_{n \gg -\infty} a_n t^n \mid a_n \in \{0, 1, \dots, p-1\} = \mathbb{F}_p \} .$$

Although these two fields have formally 'the same' elements, the basic addition and multiplication operations are different: In $\mathbb{Q}_p$, one computes with carry, but in $\mathbb{F}_p((t))$ without carry. There are several strategies to pass from one field to the other. Let us recall the most important ones.

Proceedings of the International Congress of Mathematicians, Seoul, 2014

Letting $p \to \infty$. In model theory, one can formalize the idea that $\mathbb{Q}_p$ becomes isomorphic to $\mathbb{F}_p((t))$ as $p \to \infty$. This has the following implication: A first-order statement is true for almost all fields $\mathbb{Q}_p$ (for varying p) if and only if it is true for almost all fields $\mathbb{F}_p((t))$. The first application of this was the Ax-Kochen theorem, [4], that a homogeneous polynomial of degree d in more than d^2 variables admits a solution over $\mathbb{Q}_p$, except for a finite list of primes p (which depends only on d). In fact, the same result is true over $\mathbb{F}_p((t))$ for all p. However, there are counterexamples to the general statement over $\mathbb{Q}_p$, such as a quartic form in 18 variables over $\mathbb{Q}_2$ without a solution. More strikingly, this transfer principle is used in the proof of the fundamental lemma: Ngô, [52], has proved the fundamental lemma over $\mathbb{F}_p((t))$ (for sufficiently large p), which could then be transferred to $\mathbb{Q}_p$, if p is sufficiently large.[1]

However, this strategy cannot be used to get information about any fixed prime number p. One of the ways in which one wants to compare two fields is to compare the categories of finite extension fields. This is encapsulated by the absolute Galois group $G_K = \mathrm{Gal}(\overline{K}/K)$ of a field K, where $\overline{K}$ is some separable closure of K. If K is a local field such as $\mathbb{Q}_p$ or $\mathbb{F}_p((t))$, it comes with a decreasing ramification filtration

$$G_K \supset G_K^{(0)} = I_K \supset G_K^{(1)} = P_K \supset G_K^{(2)} \supset \dots ;$$

here, $P_K \subset I_K \subset G_K$ are the wild inertia, resp. inertia subgroups. The 'tame quotient' $G_K^{\mathrm{tame}} = G_K/G_K^{(1)} = G_K/P_K$ admits an explicit description, and P_K is a (not very explicit) pro-p-group.

Restricting ramification. From the explicit description of G_K^{tame} in the case of local fields, one knows that $G_{\mathbb{Q}_p}^{\mathrm{tame}} \cong G_{\mathbb{F}_p((t))}^{\mathrm{tame}}$ canonically. In other words, there is a canonical procedure to associate to a tame extension of $\mathbb{Q}_p$ a tame extension of $\mathbb{F}_p((t))$. This result can be strengthened if one passes to extension fields. More precisely, for any $n \geq 1$,

$$G_{\mathbb{Q}_p(p^{1/n})}/G^{(n)}_{\mathbb{Q}_p(p^{1/n})} \cong G_{\mathbb{F}_p((t))(t^{1/n})}/G^{(n)}_{\mathbb{F}_p((t))(t^{1/n})} .$$

This is a result of Deligne, [21], relying on ideas of Krasner, [49], which formalizes the idea that $\mathbb{Q}_p(p^{1/n})$ and $\mathbb{F}_p((t))(t^{1/n})$ are 'close local fields' (which get 'closer' as $n \to \infty$). Note that, again, this result plays a crucial role in the Langlands program, namely it is used (through Henniart's numerical local Langlands correspondence, [37]) in the original proof of the local Langlands correspondence for GL_n over $\mathbb{Q}_p$ by Harris-Taylor, [34].[2]

There is yet another approach, which gives a comparison of the whole Galois group.

Making things perfect(oid). Let $K = \mathbb{Q}_p(p^{1/p^\infty}) = \bigcup_m \mathbb{Q}_p(p^{1/p^m})$, which we will momentarily confuse with its completion, which has the same absolute Galois group G_K. Then a theorem of Fontaine-Wintenberger, [32], states that the absolute Galois groups of G_K and $G_{\mathbb{F}_p((t))}$ are isomorphic. This can be considered as a limit case of Deligne's theorem as one lets $n = p^m$, $m \to \infty$. Indeed, note that as $\mathbb{F}_p((t))(t^{1/p^m})$ is a purely inseparable extension of $\mathbb{F}_p((t))$, $G_{\mathbb{F}_p((t))(t^{1/p^m})} \cong G_{\mathbb{F}_p((t))}$. In fact, if one lets $K^\flat$ be the completion of

$$\mathbb{F}_p((t))(t^{1/p^\infty}) = \bigcup_m \mathbb{F}_p((t))(t^{1/p^m}) ,$$

[1] One does not need model theory to do this, as Waldspurger, [66], had earlier shown this transfer principle for large p directly.

[2] The alternative proof given in [57] avoids this argument, and gives a proof of the local Langlands correspondence for GL_n over $\mathbb{Q}_p$ which is purely in characteristic 0.

then the theorem of Fontaine-Wintenberger states equivalently that $G_K \cong G_{K^\flat}$. This theorem is one of the foundational cornerstones of p-adic Hodge theory. Moreover, it is true in a wide variety of cases: Any 'deeply ramified' extension of $\mathbb{Q}_p$ can be used in place of $\mathbb{Q}_p(p^{1/p^\infty})$.

Note that the last approach gives the cleanest result: It works for any fixed p, and produces an isomorphism of the whole Galois groups. However, it comes at the expense of passing to infinite extensions. The theory of perfectoid spaces is a generalization of this procedure to higher-dimensional objects.

2. The Fontaine-Wintenberger isomorphism

To start, let us explain the general statement of the Fontaine-Wintenberger isomorphism.[3]

Definition 2.1. A perfectoid field is a complete topological field K, whose topology comes from a nonarchimedean norm $|\cdot| : K \to \mathbb{R}_{\geq 0}$ with dense image, such that $|p| < 1$ and, letting $\mathcal{O}_K = \{x \in K \mid |x| \leq 1\}$ be the ring of integers, the Frobenius map $\Phi : \mathcal{O}_K/p \to \mathcal{O}_K/p$ is surjective.

Examples include the completions of $\mathbb{Q}_p(p^{1/p^\infty})$, $\mathbb{Q}_p(\mu_{p^\infty})$, $\overline{\mathbb{Q}}_p$ and $\mathbb{F}_p((t))(t^{1/p^\infty})$, $\overline{\mathbb{F}_p((t))}$. Note that perfectoid fields can be of characteristic 0 or p. In the first case, they contain $\mathbb{Q}_p$ naturally, as $|p| < 1$. Note that $\mathbb{Q}_p$ is not a perfectoid field (although $\mathbb{Z}_p/p = \mathbb{F}_p$ has a surjective Frobenius map), because $|\cdot| : \mathbb{Q}_p \to \mathbb{R}_{\geq 0}$ has discrete image $0 \cup p^{\mathbb{Z}} \subset \mathbb{R}_{\geq 0}$. In characteristic p, perfectoid fields are the same thing as perfect complete nonarchimedean fields.

By a construction of Fontaine, one can take any perfectoid field K, and produce a perfectoid field $K^\flat$ of characteristic p, called the tilt of K. First, one defines $\mathcal{O}_{K^\flat} = \varprojlim_\Phi \mathcal{O}_K/p$, and then defines $K^\flat$ as the fraction field of $\mathcal{O}_{K^\flat}$. It comes with a natural norm, with respect to which $\mathcal{O}_{K^\flat} \subset K^\flat$ is the ring of integers. In fact, one has the following alternative description of $K^\flat$.

Lemma 2.2. *There is a natural identification of multiplicative monoids*

$$\mathcal{O}_{K^\flat} = \varprojlim_{x \mapsto x^p} \mathcal{O}_K = \{(x^{(0)}, x^{(1)}, \ldots) \mid x^{(i)} \in \mathcal{O}_K, (x^{(i+1)})^p = x^{(i)}\}\,, \quad K^\flat = \varprojlim_{x \mapsto x^p} K\,.$$

In particular, $x \mapsto x^\sharp := x^{(0)}$ defines a multiplicative map $K^\flat \to K$, and the norm $|x|_{K^\flat} = |x^\sharp|_K$ on $K^\flat$.

The crucial input is the basic fact that if $a \cong b \mod p$, then $a^{p^n} \cong b^{p^n} \mod p^{n+1}$.

As a basic example of the tilting equivalence, the perfectoid field K which is the completion of $\mathbb{Q}_p(p^{1/p^\infty})$ tilts to the perfect nonarchimedean field $K^\flat$ which is the completion of $\mathbb{F}_p((t))(t^{1/p^\infty})$. Under the identification $K^\flat = \varprojlim_{x \mapsto x^p} K$, the element t corresponds to the sequence $(p, p^{1/p}, p^{1/p^2}, \ldots)$. In particular, $t^\sharp = p$, so in a vague sense, the map $x \mapsto x^\sharp$ is the map 'replace t by p'. However, calculating it in general involves a p-adic limit, so e.g.

$$(1+t)^\sharp = \lim_{n \to \infty} (1 + p^{1/p^n})^{p^n}\,.$$

[3]It should be noted that the original result of Fontaine-Wintenberger is quite different, at least in emphasis. The theorem as stated was only proved recently, and was noticed independently (at least) by Kedlaya-Liu and the author.

This already shows that any general theory of perfectoid objects has to be of an analytic nature.

Theorem 2.3 ([47, Theorem 3.5.6],[58, Theorem 3.7]). *Let K be a perfectoid field.*

(i) *For any finite extension L/K, L is a perfectoid field.*

(ii) *The association $L \mapsto L^\flat$ defines an equivalence between the category of finite extensions of K and the category of finite extensions of $K^\flat$.*

It is formal to deduce from part (ii) that the absolute Galois groups $G_K \cong G_{K^\flat}$ are isomorphic.

3. Untilting: Work of Fargues-Fontaine

The following question arises naturally: For a given perfectoid field L of characteristic p, in how many ways can it be untilted to a perfectoid field K of characteristic 0, $K^\flat \cong L$? The answer to this question leads naturally to the Fargues-Fontaine curve, [30, 31]. In particular, they prove the following theorem.

Theorem 3.1. *Fix a perfectoid field L of characteristic p. There is a regular noetherian scheme X_L of Krull dimension 1 (locally the spectrum of a principal ideal domain) over $\mathbb{Q}_p$ whose closed points x are in bijection with equivalence classes of pairs (K, ι), where K is a perfectoid field of characteristic 0 and $\iota : L \hookrightarrow K^\flat$ is an injection which makes $K^\flat$ a finite extension of L; here, the pairs (K, ι) and $(K, \iota \circ \Phi^n)$ are regarded as equivalent for any $n \in \mathbb{Z}$. The degree $[K^\flat : L]$ is called the degree of x. Moreover, there are (infinitely many) points of degree 1.*

In particular, one can always untilt a perfectoid field L to characteristic 0, and the ways of doing so are parametrized by a 1-dimensional object. Note that if, e.g., L is algebraically closed, then all points are of degree 1 and have algebraically closed residue field. However, the curve lives only over $\mathbb{Q}_p$, and thus is not of finite type over $\mathbb{Q}_p$. Concretely,

$$X_L = \mathrm{Proj} \bigoplus_{n \geq 0} B^+(L)^{\varphi = p^n} ,$$

where $B^+(L)$ is one of Fontaine's period rings, a certain completion of $W(\mathcal{O}_L)[\frac{1}{p}]$. A point of X_L gives rise to an ideal $I \subset W(\mathcal{O}_L)[\frac{1}{p}]$ (well-defined up to the action of Frobenius), and the corresponding perfectoid field of characteristic 0 is given by $K = W(\mathcal{O}_L)[\frac{1}{p}]/I$. This gives an explicit description of untilting in terms of Witt vectors.

The work of Fargues-Fontaine has further connections with the theory of perfectoid spaces that we cannot explain in detail here, for lack of space, cf. [29]. For the rest of this article, we will usually fix a perfectoid field K in characteristic 0, which amounts to fixing a point $\infty \in X_{K^\flat}$ of degree 1.

4. Perfectoid Spaces

Definition 4.1. A perfectoid K-algebra is a Banach K-algebra R for which the subring $R^\circ \subset R$ of powerbounded elements is a bounded subring, and such that the Frobenius map

$\Phi : R^\circ/p \to R^\circ/p$ is surjective.

The simplest example is $R = K\langle T^{1/p^\infty}\rangle$ for which $R^\circ = \mathcal{O}_K\langle T^{1/p^\infty}\rangle$ is the completion of $\mathcal{O}_K[T^{1/p^\infty}] = \bigcup_m \mathcal{O}_K[T^{1/p^m}]$. In other words, perfectoid K-algebras are algebras with 'lots of (approximate) p-power roots'. Note that perfectoid K-algebras are always quite big, e.g. nonnoetherian; also, no 'smallness' hypothesis is imposed. The mixture of completeness and nonnoetherianity might cause big trouble (as, e.g., completions of nonnoetherian algebras are not in general flat)! However, it turns out that the 'bigness' condition of surjective Frobenius forces good behaviour.

One can apply Fontaine's construction to any perfectoid K-algebra. This defines the tilting functor: Let R be a perfectoid K-algebra. Set

$$R^{\flat\circ} = \varprojlim_{\Phi} R^\circ/p = \varprojlim_{x\mapsto x^p} R^\circ$$

which is a $\mathcal{O}_{K^\flat}$-algebra, and

$$R^\flat = R^{\flat\circ} \otimes_{\mathcal{O}_{K^\flat}} K^\flat = \varprojlim_{x\mapsto x^p} R\,.$$

Proposition 4.2 ([58, Theorem 5.2]). *Fix a perfectoid field K with tilt $K^\flat$.*

(i) *For any perfectoid K-algebra R, the tilt $R^\flat$ is a perfectoid $K^\flat$-algebra with subring of powerbounded elements $R^{\flat\circ} \subset R^\flat$.*

(ii) *The functor $R \mapsto R^\flat$ defines an equivalence between the category of perfectoid K-algebras and the category of perfectoid $K^\flat$-algebras.*

Note also that for any perfectoid K-algebra R, one has a continuous multiplicative map $R^\flat \to R$, $f \mapsto f^\sharp$.

As remarked earlier, any theory of perfectoid objects has to be of an analytic nature. This reflects itself algebraically in the fact that perfectoid algebras are Banach algebras. On the level of spaces, it means that we have to work in some category of nonarchimedean analytic spaces. The classical such category is Tate's category of rigid-analytic spaces, [64], but strong finiteness assumptions are built into the foundations of this theory. There are (at least) two more recent approaches to nonarchimedean analytic spaces: Berkovich's analytic spaces, [8], and Huber's adic spaces, [40]. We choose to work with Huber's adic spaces, because we feel that it is the most natural framework; e.g., it interacts well with the theory of formal models. Moreover, one glues spaces along open subsets, which is at least technically convenient.[4]

Following Huber, we make the following definition in the perfectoid world:

Definition 4.3. A perfectoid affinoid K-algebra is a pair (R, R^+), where R is a perfectoid K-algebra, and $R^+ \subset R^\circ$ is an open and integrally closed subring.

The role of the integral subalgebra R^+ is certainly secondary, and one may safely assume that $R^+ = R^\circ$ on first reading.

Proposition 4.4. *The association $(R, R^+) \mapsto (R^\flat, R^{\flat+})$ with*

$$R^\flat = \varprojlim_{x\mapsto x^p} R\,,\ R^{\flat+} = \varprojlim_{x\mapsto x^p} R^+$$

[4] Somewhat more importantly, most examples of perfectoid spaces arise as 'inverse limits' of classical finite type spaces. Berkovich spaces are not well adapted to taking inverse limits.

defines an equivalence between perfectoid affinoid K-algebras and perfectoid affinoid $K^\flat$-algebras.

To a pair (R, R^+), Huber associates a space of continuous valuations.

Definition 4.5. A valuation on R is a map $|\cdot| : R \to \Gamma \cup \{0\}$, where Γ is a totally ordered abelian group (e.g., $\Gamma = \mathbb{R}_{>0}$, but higher-rank valuations are allowed), such that $|0| = 0$, $|1| = 1$, $|xy| = |x||y|$ and $|x + y| \leq \max(|x|, |y|)$. The valuation $|\cdot|$ is continuous if for all $\gamma \in \Gamma$, the subset $\{x \in R \mid |x| < \gamma\} \subset R$ is open.

There is an obvious notion of equivalence of valuations, and one defines $\mathrm{Spa}(R, R^+)$ as the set of equivalence classes of continuous valuations $|\cdot|$ on R such that $|R^+| \leq 1$. For a point $x \in \mathrm{Spa}(R, R^+)$, we denote by $f \mapsto |f(x)|$ the associated valuation. One may find back R^+ as

$$R^+ = \{f \in R \mid |f(x)| \leq 1 \ \forall x \in \mathrm{Spa}(R, R^+)\} .$$

One equips $\mathrm{Spa}(R, R^+)$ with the topology generated by rational subsets: For $f_1, \ldots, f_n$, $g \in R$ which generate R as an ideal, the subset

$$U(f_1, \ldots, f_n; g) = \{x \in \mathrm{Spa}(R, R^+) \mid |f_i(x)| \leq |g(x)|\} \subset \mathrm{Spa}(R, R^+)$$

is a rational subset.

Proposition 4.6 ([38, Theorem 3.5]). *The space $\mathrm{Spa}(R, R^+)$ is a spectral space. In particular, it is quasicompact, quasiseparated, and the rational subsets form a basis for the topology consisting of quasicompact open subsets, stable under finite intersections.*

Again, one finds an interesting relation under tilting.[5]

Theorem 4.7 ([58, Theorem 6.3 (i)]). *For any $x \in \mathrm{Spa}(R, R^+)$, one may define a point $x^\flat \in \mathrm{Spa}(R^\flat, R^{\flat +})$ by setting $|f(x^\flat)| := |f^\sharp(x)|$ for $f \in R^\flat$. This defines a homeomorphism $\mathrm{Spa}(R, R^+) \cong \mathrm{Spa}(R^\flat, R^{\flat +})$ preserving rational subsets.*

The proof relies on the following crucial approximation lemma.[6]

Lemma 4.8 ([58, Corollary 6.7 (i)]). *Assume K is of characteristic 0. Let $f \in R$ be any element, and fix any $\epsilon > 0$. Then there exists $g \in R^\flat$ such that for all $x \in \mathrm{Spa}(R, R^+)$,*

$$|(f - g^\sharp)(x)| \leq |p|^{1-\epsilon} \max(|f(x)|, \epsilon) .$$

This means in particular that $|f(x)| = |g^\sharp(x)|$ except if both are very small. However, $f - g^\sharp$ may be quite large if f is large.

One wants to equip the topological space $X = \mathrm{Spa}(R, R^+)$ with a structure sheaf $\mathcal{O}_X$. For this, let $U = U(f_1, \ldots, f_n; g) \subset X$ be a rational subset. Equip $R[g^{-1}]$ with the topology for which the image of $R^+[\frac{f_1}{g}, \ldots, \frac{f_n}{g}] \to R[g^{-1}]$ is open and bounded. Let $R\langle \frac{f_1}{g}, \ldots, \frac{f_n}{g} \rangle$ be the completion of $R[g^{-1}]$ with respect to this topology; it comes equipped with a natural subring

$$R\langle \frac{f_1}{g}, \ldots, \frac{f_n}{g} \rangle^+ \subset R\langle \frac{f_1}{g}, \ldots, \frac{f_n}{g} \rangle .$$

[5] A closely related result was proved earlier by Kedlaya, [46].

[6] A slightly stronger version (replacing $1 - \epsilon$ by $p/(p-1) - \epsilon$) appears in [47].

Proposition 4.9 ([39, Proposition 1.3]). *The pair*

$$(\mathcal{O}_X(U), \mathcal{O}_X^+(U)) = \left(R\langle \frac{f_1}{g}, \dots, \frac{f_n}{g} \rangle, R\langle \frac{f_1}{g}, \dots, \frac{f_n}{g} \rangle^+ \right)$$

depends only on the rational subset $U \subset X$. The map

$$\mathrm{Spa}(\mathcal{O}_X(U), \mathcal{O}_X^+(U)) \to \mathrm{Spa}(R, R^+)$$

is a homeomorphism onto U, preserving rational subsets.

The propositions of Huber so far have not used the assumption that R is perfectoid. This assumption is needed, however, to prove that $\mathcal{O}_X$ is actually a sheaf. Huber proved this when R is strongly noetherian, so e.g. if R is topologically of finite type over K. Perfectoid K-algebras are virtually never (strongly) noetherian.

Theorem 4.10 ([58, Theorem 6.3]). *Let (R, R^+) be a perfectoid affinoid K-algebra with tilt $(R^\flat, R^{\flat +})$. Let $X = \mathrm{Spa}(R, R^+)$, $X^\flat = \mathrm{Spa}(R^\flat, R^{\flat +})$. For any rational subset $U \subset X$, let $U^\flat \subset X^\flat$ be its image under the homeomorphism $X \cong X^\flat$.*

(i) *The presheaves $\mathcal{O}_X$, $\mathcal{O}_{X^\flat}$ are sheaves.*

(ii) *For any rational subset $U \subset X$, the pair $(\mathcal{O}_X(U), \mathcal{O}_X^+(U))$ is a perfectoid affinoid K-algebra, which tilts to $(\mathcal{O}_{X^\flat}(U^\flat), \mathcal{O}_{X^\flat}^+(U^\flat))$.*

(iii) *For any $i > 0$, the cohomology group $H^i(X, \mathcal{O}_X) = 0$ vanishes. In fact, $H^i(X, \mathcal{O}_X^+)$ is almost zero, i.e. killed by the maximal ideal of $\mathcal{O}_K$.*

The resulting spaces $\mathrm{Spa}(R, R^+)$ (equipped with the two sheaves of topological rings $\mathcal{O}_X$, $\mathcal{O}_X^+$) are called affinoid perfectoid spaces (over K). Objects obtained by gluing such spaces are called perfectoid spaces over K.

Corollary 4.11. *The categories of perfectoid spaces over K and over $K^\flat$ are equivalent. Here, if X tilts to $X^\flat$, then the underlying topological spaces of X and $X^\flat$ are canonically homeomorphic. Moreover, a subset $U \subset X$ is affinoid perfectoid if and only if $U^\flat \subset X^\flat$ is affinoid perfectoid. For any such U, $(\mathcal{O}_X(U), \mathcal{O}_X^+(U))$ is a perfectoid affinoid K-algebra with tilt $(\mathcal{O}_{X^\flat}(U^\flat), \mathcal{O}_{X^\flat}^+(U^\flat))$.*

For any perfectoid space X, one may define its étale site $X_{\text{ét}}$.

Theorem 4.12 ([58, Theorem 7.12, Proposition 7.13]). *Under tilting, $X_{\text{ét}} \cong X^\flat_{\text{ét}}$. Moreover, if $X = \mathrm{Spa}(R, R^+)$ is affinoid perfectoid, then $H^0(X_{\text{ét}}, \mathcal{O}_X^+) = R^+$ while $H^i(X_{\text{ét}}, \mathcal{O}_X^+)$ is almost zero for $i > 0$. In particular, $H^0(X_{\text{ét}}, \mathcal{O}_X) = R$ while $H^i(X_{\text{ét}}, \mathcal{O}_X) = 0$ for $i > 0$.*

The assertion $X_{\text{ét}} \cong X^\flat_{\text{ét}}$ is a far-reaching generalization of the Fontaine-Wintenberger isomorphism. Indeed, if we put $X = \mathrm{Spa}(K, \mathcal{O}_K)$, which tilts to $X^\flat = \mathrm{Spa}(K^\flat, \mathcal{O}_{K^\flat})$, the assertion is precisely the Fontaine-Wintenberger isomorphism. The assertion about $H^i(X_{\text{ét}}, \mathcal{O}_X^+)$ is a strengthening of Faltings's almost purity theorem, which is essentially the version of it for the finite étale site. Let us state it in our setup.

Theorem 4.13 ([58, Theorem 7.9 (iii)]). *Let R be a perfectoid K-algebra, and let S/R be finite étale. Then S is a perfectoid K-algebra, and S° is a uniformly almost finite étale R°-algebra.*

The following is an easy corollary, which gives a higher-dimensional variant of the Fontaine-Wintenberger isomorphism (for the finite étale case).

Corollary 4.14. *Let R be a perfectoid K-algebra with tilt $R^\flat$. Then tilting defines an equivalence between the categories of finite étale R-algebras and finite étale $R^\flat$-algebras.*

The almost purity theorem is interesting only in characteristic 0; in characteristic p, it is easy. Originally, Faltings proved such statements in the case of good reduction, [23], and then more generally for semistable (or more generally toric) reduction, [25]. We note that in Faltings' situation, R was the completion of an inductive limit of regular algebras. Then, by Zariski-Nagata purity, the ramification locus of S° over R° is purely of codimension 1. We know by assumption that there is no ramification in characteristic 0, as S/R is finite étale. At the generic points of R°/p, it follows from (the proof of) the Fontaine-Wintenberger result that there is *almost* no ramification. If there were none, one would get that S°/R° is finite étale. Faltings made the same argument work in the almost world. It came as a surprise that no regularity assumption is needed for the theorem.

5. Example: Projective spaces

Let K be a perfectoid field with tilt $K^\flat$. Let us consider the case of projective space. In all applications of perfectoid spaces, the hard part is to find a way to pass from objects of finite type over K to perfectoid objects. This is not possible in a canonical way, and one has to make a choice.

On $\mathbb{P}^n$, one has the map $\varphi : \mathbb{P}^n \to \mathbb{P}^n$ sending $(x_0 : \ldots : x_n)$ to $(x_0^p : \ldots : x_n^p)$. Consider $\mathbb{P}^n_K$ as an adic space over K. Then there is a perfectoid space $(\mathbb{P}^n_K)^{\mathrm{perf}}$ over K such that

$$(\mathbb{P}^n_K)^{\mathrm{perf}} \sim \varprojlim_{\varphi} \mathbb{P}^n_K \, .$$

Here, $\sim \varprojlim$, read 'being similar to the inverse limit', is a technical notion that accounts for the non-existence of inverse limits in the category of adic spaces, cf. [62, Definition 2.4.1]. Explicitly, $(\mathbb{P}^n_K)^{\mathrm{perf}}$ is glued out of $n+1$ copies of

$$\mathrm{Spa}(K\langle T_1^{1/p^\infty}, \ldots, T_n^{1/p^\infty}\rangle, \mathcal{O}_K\langle T_1^{1/p^\infty}, \ldots, T_n^{1/p^\infty}\rangle)$$

in the usual way. One can make the same construction over $K^\flat$ to get $(\mathbb{P}^n_{K^\flat})^{\mathrm{perf}}$.

Theorem 5.1 ([58, Theorem 8.5]). *The perfectoid space $(\mathbb{P}^n_K)^{\mathrm{perf}}$ tilts to $(\mathbb{P}^n_{K^\flat})^{\mathrm{perf}}$. In particular, there are homeomorphisms of topological spaces underlying the adic spaces, resp. isomorphisms of étale sites,*

$$|\mathbb{P}^n_{K^\flat}| \cong |(\mathbb{P}^n_{K^\flat})^{\mathrm{perf}}| \cong |(\mathbb{P}^n_K)^{\mathrm{perf}}| \cong \varprojlim_{\varphi} |\mathbb{P}^n_K| \, .$$

$$(\mathbb{P}^n_{K^\flat})_{\text{ét}} \cong (\mathbb{P}^n_{K^\flat})^{\mathrm{perf}}_{\text{ét}} \cong (\mathbb{P}^n_K)^{\mathrm{perf}}_{\text{ét}} \cong \varprojlim_{\varphi} (\mathbb{P}^n_K)_{\text{ét}} \, .$$

These constructions give a 'projection map'

$$\pi : \mathbb{P}^n_{K^\flat} \to \mathbb{P}^n_K$$

defined on topological spaces and étale topoi, and given by $(x_0 : \ldots : x_n) \mapsto (x_0^\sharp : \ldots : x_n^\sharp)$ in coordinates.

There are many variants to this theorem. All one needs is a 'dynamical system' (X, φ) over K such that (with respect to a suitable integral model of X) φ is a lift of Frobenius. E.g., one might take the canonical lift of an ordinary abelian variety, with its canonical lift of Frobenius. In that case, the tilt will be the perfection of the ordinary abelian variety in characteristic p. However, nothing of this sort works of curves of genus ≥ 2. Currently, there are very few explicit examples of tilting for varieties besides the cases of toric varieties and (semi-)abelian varieties. An interesting case might be the one of flag varieties.

6. Weight-monodromy conjecture

One application of the theory of perfectoid spaces is to a class of cases of the weight-monodromy conjecture. Let us briefly recall the statement, cf. [18].

Let X over $\mathbb{Q}_p$ (or a finite extension thereof) be a proper smooth variety. Fix a prime $\ell \neq p$. On the étale cohomology group $V = H^i(X_{\overline{\mathbb{Q}}_p}, \overline{\mathbb{Q}}_\ell)$, the absolute Galois group $G_{\mathbb{Q}_p}$ acts. Fix a Frobenius element $\mathrm{Frob} \in G_{\mathbb{Q}_p}$. From the Weil conjectures, [19], the Rapoport-Zink spectral sequence, [54], and de Jong's alterations, [42], the following is known about the structure of V:

(i) There is a direct sum decomposition $V = \bigoplus_{j=0}^{2i} V_j$, where all eigenvalues of Frob on V_j are Weil numbers of weight j.

(ii) There is a nilpotent operator $N : V \to V$ mapping $V_j \to V_{j-2}$, coming from the action of the pro-ℓ-inertia.

Conjecture 6.1 ([18]). *For any $j = 0, \ldots, i$, the map $N^j : V_{i+j} \to V_{i-j}$ is an isomorphism.*

This is somewhat reminiscent of the Lefschetz decomposition, and is sometimes said to be 'Mirror dual' to it. There is a similar result for projective smooth families of complex manifolds over a punctured complex disc, which is known to be true by work of Schmid, [56], and Steenbrink, [63].

Deligne proved the analogue for X over $\mathbb{F}_p((t))$ in [20].[7] Our result deduces the conjecture over $\mathbb{Q}_p$ in many cases by reduction to equal characteristic, via tilting.

Theorem 6.2 ([58]). *Let X be a geometrically connected proper smooth variety over a finite extension of $\mathbb{Q}_p$ which is a set-theoretic complete intersection in a projective smooth toric variety. Then the weight-monodromy conjecture holds true for X.*

Note that this result is new even for a smooth hypersurface in projective space. Let us note that strictly speaking, the author is not aware of any (geometrically connected projective smooth) X which does provably not satisfy this assumption. However, we can also not prove it in any reasonable generality.

7. Close local fields: Work of Hattori

Recall that the theory of perfectoid spaces developed as a generalization of the Fontaine-Wintenberger result which worked with infinite extensions of $\mathbb{Q}_p$. Hattori shows that one can,

[7] Actually, he assumed that X is already defined over a curve, but this assumption can be removed.

however, use this theory to prove generalizations of Deligne's results on close local fields. Let us state here one of his results.

For a complete discrete valuation field K with valuation v (normalized with image $\mathbb{Z} \cup \{\infty\}$) and residue characteristic p, the absolute ramification index e_K is defined as $e_K = v(p)$. In particular, $e_K = \infty$ if K is of characteristic p.

Theorem 7.1 ([35, Theorem 1.2 (ii)]). *Let K_1 and K_2 be two complete discrete valuation fields of residue characteristic p, such that the residue fields $k_1 \cong k_2$ are isomorphic. Let $j \leq \min(e_{K_1}, e_{K_2})$. Then there is an isomorphism*

$$G_{K_1}/G_{K_1}^{(j)} \cong G_{K_2}/G_{K_2}^{(j)} .$$

The main novelty is that the residue fields k_i are not assumed to be perfect. Thus, Hattori has to use the Abbes-Saito ramification filtration for complete discrete valuation fields with imperfect residue fields, [1]. This is defined in terms of geometrically connected components of certain rigid-analytic varieties. Hattori's approach is to use perfectoid spaces to compare these rigid-analytic varieties in different characteristics. For this, one has to check that connected components do not change when passing to the perfectoid world, i.e. extracting a lot of p-power roots; this uses the bound on the ramification degree and an explicit computation. Then the result follows from the homeomorphism $X \cong X^\flat$ of underlying topological spaces.

In particular, this shows that the theory of perfectoid spaces gives new information on the other approaches to changing the characteristic. We note that in the representation theory of local groups, there are Hecke algebra isomorphisms for not-too-ramified types of close local fields, mirroring the Galois story on the automorphic side, cf. [43]. It would be interesting to see if perfectoid spaces can shed new light on these Hecke algebra isomorphisms as well.

8. Rigid Motives: Work of Vezzani

Another way in which perfectoid spaces have been used to study phenomena of changing the characteristic is in relation to Ayoub's category of rigid motives, cf. [5]. Rigid motives are defined by formally repeating some constructions from $\mathbb{A}^1$-homotopy theory, working with the category of smooth rigid-analytic varieties, and replacing $\mathbb{A}^1$ by the closed unit ball. For any nonarchimedean field K and any ring Λ, one gets the resulting category of rigid motives $\mathrm{RigMot}(K, \Lambda)$ with coefficients in Λ.

The following theorem is due to Vezzani:

Theorem 8.1 ([65]). *Let K be a perfectoid field with tilt $K^\flat$. For any $\mathbb{Q}$-algebra Λ, the categories $\mathrm{RigMot}(K, \Lambda) \cong \mathrm{RigMot}(K^\flat, \Lambda)$ are canonically equivalent.*

This can be regarded as a version of the Fontaine-Wintenberger isomorphism for 'rigid motivic Galois groups'. Vezzani's strategy is to compare both categories to categories of 'perfectoid motives' which one gets from (suitable) perfectoid spaces. It is rather formal that these perfectoid motives are equivalent over K and $K^\flat$, and the task becomes to relate these to classical finite-type objects.

9. p-adic Hodge theory

The subject of p-adic Hodge theory can be regarded as a parallel to Deligne's formulation of complex Hodge theory as the interrelationship between the various cohomology theories associated with compact Kähler manifolds. Let us recall the most important results in the complex setting. Fix a compact Kähler manifold X. One has the singular cohomology $H^i(X, \mathbb{Z})$, the de Rham cohomology $H^i_{\mathrm{dR}}(X)$, and the Hodge cohomology groups $H^i(X, \Omega^j_X)$.

Theorem 9.1 (Poincaré lemma). *The inclusion $\mathbb{C} \to \Omega^\bullet_X$ is a quasi-isomorphism of sheaves of complexes. In particular,*

$$H^i(X, \mathbb{Z}) \otimes \mathbb{C} = H^i(X, \mathbb{C}) \cong H^i_{\mathrm{dR}}(X) \, .$$

Theorem 9.2 (Hodge). *The Hodge-to-de Rham spectral sequence*

$$E_1^{ij} = H^j(X, \Omega^i_X) \Rightarrow H^{i+j}_{\mathrm{dR}}(X)$$

degenerates at E_1.

Theorem 9.3 (Hodge). *There is a canonical Hodge decomposition*

$$H^i(X, \mathbb{Z}) \otimes \mathbb{C} = \bigoplus_{j=0}^{i} H^j(X, \Omega^{i-j}_X) \, .$$

Now let C be a complete and algebraically closed extension of $\mathbb{Q}_p$. For example, $C = \mathbb{C}_p$, the completion of $\overline{\mathbb{Q}}_p$. Note that C is perfectoid. Let X be a proper smooth rigid-analytic variety over C. This should be regarded as the analogue of a compact complex manifold, which is not necessarily Kähler. Prior to the author's work on the subject, all work concentrated on the case of algebraic X, but it is shown in [59] that this restriction is not necessary.

Again, one has de Rham and Hodge cohomology groups $H^i_{\mathrm{dR}}(X)$, $H^i(X, \Omega^j_X)$, defined in the same way. What replaces singular cohomology is étale cohomology $H^i_{\text{ét}}(X, \mathbb{Z}_p)$. The following result generalizes a fact well-known for algebraic varieties.

Theorem 9.4 ([59, Theorem 1.1], [60, Theorem 3.17]). *Let X be a proper rigid-analytic variety over C. Then $H^i_{\text{ét}}(X, \mathbb{Z}_p)$ is a finitely generated $\mathbb{Z}_p$-module, which vanishes for $i > 2 \dim X$.*

Properness is crucial here. In fact, already for a closed unit disc, the $\mathbb{F}_p$-cohomology is infinite-dimensional, due to the presence of Artin-Schreier covers. This is in stark contrast with the ℓ-adic case ($\ell \neq p$), where strong finiteness statements are known by work of Berkovich and Huber, [9, 40].

Before explaining the proof of the theorem, recall another result from [59].

Theorem 9.5 ([59, Theorem 1.2]). *Let U be a connected affinoid rigid-analytic variety over C. Then U is a $K(\pi, 1)$ for p-torsion coefficients. In other words, for every p-torsion local system $\mathbb{L}$ on U, the natural map*

$$H^i(X_{\text{ét}}, \mathbb{L}) \to H^i(\pi_1(X, \bar{x}), \mathbb{L}_{\bar{x}})$$

is a bijection, where $\bar{x} \in X(C)$ is a base point, and $\pi_1(X, \bar{x})$ is the profinite étale fundamental group.

There is Artin's theorem on good neighborhoods which states that a smooth algebraic variety in characteristic 0 is locally a $K(\pi, 1)$. It is interesting to note that no smallness or smoothness assumption is necessary for this result in the p-adic world. Let us briefly sketch its proof as this gives a good impression on how perfectoid spaces are used in applications to p-adic Hodge theory. Let $\tilde{U} \to U$ be 'the universal cover of U', which is the inverse limit of all finite étale covers. It is not hard to see that $\tilde{U}$ is an affinoid perfectoid space. Essentially, the existence of enough p-th roots is assured as taking p-th roots is finite étale in characteristic 0. By formal nonsense, it is enough to prove that $H^i(\tilde{U}_{\text{ét}}, \mathbb{F}_p) = 0$ for $i > 0$; we already know that $H^1(\tilde{U}_{\text{ét}}, \mathbb{F}_p) = 0$ as this parametrizes finite étale $\mathbb{F}_p$-torsors, of which there are no more. Thus, we need to prove that $H^i(\tilde{U}_{\text{ét}}, \mathbb{F}_p) = 0$ for $i > 1$.

Lemma 9.6. *Let Y be an affinoid perfectoid space. For $i > 1$, $H^i(Y_{\text{ét}}, \mathbb{F}_p) = 0$.*

Proof. By tilting, we may assume that Y is of characteristic p. Then we have the Artin-Schreier sequence $0 \to \mathbb{F}_p \to \mathcal{O}_Y \to \mathcal{O}_Y \to 0$, and the result follows from vanishing of coherent cohomology: $H^i(Y, \mathcal{O}_Y) = 0$ for $i > 0$. □

Thus, the general idea is to cover X locally by pro-étale maps from perfectoid spaces, and then use qualitative properties of perfectoid spaces, which are verified in characteristic p. For this purpose, one introduces the pro-étale site $X_{\text{proét}}$, in which X is locally perfectoid in a suitable sense.[8]

By resolution of singularities for rigid-analytic varieties, the proof of the finiteness theorem reduces to the proper smooth case; moreover, it is enough to handle the case of $\mathbb{F}_p$-coefficients. In that case, the argument is involved and makes heavy use of the full machinery of perfectoid spaces, cf. [59]. Roughly, it proceeds in two steps. First, one shows that $H^i_{\text{ét}}(X, \mathcal{O}_X^+/p)$ is almost finitely generated. This makes use of the Cartan-Serre technique of shrinking covers, and the almost vanishing of $H^i(Y_{\text{ét}}, \mathcal{O}_Y^+)$ on affinoid perfectoid spaces Y. Then one uses a variant of the Artin-Schreier sequence

$$0 \to \mathbb{F}_p \to \mathcal{O}_X^+/p \to \mathcal{O}_X^+/p \to 0$$

to deduce finiteness of $\mathbb{F}_p$-cohomology. In fact, one gets the following basic comparison result at the same time.

Theorem 9.7 ([59, Theorem 1.3], [60, Theorem 3.17]). *Let X be a proper rigid-analytic variety over C. Then the natural map*

$$H^i(X_{\text{ét}}, \mathbb{F}_p) \otimes \mathcal{O}_C/p \to H^i(X_{\text{ét}}, \mathcal{O}_X^+/p)$$

is an almost isomorphism, i.e. both the kernel and the cokernel are killed by the maximal ideal of $\mathcal{O}_C$.

This is a variant on a result of Faltings, [25, Theorem §3.8]. It forms the basic result which allows one to pass from étale cohomology to coherent cohomology (including here de Rham and Hodge cohomology). Note that the result implies the following remarkable behaviour of $M = R\Gamma(X_{\text{ét}}, \mathcal{O}_X^+)$. After inverting p, $M[p^{-1}] = R\Gamma(X_{\text{ét}}, \mathcal{O}_X) = R\Gamma(X, \mathcal{O}_X)$ is usual coherent cohomology. However, after (derived) modding out p,

$$M/p = R\Gamma(X_{\text{ét}}, \mathcal{O}_X^+/p) \cong_a R\Gamma(X_{\text{ét}}, \mathbb{F}_p) \otimes \mathcal{O}_C/p$$

[8] The idea of the pro-étale site has turned out to be quite powerful for foundational questions, even in the case of schemes. For new foundations for ℓ-adic cohomology of schemes, see [10].

is almost isomorphic to étale cohomology. In particular, $M[p^{-1}]$ lives only in degrees 0 through $\dim X$, while M itself has torsion going up until degree $2\dim X$. It also shows the full strength of the result that $H^i(Y_{\text{ét}}, \mathcal{O}_Y^+)$ is almost zero for $i > 0$, if Y is an affinoid perfectoid space: Certainly, nothing similar is true for a finite type space. It means that all the torsion in the cohomology of $\mathcal{O}_X^+$ gets killed after passing to perfectoid covers. This will be at the heart of the applications to torsion in the cohomology of locally symmetric spaces, cf. Section 15.

Let us now mention the analogues of the theorems in the complex world, stated earlier. For definiteness, we assume here that $X = X_0 \times_k C$ is the base-change of some X_0 defined over a completed discretely valued extension k of $\mathbb{Q}_p$ with perfect residue field. Moreover, we assume that X_0 is proper and smooth.

Theorem 9.8 ([59, Corollary 1.8]). *The G_k-representation $H^i_{\text{ét}}(X, \mathbb{Q}_p)$ is de Rham in the sense of Fontaine, and one has the comparison between étale and de Rham cohomology*

$$H^i_{\text{ét}}(X, \mathbb{Q}_p) \otimes_{\mathbb{Q}_p} B_{\text{dR}} \cong H^i_{\text{dR}}(X_0) \otimes_k B_{\text{dR}} .$$

In particular, $H^i_{\text{dR}}(X_0)$ is the filtered k-vector space associated with the de Rham G_k-representation $H^i_{\text{ét}}(X, \mathbb{Q}_p)$.

This is a known phenomenon in p-adic Hodge theory: To get the comparison theorems, one has to extend scalars to Fontaine's big period rings. Here, we use B_{dR}, which is a complete discrete valuation field with residue field C.

Theorem 9.9 ([59, Corollary 1.8]). *The Hodge-to-de Rham spectral sequence*

$$E_1^{ij} = H^j(X, \Omega_X^i) \Rightarrow H^{i+j}_{\text{dR}}(X)$$

degenerates at E_1.

Note that no Kähler assumption is necessary here. It is interesting to note that some non-Kähler complex manifolds have p-adic analogues, such as the Hopf surface: Divide $\mathbb{A}^2 \setminus \{(0,0)\}$ by the diagonal action of multiplication by q for some $q \in k$ with $|q| < 1$ to get a proper smooth rigid-analytic variety X. This has Hodge numbers $h^{01} = \dim H^0(X, \Omega_X^1) = 0$ while $h^{10} = \dim H^1(X, \mathcal{O}_X) = 1$, so Hodge symmetry fails. However, Hodge-to-de Rham degeneration holds true for the Hopf surface. Fortunately, Iwasawa manifolds for which the Hodge-to-de Rham degeneration fails, do not have p-adic analogues.

The next result does not need a Kähler assumption either:

Theorem 9.10 ([59, Corollary 1.8], [60, Theorem 3.20]). *There is a Hodge-Tate decomposition*

$$H^i_{\text{ét}}(X, \mathbb{Q}_p) \otimes_{\mathbb{Q}_p} C \cong \bigoplus_{j=0}^{i} H^{i-j}(X, \Omega_X^j)(-j) .$$

Here, $(-j)$ denotes a Tate twist. More generally, if X is only defined over C, there is a Hodge-Tate spectral sequence

$$E_2^{ij} = H^i(X, \Omega_X^j)(-j) \Rightarrow H^{i+j}_{\text{ét}}(X, \mathbb{Q}_p) \otimes_{\mathbb{Q}_p} C .$$

It degenerates at E_2 if X is algebraic or defined over k (and probably does in general), giving a Hodge-Tate filtration on $H^i_{\text{ét}}(X, \mathbb{Q}_p) \otimes_{\mathbb{Q}_p} C$ with associated graded pieces $H^{i-j}(X, \Omega_X^j)(-j)$.

Note the interesting differences between the Hodge-Tate spectral sequence and the Hodge-de Rham spectral sequence: It starts at E_2, and i and j are interchanged. Moreover, a Tate twist appears.

10. Relative φ-modules: Work of Kedlaya-Liu

At around the same time that the author wrote [58], Kedlaya-Liu, [47], [48], worked out closely related results[9] with the goal of constructing $\mathbb{Q}_p$-local systems on period domains, as were conjectured by Rapoport-Zink, [55]. Let us briefly recall the conjecture of Rapoport-Zink, in the case of the group GL_n.

Fix a perfect field k of characteristic p, and let V be a k-isocrystal, i.e. a $W(k)[p^{-1}]$-vector space V of finite dimension n equipped with a σ-linear isomorphism $\phi : V \to V$. Moreover, fix a 'filtration type', i.e. for each integer $i \in \mathbb{Z}$ a multiplicity $n_i \geq 0$ such that $n = \sum n_i$. The space of decreasing filtrations $\mathrm{Fil}^\bullet V \subset V$ for which $\mathrm{gr}^i V$ has dimension n_i forms naturally an algebraic variety $\mathcal{F}$ over $W(k)[p^{-1}]$; we consider $\mathcal{F}$ as an adic space over $W(k)[p^{-1}]$.

If $x \in \mathcal{F}(K)$ is a point defined over a finite extension K of $W(k)[p^{-1}]$, then, by a theorem of Colmez-Fontaine, [17], the triple $(V, \phi, \mathrm{Fil}^\bullet)$ comes from a crystalline representation $\mathbb{L}(x)$ of G_K if and only if it is weakly admissible. Weak admissibility is an analogue of a semistability condition, comparing Hodge and Newton slopes. There is a maximal open subspace $\mathcal{F}^{wa} \subset \mathcal{F}$ whose classical points are the weakly admissible points, cf. [55].

Conjecture 10.1. *For any smooth subspace $X \subset \mathcal{F}$ such that the universal filtration restricted to X satisfies Griffiths transversality, there exists a natural open subset $X^a \subset X^{wa} := X \cap \mathcal{F}^{wa}$ with the same classical points, and a $\mathbb{Q}_p$-local system $\mathbb{L}(X)$ on X^a, which gives the G_K-representation $\mathbb{L}(x)$ when passing to the fibre over any $x \in X^a(K)$.*

The original conjecture of Rapoport-Zink was more optimistic in that it conjectured the existence of $\mathbb{L}(X)$ for $X = \mathcal{F}$, and not only on subspaces where Griffiths transversality is satisfied. However, this does not fit with the p-adic Hodge theory formalism. Note that if the filtration is of 'minuscule type', meaning that $n_i \neq 0$ for at most two consecutive i, then Griffiths transversality is satisfied on all of $\mathcal{F}$. This assumption is satisfied in all cases investigated in [55], which are related to p-divisible groups.

Kedlaya announced a proof of this conjecture in [45]. Very roughly, the strategy of Kedlaya-Liu is to construct the local system locally in the pro-étale site and then glue. This reduces the problem to the perfectoid case. Moreover, now one has to construct a $\mathbb{Q}_p$-local system on the perfectoid space, or equivalently its tilt. But in characteristic p, $\mathbb{Q}_p$-local systems can be constructed from φ-modules by Artin-Schreier-Witt theory. Thus, first they build a φ-module over a relative Robba ring. Then they need to show that the locus where this φ-module is pure of slope 0 is open, and that locally on this locus, an integral structure exists. These theorems are proved in [47]; they generalize previous results of Kedlaya on slope filtrations and the existence of integral structures in the absolute setting, [44].

11. Universal covers of p-divisible groups

The following definition of a universal cover arose repeatedly in recent years, cf. e.g. [27], [30]. We identify a formal scheme S with the functor it represents on (discrete) rings, so e.g.

$$(\mathrm{Spf} \varprojlim A/I^n)(R) = \varinjlim \mathrm{Hom}(A/I^n, R) \ .$$

[9] In particular, they proved Corollary 4.14 independently.

By a commutative group G over S, we mean an fqpc sheaf of commutative groups on the category of discrete rings living over S. In other words, for any discrete ring R with an R-valued point $S(R)$, one has a commutative group $G(R)$, satisfying fpqc descent. We are particularly interested in the cases where G is an abelian variety or a p-divisible group.

Definition 11.1. Let S be a formal scheme over $\mathrm{Spf}\,\mathbb{Z}_p$, and let G/S be a commutative group. The universal cover $\tilde{G}$ of G is defined as $\tilde{G} = \varprojlim_{\times p} G$.

For example, if $G = \mathrm{Spf}\, R[[T_1, \ldots, T_d]]$ is a formal p-divisible group over a ring R, then $\tilde{G} \cong \mathrm{Spf}\, R[[T_1^{1/p^\infty}, \ldots, T_d^{1/p^\infty}]]$. In particular, if $R = \mathcal{O}_K$ is the ring of integers in a perfectoid field K, then the generic fibre $\tilde{G}_\eta$ of $\tilde{G}$ is a perfectoid space over K. If $G = \mathbb{G}_a$ is the additive group, then $\tilde{G} = 0$.

For any formal scheme S over $\mathrm{Spf}\,\mathbb{Z}_p$, we may consider the categories of universal covers of abelian varieties, resp. universal covers of p-divisible groups, over S, as full subcategories of the category of commutative groups over S.

Proposition 11.2. *Let $S' \subset S$ be a closed immersion of formal schemes defined by a topologically nilpotent ideal. Then the categories of universal covers of abelian varieties (resp. p-divisible groups) over S and S' are equivalent.*

Thus, the universal cover may be considered as a crystal on the infinitesimal site. In particular, let us fix an abelian variety or a p-divisible group G_0 over a perfect field k of characteristic p, of height h. It has a universal deformation space $S \cong \mathrm{Spf}\, W(k)[[T_1, \ldots, T_k]]$ (cf. [41]), and a universal deformation G/S. However, the universal cover $\tilde{G}$ is constant, equal to the evaluation of the crystal $\tilde{G}_0$ on the thickening $S \to \mathrm{Spec}\, k$.

Note that inside $\tilde{G}$ one has the Tate module $T_pG = \ker(\tilde{G} \to G) = \varprojlim_{\times p} G[p^n]$. If one fixes a C-valued point of the generic fibre of S, where C is an algebraically closed complete extension of $W(k)[p^{-1}]$, then $\Lambda = (T_pG)(\mathcal{O}_C) \cong \mathbb{Z}_p^h \subset \tilde{G}(\mathcal{O}_C)$ is a $\mathbb{Z}_p$-lattice. Informally, one gets back $G = \tilde{G}/T_pG$ by quotienting $\tilde{G}$ by this $\mathbb{Z}_p$-lattice. Here, $\tilde{G}$ is independent of the chosen point, but the $\mathbb{Z}_p$-lattice varies. This is reminiscent of the complex uniformization of abelian varieties: Their universal cover is constant, and different abelian varieties correspond to different $\mathbb{Z}$-lattices in the universal cover. Riemann's theorem gives a condition on when the quotient exists as an algebraic variety in terms of the existence of a polarization.

The following theorem is proved in joint work with Weinstein. We refer the reader to [62] for a more detailed discussion of this result.[10]

Theorem 11.3 ([62, Theorem D]). *Fix a p-divisible group G_0 over a perfect field k of height h and dimension d, as well as a complete and algebraically closed extension C of $W(k)[p^{-1}]$. Consider the category of lifts (G, ρ) of G_0 to $\mathcal{O}_C$ up to quasi-isogeny: Here, $G/\mathcal{O}_C$ is a p-divisible group, and $\rho : G_0 \times_k \mathcal{O}_C/p \to G \times_{\mathcal{O}_C} \mathcal{O}_C/p$ is a quasi-isogeny. Then the category of lifts (G, ρ) is equivalent to the category of $\mathbb{Z}_p$-lattices $\Lambda \cong \mathbb{Z}_p^h \subset \tilde{G}_0(\mathcal{O}_C)$ for which there exists a (necessarily unique) $h - d$-dimensional subspace $W \subset M(G_0)(\mathcal{O}_C)[p^{-1}] \cong C^h$ such that the image of Λ under the quasi-logarithm map*

$$\mathrm{qlog} : \tilde{G}_0(\mathcal{O}_C) \to M(G_0)(\mathcal{O}_C)[p^{-1}]$$

[10] One may deduce a similar result for abelian varieties by using Serre-Tate theory if one incorporates a polarization to guarantee algebraization.

lies in W, and

$$0 \to \Lambda[p^{-1}] \to \tilde{G}_0(\mathcal{O}_C) \to C^h/W \to 0$$

is exact.

This gives one analogue of Riemann's theorem on the classification of complex abelian varieties. The following theorem, again proved in joint work with Weinstein, [62], and closely related to the previous theorem, gives a different such analogue. For this, we use that any p-divisible group G over $\mathcal{O}_C$ has a Hodge-Tate filtration

$$0 \to (\operatorname{Lie} G) \otimes_{\mathcal{O}_C} C(1) \to T_p G \otimes_{\mathbb{Z}_p} C \to (\operatorname{Lie} G^*)^* \otimes_{\mathcal{O}_C} C \to 0\,,$$

which is an analogue of the Hodge-Tate filtration defined above for proper smooth varieties over C, cf. Theorem 9.10. This Hodge-Tate filtration for p-divisible groups was known previously, and is due to Faltings, [24], cf. also Fargues, [28].

Theorem 11.4 ([62, Theorem B]). *The category of p-divisible groups over $\mathcal{O}_C$ is equivalent to the category of pairs (Λ, W) where Λ is a finite free $\mathbb{Z}_p$-module, and $W \subset \Lambda \otimes_{\mathbb{Z}_p} C$ is a C-subvectorspace.*

The functor is given by $G \mapsto (T_p G, \operatorname{Lie} G \otimes_{\mathcal{O}_C} C(1))$. This is analogous to the classification of complex abelian varieties by their first singular homology, together with the Hodge filtration.

12. Lubin-Tate spaces: Work of Weinstein

Weinstein has observed that the Lubin-Tate tower at infinite level carries a natural structure as a perfectoid space. For this, fix an integer $n \geq 1$ and a p-divisible group G_0 of dimension 1 and height n. The Lubin-Tate tower at infinite level $\mathcal{M}_{G_0,\infty}$ parametrizes triples (G, ρ, α) where (G, ρ) is a deformation of G_0 up to quasi-isogeny as before, and $\alpha : \mathbb{Z}_p^n \to T_p G$ is an infinite level structure.

One may define a p-divisible group $\bigwedge G_0$ of G_0 of dimension 1 and height 1 by taking the highest exterior power of the Dieudonné module $M(G_0)$, and passing back to p-divisible groups. This uses crucially that G_0 is of dimension 1. One may construct an alternating map

$$\det : \tilde{G}_0 \otimes \ldots \otimes \tilde{G}_0 \to \widetilde{\bigwedge G_0}\,.$$

This follows from the work of Hedayatzadeh, [36], or from a result in Dieudonné theory in the joint work with Weinstein, [62]. Fix a perfectoid field K; then this gives a similar map on the generic fibre, base-changed to K:

$$\det : \tilde{G}_{0,K} \otimes \ldots \otimes \tilde{G}_{0,K} \to \widetilde{\bigwedge G_0}_K\,.$$

Inside $\widetilde{\bigwedge G_0}_K$, one has the rational Tate module $V_p(\bigwedge G_0) \subset \widetilde{\bigwedge G_0}_K$ and an exact sequence

$$0 \to V_p(\bigwedge G_0) \to \widetilde{\bigwedge G_0}_K \xrightarrow{\log} \mathbb{G}_{a,K} \to 0\,.$$

The following theorem is easy to deduce from Theorem 11.3, but was proved earlier directly by Weinstein.

Theorem 12.1 (Weinstein). *The following diagram is cartesian:*

$$\begin{array}{ccc} \mathcal{M}_{G_0,\infty} & \hookrightarrow & \left(\tilde{G}_{0,K}\right)^n \\ \downarrow & & \downarrow \det \\ V_p(\bigwedge G_0) \setminus \{0\} & \hookrightarrow & \widetilde{\bigwedge G_0}_K \end{array}$$

All intervening objects are perfectoid spaces over K, and the inclusions are locally closed (i.e., open subsets of Zariski closed subsets).

All objects in this diagram can be made completely explicit. Weinstein has used this to find explicit affinoid perfectoid subsets of $\mathcal{M}_{G_0,\infty}$ whose cohomology realizes the local Langlands correspondence for specific supercuspidal representations, cf. [12]. Recall that it is known (by the work of Harris-Taylor, [34]) that the cohomology of $\mathcal{M}_{G_0,\infty}$ realizes the local Langlands correspondence for all supercuspidal representations of $\mathrm{GL}_n(\mathbb{Q}_p)$. It is remarkable that while at any finite level, one cannot give an explicit description of the Lubin-Tate tower, it is possible to describe $\mathcal{M}_{G_0,\infty}$, together with all group actions, explicitly.

In [62], it is proved that more general Rapoport-Zink spaces become perfectoid at infinite level, and a description purely in terms of p-adic Hodge theory is given. This made it possible to prove the duality isomorphism for basic Rapoport-Zink spaces. In particular, one gets that Drinfeld and Lubin-Tate tower are isomorphic at infinite level as perfectoid spaces. This improves on earlier results of Faltings, [26], and Fargues, [28], who proved such isomorphisms, but had to struggle with formalizing them, as no category was known in which both infinite level spaces lived a priori. Their method is to work with suitable formal models; for this, new formal models have to be constructed first, which is at least technically challenging.

It was recently suggested by Rapoport-Viehmann, [53], that there should exist a theory of 'local Shimura varieties', which should relate to Rapoport-Zink spaces in the same way that general Shimura varieties relate to Shimura varieties of PEL type. The new perspective on Rapoport-Zink spaces mentioned above should make it possible to prove (parts of) their conjectures.

13. p-adic cohomology of the Lubin-Tate tower

The Lubin-Tate tower plays an important role in the Langlands program because its ℓ-adic cohomology for $\ell \neq p$ realizes the local Langlands correspondence, cf. [34]. In the emerging p-adic local Langlands program, which has taken a definitive form only for $\mathrm{GL}_2(\mathbb{Q}_p)$, cf. [13], one hopes for a similar realization of the p-adic local Langlands correspondence. However, the $\mathbb{F}_p$-cohomology of the Lubin-Tate tower is too infinite due to the presence of many Artin-Schreier covers. Still, a variant of Theorem 9.4 holds true in this context; for simplicity, we state only the version with $\mathbb{F}_p$-coefficients; a similar result holds true with $\mathbb{Z}_p$-coefficients.

Let F be a finite extension of $\mathbb{Q}_p$. Fix an admissible $\mathbb{F}_p$-representation π of $\mathrm{GL}_n(F)$. Using the Lubin-Tate tower at infinite level, which is a $\mathrm{GL}_n(F)$-torsor over $\mathbb{P}^{n-1}_{\breve{F}}$, where $\breve{F}$ denotes the completion of the maximal unramified extension of F, one gets an étale sheaf $\mathcal{F}_\pi$ on $\mathbb{P}^{n-1}_{\breve{F}}$. It is naturally $D^\times$-equivariant, and equipped with a Weil descent datum. Here, D is

the division algebra of invariant $1/n$ over F. The following theorem is work in progress of the author, and relies on the techniques of the proof of Theorem 9.4 along with the duality between Lubin-Tate and Drinfeld tower.

Theorem 13.1. *Let $C/\breve{F}$ be complete and algebraically closed. Then $H^i(\mathbb{P}^{n-1}_C, \mathcal{F}_\pi)$ is an admissible $D^\times$-representation, which vanishes for $i > 2(n-1)$, and is independent of C. The resulting functor from admissible $\mathrm{GL}_n(F)$-representations to admissible $D^\times \times G_F$-representations is compatible with some global correspondences.*

This makes it possible to pass from $\mathrm{GL}_n(F)$-representations to Galois representations in a purely local way. In the global setup, it proves that the $\mathrm{GL}_n(F)$-representation determines the local Galois group representation.

14. Shimura varieties

Fix a reductive group G over $\mathbb{Q}$ with a Shimura datum of Hodge type, giving rise to a Shimura variety S_K, $K \subset G(\mathbb{A}_f)$, over the reflex field E. There is a Hecke-equivariant compactification S^*_K, finite under the minimal compactification $S^*_K \to S^*_K$, and a flag variety $\mathcal{F}$ with G-action, such that the following are true.[11]

Theorem 14.1. *Fix a tame level $K^p \subset G(\mathbb{A}_f^p)$ and a map $E \to C$ to a complete and algebraically closed extension C of $\mathbb{Q}_p$. Let $(S^*_K)^{\mathrm{ad}}$ denote the adic space associated with $S^*_K \otimes_E C$. Then there is a perfectoid space $S^*_{K^p}$ over C such that*

$$S^*_{K^p} \sim \varprojlim_{K_p} (S^*_{K_pK^p})^{\mathrm{ad}} .$$

Moreover, there is a $G(\mathbb{Q}_p)$-equivariant Hodge-Tate period map

$$\pi_{\mathrm{HT}} : S^*_{K^p} \to \mathcal{F} .$$

The map π_{HT} is equivariant for the Hecke operators prime to p with respect to the trivial action on $\mathcal{F}$; in particular, π_{HT} contracts $G(\mathbb{A}_f^p)$-orbits. There is a cover of $\mathcal{F}$ by affinoid subsets $U \subset \mathcal{F}$ for which $\pi^{-1}_{\mathrm{HT}}(U) \subset S^*_{K^p}$ is an affinoid perfectoid subset.

The geometry of π_{HT} is very interesting. Consider the case of the modular curve. Here, $\mathcal{F} = \mathbb{P}^1$, and π_{HT} is a p-adic analogue of the embedding of the complex upper half-plane (which is a path-connected component of the inverse limit over all levels $\varprojlim_K S_K(\mathbb{C})$) into $\mathbb{P}^1(\mathbb{C})$. In both cases, the map is given by the Hodge filtration.

In the case of the modular curve, $S^*_{K^p} = S^*_{K^p}$ has a stratification into the ordinary and the supersingular locus, $S^{\mathrm{ord}}_{K^p}$ and $S^{\mathrm{ss}}_{K^p}$.[12] The flag variety is $\mathcal{F} = \mathbb{P}^1$. Then, under π_{HT}, all of $S^{\mathrm{ord}}_{K^p}$ maps into $\mathbb{P}^1(\mathbb{Q}_p)$, while the supersingular locus $S^{\mathrm{ss}}_{K^p}$ maps into Ω^2. Here, $\Omega^2 = \mathbb{P}^1 \setminus \mathbb{P}^1(\mathbb{Q}_p)$ is Drinfeld's upper half-plane, which is reminiscent of the complex upper and lower half-plane, which can be written as $\mathbb{P}^1 \setminus \mathbb{P}^1(\mathbb{R})$. It follows that π_{HT} contracts

[11] It should be possible to use the minimal compactification itself, and make $\mathcal{F}$ more explicit, but so far this has not been worked out.

[12] We regard some points of the adic space corresponding to rank-2-valuations as part of the ordinary locus which would usually be considered as part of the supersingular locus. We do so by replacing the ordinary part by its closure.

connected components of the ordinary locus to points, whereas it does something interesting on the supersingular locus.

On the ordinary locus, the map is given by the position of the canonical subgroup. On the supersingular locus, $S^{\mathrm{ss}}_{K^p}$ is a finite disjoint union of Lubin-Tate towers at infinite level (for $n = 2$); these are isomorphic to the Drinfeld tower at infinite level, which is a pro-finite étale cover of Ω^2. The composite is π_{HT}. In particular, the isomorphism between Lubin-Tate and Drinfeld tower is built into the geometry of π_{HT}.

Let us note another perspective on what the Hodge-Tate period map does. Namely, by Theorem 11.4, giving the Hodge filtration is equivalent to giving the p-divisible group. This means that the Hodge-Tate period map, on geometric points of the good reduction locus, is the map sending an abelian variety to its p-divisible group (equipped with all extra structure).

15. Torsion cohomology of locally symmetric spaces

As the final topic, we summarize the application of these ideas to the study of torsion in the cohomology of locally symmetric spaces.

Fix a reductive group G over $\mathbb{Q}$. For any (sufficiently small) compact open subgroup $K \subset G(\mathbb{A}_f)$, one has the locally symmetric space

$$Y_K = G(\mathbb{Q})\backslash (G(\mathbb{R})/K_\infty A^\circ_\infty \times G(\mathbb{A}_f)/K) \ ,$$

where $K_\infty \subset G(\mathbb{R})$ is a maximal compact subgroup, and $A_\infty \subset G(\mathbb{R})$ are the $\mathbb{R}$-valued points of the maximal $\mathbb{Q}$-split central torus, with identity component A°_∞. Fixing a tame level $K^p \subset G(\mathbb{A}_f^p)$, one defines the completed cohomology groups

$$\tilde{H}^i(K^p) = \varprojlim_n \varinjlim_{K_p} H^i(Y_{K_pK^p}, \mathbb{Z}/p^n\mathbb{Z}) \ , \tilde{H}^i_c(K^p) = \varprojlim_n \varinjlim_{K_p} H^i_c(Y_{K_pK^p}, \mathbb{Z}/p^n\mathbb{Z}) \ .$$

Also recall the cohomological degree q_0, which is 'the first interesting cohomological degree' (namely, the first one to which tempered automorphic representations of G contribute). The following conjecture was proposed by Calegari and Emerton, [14].

Conjecture 15.1. *The groups $\tilde{H}^i(K^p)$, $\tilde{H}^i_c(K^p)$ vanish for $i > q_0$.*

Concretely, this means that all cohomology classes in higher degree become infinitely p-divisible as one goes up along all levels at p. If G is a torus, the conjecture is equivalent to Leopoldt's conjecture. On the other hand, we proved the following theorem.

Theorem 15.2 ([61, Theorem I.7]). *Assume that G gives rise to a Shimura variety, so that q_0 is the (complex) dimension of the associated Shimura variety. Then Conjecture 15.1 holds true for compactly supported cohomology.*

If one establishes that also toroidal compactifications become perfectoid at infinite level, then one gets the same result for usual cohomology. Unfortunately, for all tori which give rise to Shimura varieties, the Leopoldt conjecture is trivially satisfied, as the group of units is finite.

The key to the proof is to translate everything into the setting of Shimura varieties at infinite level as perfectoid spaces. In that case, one can use the basic comparison theorem to

pass to the cohomology of $\mathcal{O}^+/p$. But at infinite level, one has almost vanishing of higher cohomology of $\mathcal{O}^+/p$ on affinoids as the space is perfectoid. This shows vanishing above the middle dimension, which is exactly the desired statement.

In fact, the same argument proves the following theorem over $\mathbb{C}$, which the author does not know how to prove directly.

Theorem 15.3. *Let $X \subset \mathbb{P}^n_{\mathbb{C}}$ be a closed subvariety of dimension d. For any $m \geq 0$, let $X_m \subset \mathbb{P}^n_{\mathbb{C}}$ be the pullback of X under the map $\mathbb{P}^n_{\mathbb{C}} \to \mathbb{P}^n_{\mathbb{C}}$ sending $(x_0 : \ldots : x_n)$ to $(x_0^{p^m} : \ldots : x_n^{p^m})$. Then, for any $i > d$,*

$$\varinjlim_m H^i(X_m, \mathbb{F}_p) = 0 \, .$$

For classes in the image of cup product with $c_1(\mathcal{O}(1))$, this follows from the fact that $c_1(\mathcal{O}(1))$ becomes infinitely p-divisible. By hard Lefschetz, this accounts for everything rationally, but it does not say anything about possible p-torsion in the cohomology.

16. Galois representations

It was conjectured since the 1970's by Grunewald that torsion in the cohomology of locally symmetric spaces gives rise to Galois representations. This conjecture was made precise by Ash, [2], and is a 'mod p analogue' of (one direction of) the global Langlands conjectures. Since then, it was numerically verified in many cases: what happens is that a Hecke eigenvalue system matches Frobenius eigenvalues of a Galois representations for the first few hundred primes. However, even in these examples, one could not prove that this happens for *all* primes.

Theorem 16.1 ([61, Theorem I.3]). *Let G be the restriction of scalars of GL_n from a totally real or CM field F. Fix any compact open subgroup $K \subset G(\mathbb{A}_f)$. Then, for any system of Hecke eigenvalues ψ appearing in $H^i(Y_K, \overline{\mathbb{F}}_p)$, there exists a (unique) continuous semisimple Galois representation*

$$\rho_\psi : G_F \to \mathrm{GL}_n(\overline{\mathbb{F}}_p)$$

such that for all but an explicit finite set of 'ramified' places v of F, the characteristic polynomial of $\rho_\psi(\mathrm{Frob}_v)$ is described by the Hecke eigenvalues.

Moreover, there is a version of this theorem for $\mathbb{Z}/p^n\mathbb{Z}$-cohomology, which in the inverse limit over n gives results for classical automorphic representations. The following result was proved earlier by Harris-Lan-Taylor-Thorne, [33], by a different method.

Theorem 16.2 ([61, Theorem I.4]). *Let π be a regular algebraic cuspidal automorphic representation of $\mathrm{GL}_n(\mathbb{A}_F)$, where F is totally real or CM. Fix an isomorphism $\mathbb{C} \cong \overline{\mathbb{Q}}_p$. Then there exists a unique continuous semisimple Galois representation*

$$\rho_{\pi,p} : G_F \to \mathrm{GL}_n(\overline{\mathbb{Q}}_p)$$

such that for all but an explicit finite set of 'ramified' places v of F, the characteristic polynomial of $\rho_{\pi,p}(\mathrm{Frob}_v)$ is described by the Satake parameters.

It should be noted that in general, the cohomology of the spaces Y_K has a lot of torsion. The simplest example is the case of GL_2 over an imaginary-quadratic field in which the relevant Y_K are hyperbolic 3-manifolds. In that case, computations, as well as theoretical results, show a huge amount of torsion, cf. e.g. [7]. Therefore, the thrust of the above theorem lies in the p-torsion part of the cohomology. Moreover, recent work of Calegari-Geraghty, [15], explains how one may use sufficiently fine information about existence of Galois representations for torsion classes to prove automorphy lifting theorems for GL_n over F. Together with the strong potential automorphy machinery as in the work of Barnet-Lamb–Gee–Geraghty–Taylor, [6], this gives some hope that one can establish some potential converse results to Theorem 16.2.

Let us sketch the proof of Theorem 16.1 in the case $F = \mathbb{Q}$. Consider the Siegel moduli space S_K, $K \subset \mathrm{GSp}_{2n}(\mathbb{A}_f)$, of principally polarized abelian varieties of dimension n. From the Borel-Serre compactification, [11], it follows that the cohomology of the locally symmetric space for GL_n contributes to the cohomology of the Siegel moduli space. Note that the Borel-Serre compactification is a compactification as a real manifold with corners; this makes it possible that a purely real manifold appears in the boundary of the algebraic variety S_K. Thus, the task becomes to understand torsion in the cohomology of S_K.

Theorem 16.3 ([61, Theorem I.5]). *Let S_K, $K \subset G(\mathbb{A}_f)$, be any Shimura variety of Hodge type. Then, for any system of Hecke eigenvalues ψ appearing in $H^i_c(S_{K,\mathbb{C}}, \overline{\mathbb{F}}_p)$, there exists a cuspidal eigenform f (possibly of larger level at p, and undetermined weight) such that the Hecke eigenvalues of f are congruent to ψ modulo p.*

This produces congruences between torsion classes and classical cusp forms in large generality. Note that the classes in which we are interested start life as classes coming from the boundary; still, the theorem produces congruences to cusp forms. In particular, for non-torsion classes, it is interesting as it produces congruences between Eisenstein series and cusp forms. However, in the complementary case where S_K is proper, the theorem is also interesting as it controls all possible torsion classes. For example, it proves the existence of Galois representations for all torsion classes in $U(1, n-1)$-Shimura varieties, which is required in recent work of Emerton and Gee, [22]. The point is that one knows how to attach Galois representations to cusp forms in great generality, through the work on automorphic forms on classical groups by Arthur [3] (cf. also [51] for unitary groups) and the work of Clozel, Kottwitz and Harris-Taylor among others on the cohomology of Shimura varieties, [16, 34, 50].

To prove the theorem, one starts by using the basic comparison theorem

$$H^i_{c,\text{ét}}(S_{K,C}, \mathbb{F}_p) \otimes \mathcal{O}_C/p \cong_a H^i_{\text{ét}}(S^*_{K,C}, I^+/p)\ ,$$

where $I^+ \subset \mathcal{O}^+$ is the ideal sheaf of functions vanishing at the boundary. This variant of Theorem 9.7 is proved in [60, Theorem 3.13]. This provides a first bridge to the sheaf of cusp forms I^+, but one still has to compute cohomology on the étale site. Next, one passes to infinite level at p, and reduces to controlling $H^i_{\text{ét}}(S^*_{\overline{K}^p}, I^+/p)$. Here, $S^*_{\overline{K}^p}$ is perfectoid, so we know that $H^i_{\text{ét}}(U, I^+/p)$ is almost zero for $i > 0$ and affinoid perfectoid subsets $U \subset S^*_{\overline{K}^p}$; this is a slight variant on Theorem 4.12. This means that $H^i_{\text{ét}}(S^*_{\overline{K}^p}, I^+/p)$ can (almost) be computed by a Cech complex whose terms are the sections of I^+/p on affinoid subsets. The remaining task is to approximate these forms on U by globally defined forms (of finite level), without messing up the Hecke eigenvalues. Usually, the strategy is to multiply by a multiple

of the Hasse invariant. This kills all poles away from the ordinary locus, and works if U is the ordinary locus. However, in our case we need to do the same for a covering of all of $S^*_{\overline{K}^p}$.

The crucial property of the Hasse invariant is that it commutes with all Hecke operators prime to p. In our setup, we can use the following construction: As

$$\pi_{\mathrm{HT}} : S^*_{\overline{K}^p} \to \mathcal{F}$$

is equivariant with respect to the trivial action of the Hecke operators prime to p on $\mathcal{F}$, any function that gets pulled back from $\mathcal{F}$ will commute with all Hecke operators prime to p. The same stays true for sections of automorphic vector bundles; automorphic vector bundles come via pullback from $\mathcal{F}$.[13] In this way, one gets enough 'fake-Hasse invariants' to proceed, and prove the result.

Acknowledgements. This work was done while the author was a Clay Research Fellow.

Stabilisation de la partie géométrique de la formule des traces tordue

J.-L. Waldspurger *

Résumé. We explain what is twisted endoscopy. We give the formulation of the geometric part of the twisted trace formula, following the works of Clozel-Labesse-Langlands and Arthur. We explain his stabilization, which is a work in progress, joint with Moeglin.

Mathematics Subject Classification (2010). AMS 11F72, 20G35, 22E30, 22E35.

Keywords. twisted endoscopy, twisted trace formula.

1. Introduction

Langlands a posé des conjectures qui classifient les représentations automorphes d'un groupe réductif connexe défini sur un corps de nombres. La forme fine de ces conjectures requiert l'usage de la théorie de l'endoscopie, elle-aussi imaginée par Langlands. En retour, cette théorie permet d'établir dans certains cas très particuliers l'existence prédite par les conjectures de correspondances entre représentations automorphes sur différents groupes. La méthode passe par la "stabilisation de la formule des traces d'Arthur-Selberg", cette formule étant l'un des outils les plus puissants de la théorie des formes automorphes. Cette stabilisation a été établie par Arthur [1–3]. Depuis les travaux de Langlands puis d'Arthur et Clozel sur le changement de base ([9, 16]), on sait qu'il est utile d'étendre la formule des traces comme la théorie de l'endoscopie à une situation "tordue", c'est-à-dire où le groupe est muni d'un automorphisme (il revient plus ou moins au même de considérer un groupe non connexe). Arthur a tiré des applications spectaculaires de cette théorie appliquée à un groupe $GL(n)$ tordu par un automorphisme extérieur non trivial, cf. [4]. Dans le cadre tordu, la formule des traces a été établie par Clozel, Labesse et Langlands et développée par Arthur. Kottwitz, Labesse et Shelstad ont élaboré après Langlands la théorie de l'endoscopie tordue. Dans un travail en voie d'achèvement, en collaboration avec Moeglin, nous stabilisons la formule des traces tordue, en suivant la méthode d'Arthur. Dans la section 2, je tente d'expliquer ce qu'est l'endoscopie tordue sur un corps de base local et j'énonce les résultats de stabilisation locaux concernant les intégrales orbitales. Dans la section 3, le corps de base devient un corps de nombres. Je décris la partie géométrique de la formule des traces tordue et j'explique sa stabilisation. Comme je l'ai dit, ce travail n'est pas encore complètement achevé et reste encore soumis à une hypothèse, à savoir la validité du lemme fondamental pour toutes les fonctions de l'algèbre de Hecke. Ngô Bao Chau a démontré ce lemme pour la fonction unité de cette algèbre [17]. Sa généralisation ne fait pas de doute et est certainement incomparablement plus facile que le théorème de Ngô Bao Chau.

2. La théorie locale

Cette section s'appuie sur les articles [11, 13, 14, 18]. On a donné une présentation plus personnelle de la théorie dans [19].

2.1. Espaces tordus. Soient F un corps local de caractéristique nulle et $\bar{F}$ une clôture algébrique de F. On pose $\Gamma_F = Gal(\bar{F}/F)$ et on note W_F le groupe de Weil de F. Soient G un groupe réductif connexe défini sur F et $\tilde{G}$ un espace tordu sous G. Cela signifie que $\tilde{G}$ est une variété algébrique sur F muni de deux actions de G

$$\begin{array}{ccc} G\times\tilde{G}\times G & \to & \tilde{G} \\ (g,\gamma,g') & \mapsto & g\gamma g' \end{array}$$

définies sur F, de sorte que, pour tout $\gamma\in\tilde{G}$, les applications $g\mapsto g\gamma$ et $g'\mapsto\gamma g'$ soient bijectives. Pour $\gamma\in\tilde{G}$, on note ad_γ l'automorphisme de G tel que $\gamma g' = ad_\gamma(g')\gamma$ pour tout $g'\in G$. Notons θ la restriction de ad_γ au centre $Z(G)$ de G. Elle ne dépend pas de l'élément $\gamma\in\tilde{G}$. On impose les deux conditions :

$\tilde{G}(F)\neq\emptyset$ et l'automorphisme θ de $Z(G)$ est d'ordre fini.

Outre les données G et $\tilde{G}$, on fixe un caractère ω de $G(F)$, c'est-à-dire un homomorphisme continu $\omega : G(F)\to\mathbb{C}^\times$.

Pour $\gamma\in\tilde{G}$, on note $Z_G(\gamma)$ l'ensemble de points fixes de ad_γ et G_γ la composante neutre de ce groupe. Une paire de Borel de G est un couple (B,T), où B est un sous-groupe de Borel de G et T est un sous-tore maximal de B (on ne suppose pas B et T définis sur F). Un élément $\gamma\in\tilde{G}$ est dit semi-simple s'il existe une paire de Borel (B,T) de G qui est conservée par ad_γ. Tout élément $\gamma\in\tilde{G}$ s'écrit de façon unique comme produit $\gamma = u\gamma_{ss}$ où γ_{ss} est semi-simple et u est un élément unipotent de $G_{\gamma_{ss}}$. On dit que γ est fortement régulier s'il est semi-simple et si $Z_G(\gamma)$ est commutatif.

On dit que G est quasi-déployé s'il existe une paire de Borel (B,T) définie sur F. On dit que $\tilde{G}$ est à torsion intérieure si ad_γ est un automorphisme intérieur de G pour tout $\gamma\in\tilde{G}$ (ou pour un $\gamma\in\tilde{G}$, c'est équivalent). Un tel espace tordu à torsion intérieure est isomorphe à G sur $\bar{F}$ mais pas forcément sur F. Par exemple, on peut avoir $G = SL(n)$ et $\tilde{G} = \{g\in GL(n); det(g) = d\}$, où d est un élément fixé de $F^\times$. Dans ce cas, $\tilde{G}$ est isomorphe à G sur F si et seulement si d est la puissance n-ième d'un élément de $F^\times$.

2.2. Intégrales orbitales. On note $C_c^\infty(\tilde{G}(F))$ l'espace des fonctions $f:\tilde{G}(F)\to\mathbb{C}$ dont le support est compact et qui sont lisses, c'est-à-dire localement constantes si F est non-archimédien, C^∞ si F est archimédien. Pour tout groupe réductif H défini sur F, on note par la lettre gothique $\mathfrak{h}$ son algèbre de Lie. Soit $\gamma\in\tilde{G}(F)$. Notons γ_{ss} sa partie semi-simple, posons

$$D^{\tilde{G}}(\gamma) = |det(1-ad_{\gamma_{ss}})_{|\mathfrak{g}/\mathfrak{g}_{\gamma_{ss}}}|_F,$$

où $|.|_F$ est la valeur absolue usuelle de F. Fixons des mesures de Haar sur $G(F)$ et $G_\gamma(F)$. Soit $f\in C_c^\infty(\tilde{G}(F))$. Si ω n'est pas trivial sur $G_\gamma(F)$, on pose $I^{\tilde{G}}(\gamma,\omega,f) = 0$. Si ω est trivial sur $G_\gamma(F)$, on pose

$$I^{\tilde{G}}(\gamma,\omega,f) = D^{\tilde{G}}(\gamma)^{1/2}\int_{G_\gamma(F)\backslash G(F)}\omega(g)f(g^{-1}\gamma g)\,dg.$$

On note $I(\tilde{G}(F),\omega)$ le quotient de $C_c^\infty(\tilde{G}(F))$ par le sous-espace des fonctions f telles que $I^{\tilde{G}}(\gamma,\omega,f)=0$ pour tout $\gamma\in\tilde{G}(F)$.

Supposons G quasi-déployé, $\tilde{G}$ à torsion intérieure et $\omega=1$. On supprime ω des notations. Soit γ un élément semi-simple fortement régulier de $\tilde{G}(F)$. La classe de conjugaison stable de γ est l'ensemble des $\gamma'\in\tilde{G}(F)$ tels qu'il existe $g\in G(\bar{F})$ de sorte que $\gamma'=g^{-1}\gamma g$. En général, cette classe est plus grosse que la classe de conjugaison de γ par $G(F)$: l'exemple simple $G=\tilde{G}=SL(2)$ permet de s'en convaincre. Fixons des mesures de Haar sur $G(F)$ et $G_\gamma(F)$. Pour γ' stablement conjugué à γ, les tores G_γ et $G_{\gamma'}$ sont isomorphes et la mesure sur $G_\gamma(F)$ en détermine une sur $G_{\gamma'}(F)$. Pour $f\in C_c^\infty(\tilde{G}(F))$, on pose

$$S^{\tilde{G}}(\gamma,f)=\sum_{\gamma'}I^{\tilde{G}}(\gamma',f),$$

où γ' parcourt un ensemble de représentants des classes de conjugaison par $G(F)$ dans la classe de conjugaison stable de γ. On note $SI(\tilde{G}(F))$ le quotient de $C_c^\infty(\tilde{G}(F))$ par le sous-espace des f telles que $S^{\tilde{G}}(\gamma,f)=0$ pour tout γ comme ci-dessus. C'est un quotient de $I(\tilde{G}(F))$.

Revenons au cas général. L'analyse harmonique ω-équivariante est l'étude de l'espace $I(\tilde{G}(F),\omega)$. Les travaux de ces dernières décennies sur la formule des traces ont mis en évidence l'importance plus fondamentale des espaces $SI(\tilde{G}(F))$ du cas particulier ci-dessus. La théorie de l'endoscopie tordue affirme en substance qu'étudier l'espace $I(\tilde{G}(F),\omega)$ revient à étudier les espaces $SI(\tilde{G}'_i(F))$, où $(G'_i,\tilde{G}'_i)_{i=1,\dots,n}$ est une certaine famille finie de couples déduits de $(G,\tilde{G},\omega)$ et vérifiant les hypothèses plus simples ci-dessus. Nous développerons les constructions de cette théorie dans les paragraphes suivants.

2.3. *L*-groupes. Une paire de Borel épinglée est un triplet $\mathcal{E}=(B,T,(E_\alpha)_{\alpha\in\Delta})$, où (B,T) est une paire de Borel, Δ est l'ensemble des racines simples de T dans l'algèbre de Lie $\mathfrak{u}$ du radical unipotent de B et, pour tout $\alpha\in\Delta$, E_α est un élément non nul de la droite radicielle $\mathfrak{u}_\alpha\subset\mathfrak{u}$ associée à α. Deux paires de Borel (resp. épinglées) de G sont conjuguées par un élément de G. Fixons une paire de Borel (B,T). On définit une action "quasi-déployée" de Γ_F sur T de la façon suivante. Pour tout $\sigma\in\Gamma_F$, fixons $g(\sigma)\in G$ tel que $ad_{g(\sigma)}\circ\sigma(B,T)=(B,T)$ (pour $g\in G$, ad_g est l'automorphisme $x\mapsto gxg^{-1}$ de G). On note σ_{G^*} l'automorphisme $ad_{g(\sigma)}\circ\sigma$ de T. Il ne dépend pas du choix de $g(\sigma)$ et $\sigma\mapsto\sigma_{G^*}$ est l'action cherchée. Il y a aussi un automorphisme θ de T ainsi défini : on choisit $\gamma\in\tilde{G}$ tel que ad_γ conserve (B,T) (il existe de tels γ) ; alors θ est la restriction de ad_γ à T, laquelle ne dépend pas du choix de γ.

Un groupe dual de G est un groupe réductif connexe $\hat{G}$ sur $\mathbb{C}$, muni d'une paire de Borel épinglée $\hat{\mathcal{E}}=(\hat{B},\hat{T},(\hat{E}_{\hat{\alpha}})_{\hat{\alpha}\in\hat{\Delta}})$ et d'une action algébrique de Γ_F satisfaisant aux conditions suivantes. L'action de Γ_F conserve $\hat{\mathcal{E}}$. C'est-à-dire que, pour $\sigma\in\Gamma_F$, on a $\sigma(\hat{B},\hat{T})=(\hat{B},\hat{T})$ et σ agit par une permutation $\hat{\alpha}\mapsto\sigma(\hat{\alpha})$ sur $\hat{\Delta}$ de sorte que $\sigma(\hat{E}_{\hat{\alpha}})=\hat{E}_{\sigma(\hat{\alpha})}$. Pour toute paire de Borel (B,T) de G, on se donne des isomorphismes en dualité $X_*(T)\simeq X^*(\hat{T})$, $X^*(T)\simeq X_*(\hat{T})$ (avec la notation habituelle pour ces groupes de caractères et de cocaractères), qui échangent ensembles de racines et de coracines, qui respectent les ordres sur ces ensembles définis par B et $\hat{B}$ et qui sont équivariants pour les actions de Γ_F, le tore T étant muni de l'action quasi-déployée associée à (B,T). On demande que si on remplace (B,T) par $ad_g(B,T)$, pour $g\in G$, les isomorphismes relatifs à $ad_g(B,T)$ se déduisent de ceux relatifs à (B,T) par composition avec les isomorphismes déduits de ad_g. On fixe un

tel groupe dual et on pose ${}^LG = \hat{G} \rtimes W_F$, où W_F agit sur $\hat{G}$ via l'homomorphisme naturel $W_F \to \Gamma_F$. Pour une paire de Borel (B,T), l'automorphisme θ de T se transporte en un automorphisme $\hat{\theta}$ de $\hat{T}$: si $x_* \in X_*(T)$ correspond à $\hat{x}^* \in X^*(\hat{T})$, $\theta \circ x_*$ correspond à $\hat{x}^* \circ \hat{\theta}$. Cet automorphisme ne dépend pas du choix de (B,T) et se prolonge en un automorphisme $\hat{\theta}$ de $\hat{G}$ qui conserve $\hat{\mathcal{E}}$ et commute à l'action galoisienne. On peut considérer l'ensemble $\hat{G}\hat{\theta}$ comme un espace tordu sous $\hat{G}$.

On a fixé en 2.1 un caractère ω de $G(F)$. Il convient de modifier cette donnée en fixant plutôt un élément $\mathbf{a}$ du groupe de cohomologie $H^1(W_F; Z(\hat{G}))$. Selon une construction de Langlands, cet élément détermine un caractère ω de $G(F)$. Si F est non-archimédien, la correspondance $\mathbf{a} \mapsto \omega$ est bijective. Mais, si F est archimédien, elle est seulement surjective et fixer $\mathbf{a}$ est plus précis que fixer ω.

2.4. Données endoscopiques. Une donnée endoscopique pour $(G, \tilde{G}, \mathbf{a})$ est un triplet $\mathbf{G}' = (G', \mathcal{G}', \tilde{s})$, où G' est un groupe réductif connexe quasi-déployé sur F, $\mathcal{G}'$ est un sous-groupe de ${}^LG$ et $\tilde{s}$ est un élément semi-simple de l'espace tordu $\hat{G}\hat{\theta}$, ces données vérifiant les conditions qui suivent. Notons $\hat{G}_{\tilde{s}}$ la composante neutre du commutant de $\tilde{s}$ dans $\hat{G}$. On suppose qu'il y a une suite exacte

$$1 \to \hat{G}_{\tilde{s}} \to \mathcal{G}' \to W_F \to 1$$

et que cette suite est scindée, c'est-à-dire qu'il y a un homomorphisme continu $W_F \to \mathcal{G}'$ qui est une section de la deuxième flèche. Fixons une paire de Borel épinglée de $\hat{G}_{\tilde{s}}$. Pour tout $w \in W_F$, fixons $g_w = (g(w), w) \in \mathcal{G}'$ tel que $ad_{g(w)} \circ w$ la conserve. Alors l'application qui, à w, associe l'automorphisme $ad_{g(w)} \circ w$ de $\hat{G}_{\tilde{s}}$ se quotiente ou s'étend (selon que F est archimédien ou non) en une action de Γ_F sur $\hat{G}_{\tilde{s}}$. On suppose que, muni de cette action, $\hat{G}_{\tilde{s}}$ est un groupe dual de G'. Cela nous autorise à noter $\hat{G}'$ ce groupe $\hat{G}_{\tilde{s}}$. On suppose enfin qu'il existe un cocycle $a : W_F \to Z(\hat{G})$, dont la classe est $\mathbf{a}$, de sorte que, pour tout $(g,w) \in \mathcal{G}'$, on ait l'égalité $s\hat{\theta}(g)w(s)^{-1} = a(w)g$, où on a écrit $\tilde{s} = s\hat{\theta}$ avec $s \in \hat{G}$.

Deux données endoscopiques $\mathbf{G}'_1 = (G'_1, \mathcal{G}'_1, \tilde{s}_1)$ et $\mathbf{G}'_2 = (G'_2, \mathcal{G}'_2, \tilde{s}_2)$ sont dites équivalentes s'il existe $x \in \hat{G}$ tel que $x\mathcal{G}'_1x^{-1} = \mathcal{G}'_2$ et $x\tilde{s}_1x^{-1} \in Z(\hat{G})\tilde{s}_2$. On peut toujours remplacer une donnée endoscopique par une donnée équivalente $\mathbf{G}' = (G', \mathcal{G}', \tilde{s})$ de sorte que les conditions suivantes soient vérifiées : $\tilde{s} = s\hat{\theta}$, avec $s \in \hat{T}$; l'action galoisienne sur $\hat{G}'$ conserve une paire de Borel épinglée dont la paire de Borel $(\hat{B}', \hat{T}')$ sous-jacente est $(\hat{B} \cap \hat{G}', \hat{T}^{\hat{\theta},0})$, le deuxième groupe désignant la composante neutre du sous-groupe des points fixes de $\hat{\theta}$ agissant dans $\hat{T}$. Dans la suite, on ne considère que de telles données. Soient (B,T), resp. (B',T'), une paire de Borel de G, resp. G'. Des homomorphismes

$$X_*(T) \simeq X^*(\hat{T}) \overset{restriction}{\to} X^*(\hat{T}^{\hat{\theta},0}) = X^*(\hat{T}') \simeq X_*(T')$$

se déduit un homomorphisme $\xi : T \to T'$. Il se quotiente en un isomorphisme $T/(1-\theta)(T) \simeq T'$, où $1-\theta$ est l'homomorphisme $t \mapsto t\theta(t)^{-1}$ de T dans lui-même. On montre que ξ se restreint en un homomorphisme $\xi : Z(G) \to Z(G')$ qui ne dépend pas des choix de paires de Borel.

On dit que la donnée $\mathbf{G}' = (G', \mathcal{G}', \tilde{s})$ est elliptique si $Z(\hat{G}')^{\Gamma_F,0} = Z(\hat{G})^{\Gamma_F,\hat{\theta},0}$, avec une notation similaire à celle ci-dessus.

2.5. L'espace endoscopique. Pour une paire de Borel épinglée $\mathcal{E}$ de G, notons $Z(\tilde{G}, \mathcal{E})$ l'ensemble des $\gamma \in \tilde{G}$ tels que ad_γ conserve $\mathcal{E}$. Notons $\mathcal{Z}(\tilde{G}, \mathcal{E})$ le quotient de $Z(\tilde{G}, \mathcal{E})$

par l'action par conjugaison de $Z(G)$. Si $\mathcal{E}'$ est une autre paire de Borel épinglée, on choisit $g \in G$ tel que $ad_g(\mathcal{E}) = \mathcal{E}'$. Alors ad_g définit un isomorphisme de $\mathcal{Z}(\tilde{G}, \mathcal{E})$ sur $\mathcal{Z}(\tilde{G}, \mathcal{E}')$ qui ne dépend pas du choix de g. On note $\mathcal{Z}(\tilde{G})$ la limite inductive des $\mathcal{Z}(\tilde{G}, \mathcal{E})$, la limite étant prise sur les paires de Borel épinglées $\mathcal{E}$ de G, les applications de transition étant les isomorphismes canoniques que l'on vient de définir. Cet objet $\mathcal{Z}(\tilde{G})$ étant canonique, il récupère une action de Γ_F. C'est un espace tordu sous $\mathcal{Z}(G) := Z(G)/(1-\theta)(Z(G))$.

Soit $\mathbf{G}' = (G', \mathcal{G}', \tilde{s})$ une donnée endoscopique pour $(G, \tilde{G}, \mathbf{a})$. On définit l'espace endoscopique $\tilde{G}'$ comme le quotient de $G' \times \mathcal{Z}(\tilde{G})$ par la relation d'équivalence $(g'\xi(z), \tilde{z}) \equiv (g', z\tilde{z})$ pour tout $z \in Z(G)$. L'action galoisienne sur $G' \times \mathcal{Z}(\tilde{G})$ se descend en une action galoisienne sur $\tilde{G}'$. On a des actions à droite et à gauche de G' sur $\tilde{G}'$ qui proviennent des multiplications sur la première composante de $G' \times \mathcal{Z}(\tilde{G})$. Ainsi $\tilde{G}'$ est un espace tordu sous G' qui est à torsion intérieure. Remarquons que $\tilde{G}'(F)$ peut être vide. La construction fournit une application naturelle $\mathcal{Z}(\tilde{G}) \to \mathcal{Z}(\tilde{G}')$. Ce dernier ensemble est celui des $\delta \in \tilde{G}'$ tels que ad_δ soit l'identité.

2.6. Correspondance endoscopique. Soit $\mathbf{G}' = (G', \mathcal{G}', \tilde{s})$ une donnée endoscopique pour $(G, \tilde{G}, \mathbf{a})$. Appelons diagramme un sextuplet $(\epsilon, B', T', B, T, \eta)$, où $\epsilon \in \tilde{G}'(F)$, $\eta \in \tilde{G}(F)$, (B', T'), resp. (B, T), est une paire de Borel de G', resp. G, vérifiant les conditions suivantes. Les automorphismes ad_ϵ et ad_η conservent respectivement (B', T') et (B, T) (les éléments ϵ et η sont donc semi-simples). Les tores T et T' sont définis sur F, ainsi que l'homomorphisme $\xi : T \to T'$ associé aux paires de Borel. Etendons les deux paires de Borel en des paires de Borel épinglées $\mathcal{E}$ et $\mathcal{E}'$. On peut écrire $\eta = te$, avec $t \in T$ et $e \in Z(\tilde{G}, \mathcal{E})$. L'élément e a une image naturelle e' dans $\mathcal{Z}(\tilde{G}') = Z(\tilde{G}', \mathcal{E}')$. On impose que $\epsilon = \xi(t)e'$. Cela ne dépend pas des choix d'épinglages.

Pour des éléments $\epsilon \in \tilde{G}'(F)$ et $\eta \in \tilde{G}(F)$, on dit que ces éléments se correspondent s'il existe un diagramme les joignant. On dit que $\mathbf{G}'$ est relevant s'il existe un diagramme.

Pour un élément semi-simple $\eta \in \tilde{G}$, on introduit le groupe $I_\eta = G_\eta Z(G)^\theta$. Soient $\eta, \eta' \in \tilde{G}(F)$ deux éléments semi-simples. On dit qu'ils sont stablement conjugués s'il existe $y \in G$ tel que $y^{-1}\eta y = \eta'$ et $y\sigma(y)^{-1} \in I_\eta$ pour tout $\sigma \in \Gamma_F$. Cette définition généralise celle posée en 2.2. La classe de conjugaison stable de η est l'ensemble des éléments stablement conjugués à η. Soient $\mathcal{O}'$, resp. $\mathcal{O}$, une classe de conjugaison stable d'éléments semi-simples dans $\tilde{G}'(F)$, resp. $\tilde{G}(F)$. On dit qu'elles se correspondent s'il existe $\epsilon \in \mathcal{O}'$ et $\eta \in \mathcal{O}$ qui se correspondent (si $\mathcal{O}$ est formé d'éléments fortement réguliers, c'est équivalent à ce que ϵ et η se correspondent pour tous $\epsilon \in \mathcal{O}'$ et $\eta \in \mathcal{O}$). On montre qu'à une classe $\mathcal{O}'$ correspond au plus une classe $\mathcal{O}$ et qu'inversement, l'ensemble des classes $\mathcal{O}'$ qui correspondent à une classe $\mathcal{O}$ est fini (éventuellement vide).

2.7. Transfert. Soit $\mathbf{G}' = (G', \mathcal{G}', \tilde{s})$ une donnée endoscopique relevante de $(G, \tilde{G}, \mathbf{a})$. Considérons une suite exacte

$$1 \to C_1 \to G_1' \to G' \to 1,$$

où G_1' est un groupe réductif et quasi-déployé sur F et C_1 est un sous-tore central induit (c'est-à-dire que $X_*(C_1)$ possède une base permutée par l'action galoisienne). Considérons un espace tordu $\tilde{G}_1'$ sous G_1', à torsion intérieure et tel que $\tilde{G}_1'(F) \neq \emptyset$. Supposons donnée une application $\tilde{G}_1' \to \tilde{G}'$ compatible avec la projection $G_1' \to G'$. Supposons donné un plongement $\hat{\xi}_1 : \mathcal{G}' \to {}^L G_1'$ compatible aux projections sur W_F, dont la restriction à $\hat{G}' \subset \mathcal{G}'$ est un homomorphisme $\hat{G}' \to \hat{G}_1'$ dual à la projection $G_1' \to G'$. De telles données existent,

cf. [11] 2.2. Pour $(\delta_1,\gamma)\in\tilde{G}'_1(F)\times\tilde{G}(F)$, on dit que δ_1 et γ se correspondent si δ et γ se correspondent, où δ est l'image de δ_1 dans $\tilde{G}'(F)$. Kottwitz et Shelstad ont défini un facteur de transfert $\Delta_1:\tilde{G}'_1(F)\times\tilde{G}(F)\to\mathbb{C}$, cf. [11] chapitre 4 et [12]. On a $\Delta_1(\delta_1,\gamma)\neq 0$ si et seulement si δ_1 et γ se correspondent et γ est fortement régulier. Pour de tels éléments, $\Delta_1(\delta_1,\gamma)$ ne dépend que de la classe de conjugaison stable de δ_1 et on a la formule

$$\Delta_1(c_1\delta_1,g^{-1}\gamma g)=\lambda_1(c_1)^{-1}\omega(g)\Delta_1(\delta_1,\gamma)$$

pour tous $c_1\in C_1(F)$ et $g\in G(F)$, où λ_1 est un caractère de $C_1(F)$ déduit des données.

Notons $C^\infty_{c,\lambda_1}(\tilde{G}'_1(F))$ l'espace des fonctions $f_1:\tilde{G}'_1(F)\to\mathbb{C}$ qui sont lisses, à support compact modulo $C_1(F)$ et telles que $f_1(c_1\delta_1)=\lambda_1(c_1)^{-1}f_1(\delta_1)$ pour tous $c_1\in C_1(F)$ et $\delta_1\in\tilde{G}'_1(F)$. Les définitions du paragraphe 2.2 s'adaptent à cet espace, on ajoute des λ_1 en indices. Pour $f\in C^\infty_c(\tilde{G}(F))$ et $f_1\in C^\infty_{c,\lambda_1}(\tilde{G}'_1(F))$, on dit que f_1 est un transfert de f si on a l'égalité

$$S^{\tilde{G}'_1}_{\lambda_1}(\delta_1,f_1)=\sum_\gamma\Delta_1(\delta_1,\gamma)[Z_G(\gamma;F):G_\gamma(F)]^{-1}I^{\tilde{G}}(\gamma,\omega,f)$$

pour tout δ_1 dans un ensemble ouvert dense de $\tilde{G}'_1(F)$, où γ parcourt l'ensemble des éléments de $\tilde{G}(F)$ correspondant à δ_1, modulo conjugaison par $G(F)$. Pour donner un sens à cette égalité, il faut fixer des mesures de Haar sur tous les groupes intervenant. Celles sur les tores $G_\gamma(F)$ et $G'_{1,\delta_1}(F)$ doivent être reliées.

Théorème 2.1. *Tout $f\in C^\infty_c(\tilde{G}(F))$ admet un transfert $f_1\in C^\infty_{c,\lambda_1}(\tilde{G}'_1(F))$.*

Ce théorème résulte de [17] et [20] 1.5 dans le cas non archimédien. Il est dû à Shelstad [18] dans le cas archimédien. On montre que les choix de mesures de Haar disparaissent si l'on introduit pour tout groupe réductif H sur F la droite complexe $Mes(H(F))$ portée par une mesure de Haar sur $H(F)$ et si l'on considère le transfert comme une application linéaire

$$I(\tilde{G}(F),\omega)\otimes Mes(G(F))\to SI_{\lambda_1}(\tilde{G}'_1(F))\otimes Mes(G'(F)).$$

Cette application dépend des données G'_1, $\tilde{G}'_1$, C_1, $\hat{\xi}_1$, ainsi que du choix de Δ_1. Ce facteur n'est en effet pas uniquement déterminé, mais seulement à homothétie près. Considérons d'autres données G'_2,...,Δ_2 vérifiant les mêmes hypothèses. Il s'avère que l'on peut définir un isomorphisme canonique

$$C^\infty_{c,\lambda_1}(\tilde{G}'_1(F))\simeq C^\infty_{c,\lambda_2}(\tilde{G}'_2(F))$$

qui commute au transfert. C'est-à-dire que, pour $f\in C^\infty_c(\tilde{G}(F))$ et $f_1\in C^\infty_{c,\lambda_1}(\tilde{G}'_1(F))$, f_1 est un transfert de f si et seulement si l'image f_2 de f_1 par l'isomorphisme ci-dessus est un transfert de f. On peut alors définir un espace noté $C^\infty_c(\mathbf{G}')$ qui est la limite inductive des espaces $C^\infty_{c,\lambda_1}(\tilde{G}'_1(F))$, la limite étant prise sur toutes les données auxiliaires G'_1,...,Δ_1, les applications de transition étant les isomorphismes ci-dessus. Cette définition pose un problème logique, les données auxiliaires ne formant pas un ensemble, mais ce problème est facile à résoudre. Une construction analogue permet de définir des espaces $I(\mathbf{G}')$ et $SI(\mathbf{G}')$. L'application de transfert devient une application linéaire canonique

$$\begin{array}{ccc} I(\tilde{G}(F),\omega)\otimes Mes(G(F)) & \to & SI(\mathbf{G}')\otimes Mes(G'(F)) \\ \mathbf{f} & \mapsto & \mathbf{f}^{\mathbf{G}'} \end{array}$$

2.8. Les espaces de distributions. On note $D_{orb}(\tilde{G}(F),\omega)$ l'espace de formes linéaires sur $I(\tilde{G}(F),\omega)$ (que l'on peut relever en des formes linéaires sur $C_c^\infty(\tilde{G}(F))$) engendré par les intégrales orbitales $f \mapsto I^{\tilde{G}}(\gamma,\omega,f)$, cf. 2.2, quand γ décrit $\tilde{G}(F)$. Quand F est non-archimédien, c'est aussi l'espace des formes linéaires qui, relevées en des formes linéaires sur $C_c^\infty(\tilde{G}(F))$, sont supportées par un nombre fini de classes de conjugaison par $G(F)$. Il est plus canonique d'introduire comme en 2.7 la droite complexe $Mes(G(F))$ et sa duale $Mes(G(F))^*$ et de considérer les espaces $I(\tilde{G}(F),\omega)\otimes Mes(G(F))$ et $D_{orb}(\tilde{G}(F),\omega)\otimes Mes(G(F))^*$. Pour $\mathbf{f}\in I(\tilde{G}(F),\omega)\otimes Mes(G(F))$ et $\boldsymbol{\gamma}\in D_{orb}(\tilde{G}(F),\omega)\otimes Mes(G(F))^*$, on note $I^{\tilde{G}}(\boldsymbol{\gamma},\mathbf{f})$ l'évaluation de $\boldsymbol{\gamma}$ sur $\mathbf{f}$. Supposons que G soit quasi-déployé, que $\tilde{G}$ soit à torsion intérieure et que $\mathbf{a}=1$. On note $D_{orb}^{st}(\tilde{G}(F))$ le sous-espace des éléments de $D_{géom}(\tilde{G}(F))$ qui sont stables, c'est-à-dire se quotientent en une forme linéaire sur $SI(\tilde{G}(F))$. Pour $\mathbf{f}\in SI(\tilde{G}(F))\otimes Mes(G(F))$ et $\boldsymbol{\delta}\in D_{orb}^{st}(\tilde{G}(F))\otimes Mes(G(F))^*$, on note $S^{\tilde{G}}(\boldsymbol{\delta},\mathbf{f})$ l'évaluation de $\boldsymbol{\delta}$ sur $\mathbf{f}$.

Soit $\mathbf{G}'=(G',\mathcal{G}',\tilde{s})$ une donnée endoscopique relevante de $(G,\tilde{G},\mathbf{a})$. On a défini l'espace $SI(\mathbf{G}')$ comme limite inductive d'espaces $SI_{\lambda_1}(\tilde{G}'_1(F))$ construits à l'aide de données auxiliaires. Une construction analogue permet de définir un espace $D_{orb}^{st}(\mathbf{G}')$ de formes linéaires sur $SI(\mathbf{G}')$. Supposons F non-archimédien. Dualement à l'application de transfert du paragraphe précédent, on a une application linéaire

$$transfert : D_{orb}^{st}(\mathbf{G}')\otimes Mes(G'(F))^* \to D_{orb}(\tilde{G}(F),\omega)\otimes Mes(G(F))^*.$$

Le cas archimédien est plus compliqué, cf. 2.13.

2.9. Espaces de Levi. Soient P un sous-groupe parabolique de G et M une composante de Levi de P, tous deux définis sur F (on appelle M un Levi de G). Notons $\tilde{M}$ l'ensemble des $\gamma\in\tilde{G}$ tels que ad_γ conserve P et M. Supposons $\tilde{M}$ non vide. On appelle alors $\tilde{M}$ un espace de Levi de $\tilde{G}$. C'est un espace tordu sous M. On peut identifier le groupe dual $\hat{M}$ à un sous-groupe de Levi de $\hat{G}$, que l'on peut supposer standard et invariant par $\hat{\theta}$ comme par l'action galoisienne. L'élément $\mathbf{a}\in H^1(W_F;Z(\hat{G}))$ se pousse en un élément $\mathbf{a}_M\in H^1(W_F;Z(\hat{M}))$. Soit $\mathbf{M}'=(M',\mathcal{M}',\tilde{\zeta})$ une donnée endoscopique elliptique pour $(M,\tilde{M},\mathbf{a}_M)$. Dans la définition de 2.4 intervient un cocycle, ici $a_M : W_F\to Z(\hat{M})$, de classe $\mathbf{a}_M$. On voit que, quitte à remplacer $\mathbf{M}'$ par une donnée équivalente, on peut supposer que ce cocycle est à valeurs dans $Z(\hat{G})$. Sa classe dans $H^1(W_F;Z(\hat{G}))$ est alors $\mathbf{a}$. On suppose qu'il en est ainsi.

Soit $\tilde{s}\in\tilde{\zeta}Z(\hat{M})^{\Gamma_F,\hat{\theta}}/Z(\hat{G})^{\Gamma_F,\hat{\theta}}$. On montre qu'il existe une donnée endoscopique $\mathbf{G}'(\tilde{s})=(G'(\tilde{s}),\mathcal{G}'(\tilde{s}),\tilde{s})$ de $(G,\tilde{G},\mathbf{a})$ caractérisée par les propriétés suivantes : $\hat{G}'(\tilde{s})$ est la composante neutre du commutant de $\tilde{s}$ dans $\hat{G}$; $\mathcal{G}'(\tilde{s})$ est le sous-groupe de ${}^LG$ engendré par $\hat{G}'(\tilde{s})$ et $\mathcal{M}'$ (en fait, c'est simplement le produit $\hat{G}'(\tilde{s})\mathcal{M}'=\mathcal{M}'\hat{G}'(\tilde{s})$). Le groupe M' s'identifie à un Levi de $G'(\tilde{s})$ et $\tilde{M}'$ s'identifie conformément à un espace de Levi de $\tilde{G}'(\tilde{s})$. On définit une constante $i_{\tilde{M}'}(\tilde{G},\tilde{G}'(\tilde{s}))$. Si $\mathbf{G}'(\tilde{s})$ n'est pas elliptique, elle est nulle. Si $\mathbf{G}'(\tilde{s})$ est elliptique, on montre qu'il y a un homomorphisme naturel

$$Z(\hat{M})^{\Gamma_F,\hat{\theta}}/Z(\hat{G})^{\Gamma_F,\hat{\theta}}\to Z(\hat{M}')^{\Gamma_F}/Z(\hat{G}'(\tilde{s}))^{\Gamma_F}.$$

Il est surjectif et de noyau fini. Alors $i_{\tilde{M}'}(\tilde{G},\tilde{G}'(\tilde{s}))$ est l'inverse du nombre d'éléments de ce noyau.

Soient $\tilde{M}$ un espace de Levi de $\tilde{G}$ et M le Levi de G associé. On note A_M le plus grand sous-tore de $Z(M)$ déployé sur F et $A_{\tilde{M}}$ le plus grand sous-tore de A_M sur lequel

ad_γ agit trivialement pour tout $\gamma \in \tilde{M}$ (ou pour un $\gamma \in \tilde{M}$, c'est équivalent). On pose $\mathcal{A}_{\tilde{M}} = X_*(A_{\tilde{M}}) \otimes_{\mathbb{Z}} \mathbb{R}$. On doit fixer pour tout espace de Levi $\tilde{M}$ une mesure de Haar sur $\mathcal{A}_{\tilde{M}}$. De même, pour toute donnée endoscopique $\mathbf{G}' = (G', \mathcal{G}', \tilde{s})$ de $(G, \tilde{G}, \mathbf{a})$ et pour tout espace de Levi $\tilde{M}'$ de $\tilde{G}'$, on doit fixer une mesure de Haar sur $\mathcal{A}_{\tilde{M}'}$. On doit imposer des conditions de compatibilité à ces divers choix. En particulier, si $\mathbf{G}'$ est elliptique, il y a un isomorphisme naturel $\mathcal{A}_{\tilde{G}} \simeq \mathcal{A}_{\tilde{G}'}$ et on impose que les mesures se correspondent par cet isomorphisme.

2.10. Intégrales orbitales pondérées. Les définitions de ce paragraphe sont dues (comme bien d'autres) à Arthur. Considérons un espace de Levi $\tilde{M}$ de $\tilde{G}$. Soient $\gamma \in \tilde{G}(F)$ et $f \in C_c^\infty(\tilde{G}(F))$. Supposons d'abord $M_\gamma = G_\gamma$. Si ω est non trivial sur $M_\gamma(F)$, on pose $J_{\tilde{M}}^{\tilde{G}}(\gamma, \omega, f) = 0$. Supposons ω trivial sur $M_\gamma(F)$. On choisit des mesures de Haar sur tous les groupes intervenant et on pose

$$J_{\tilde{M}}^{\tilde{G}}(\gamma, \omega, f) = D^{\tilde{G}}(\gamma)^{1/2} \int_{M_\gamma(F)\backslash G(F)} \omega(g) f(g^{-1}\gamma g) v_{\tilde{M}}(g)\, dg$$

où $v_{\tilde{M}}$ est un "poids" défini en [5] paragraphe 1 (à l'aide du choix d'un "bon" sous-groupe compact maximal de $G(F)$).

La définition de $J_{\tilde{M}}^{\tilde{G}}(\gamma, \omega, f)$ quand la condition $M_\gamma = G_\gamma$ n'est pas vérifiée est beaucoup plus délicate. Pour $a \in A_{\tilde{M}}(F)$ en position générale, on a $M_{a\gamma} = G_{a\gamma}$ et le terme $J_{\tilde{M}}^{\tilde{G}}(a\gamma, \omega, f)$ est défini. Plus généralement, $J_{\tilde{L}}^{\tilde{G}}(a\gamma, \omega, f)$ est défini pour tout espace de Levi $\tilde{L} \supset \tilde{M}$. Alors $J_{\tilde{M}}^{\tilde{G}}(\gamma, \omega, f)$ est défini comme la limite quand a tend vers 1 d'une certaine combinaison linéaire (à coefficients dépendant de a) de ces intégrales $J_{\tilde{L}}^{\tilde{G}}(a\gamma, \omega, f)$.

De nouveau, il est plus canonique de remplacer f par un élément de $C_c^\infty(\tilde{G}(F)) \otimes Mes(G(F))$. On s'aperçoit qu'alors les données de γ et d'une mesure sur $M_\gamma(F)$ suffisent pour définir les termes ci-dessus. Or ces données définissent aussi une intégrale orbitale sur $\tilde{M}(F)$, c'est-à-dire un élément de $D_{orb}(\tilde{M}(F), \omega) \otimes Mes(M(F))^*$. Par linéarité, on peut alors définir $J_{\tilde{M}}^{\tilde{G}}(\boldsymbol{\gamma}, \mathbf{f})$ pour $\boldsymbol{\gamma} \in D_{orb}(\tilde{M}(F), \omega) \otimes Mes(M(F))^*$ et $\mathbf{f} \in C_c^\infty(\tilde{G}(F)) \otimes Mes(G(F))$. Hormis le cas $\tilde{M} = \tilde{G}$, les applications linéaires $\mathbf{f} \mapsto J_{\tilde{M}}^{\tilde{G}}(\boldsymbol{\gamma}, \mathbf{f})$ ne sont pas ω-équivariantes, c'est-à-dire ne se quotientent pas en des applications linéaires sur $I(\tilde{G}(F), \omega) \otimes Mes(G(F))$. Arthur a défini des avatars ω-équivariants de ces applications, cf. [6] section 2. On n'en donnera pas la définition qui passe par la théorie des représentations (les objets obtenus ne sont plus, en fait, de nature "géométrique"). On note $I_{\tilde{M}}^{\tilde{G}}(\boldsymbol{\gamma}, \mathbf{f})$ l'avatar ω-équivariant de $J_{\tilde{M}}^{\tilde{G}}(\boldsymbol{\gamma}, \mathbf{f})$. C'est une forme bilinéaire en $\boldsymbol{\gamma} \in D_{orb}(\tilde{M}(F), \omega) \otimes Mes(M(F))^*$ et $\mathbf{f} \in I(\tilde{G}(F), \omega) \otimes Mes(G(F))$. Comme on le verra en 3.3, ces formes bilinéaires sont les objets locaux qui interviennent dans la partie géométrique de la formule des traces.

Variante. Supposons G quasi-déployé, $\tilde{G}$ à torsion intérieure et $\mathbf{a} = 1$. Comme on l'a dit, pour γ tel que $M_\gamma \neq G_\gamma$, les termes $J_{\tilde{M}}^{\tilde{G}}(\gamma, f)$ sont définis par un procédé de limite. En fait, il y a plusieurs procédés possibles. Notons η la partie semi-simple de γ et fixons un sous-tore maximal T de G_η. Notons $\Sigma^{G_\eta}(T)$ l'ensemble des racines de T dans l'algèbre de Lie de G_η. A toute fonction $B_\eta : \Sigma^{G_\eta}(T) \to \mathbb{Q}_{>0}$ vérifiant des propriétés très restrictives (par exemple une fonction constante), on peut associer un procédé de passage à la limite. Plus globalement, supposons que, pour tout élément semi-simple $\eta \in \tilde{G}(F)$, on s'est donné une

telle fonction B_η, ces fonctions étant reliées elles-mêmes par des conditions de compatibilité. On appelle ces données un système de fonctions B. Alors on peut définir pour tout $\gamma \in \tilde{M}(F)$ un terme $J_{\tilde{M}}^{\tilde{G}}(\gamma, B, f)$. Il est égal à $J_{\tilde{M}}^{\tilde{G}}(\gamma, f)$ si $M_\gamma = G_\gamma$ mais ne l'est pas, en général, si cette condition n'est pas vérifiée. Comme ci-dessus, on en déduit des avatars invariants $I_{\tilde{M}}^{\tilde{G}}(\boldsymbol{\gamma}, B, \mathbf{f})$.

2.11. Intégrales orbitales pondérées stables. Supposons le corps F non-archimédien, G quasi-déployé, $\tilde{G}$ à torsion intérieure et $\mathbf{a} = 1$. On supprime les termes $\mathbf{a}$ et $\hat{\theta}$ des notations. Soit $\tilde{M}$ un espace de Levi de $\tilde{G}$. Le triplet $\mathbf{M} = (M, {}^L M, 1)$ est une donnée endoscopique de $(M, \tilde{M})$ (la donnée "maximale"). Pour $\boldsymbol{\delta} \in D_{orb}^{st}(\tilde{M}(F)) \otimes Mes(M(F))^*$ et $\mathbf{f} \in I(\tilde{G}(F)) \otimes Mes(G(F))$, on définit un terme $S_{\tilde{M}}^{\tilde{G}}(\boldsymbol{\delta}, \mathbf{f})$ par la formule

$$S_{\tilde{M}}^{\tilde{G}}(\boldsymbol{\delta}, \mathbf{f}) = I_{\tilde{M}}^{\tilde{G}}(\boldsymbol{\delta}, \mathbf{f}) - \sum_{s \in Z(\hat{M})^{\Gamma_F}/Z(\hat{G})^{\Gamma_F}, s \neq 1} i_{\tilde{M}}(\tilde{G}, \tilde{G}'(s)) S_{\mathbf{M}}^{\mathbf{G}'(s)}(\boldsymbol{\delta}, \mathbf{f}^{\mathbf{G}'(s)}),$$

cf. [8] section 5. Expliquons cette formule. Le premier terme $I_{\tilde{M}}^{\tilde{G}}(\boldsymbol{\delta}, \mathbf{f})$ a déjà été défini. Pour s intervenant dans la somme, l'hypothèse $s \neq 1$ entraîne que $dim(G'(s)_{SC}) < dim(G_{SC})$, où par exemple G_{SC} est le revêtement simplement connexe du groupe dérivé de G. Supposons un instant que, dans les constructions de 2.7, on puisse choisir pour données auxiliaires $G'_1(s) = G'(s)$, $\tilde{G}'_1(s) = \tilde{G}'(s)$. En raisonnant par récurrence sur la dimension de G_{SC}, on peut supposer défini le terme $S_{\tilde{M}}^{\tilde{G}'(s)}(\boldsymbol{\delta}, \boldsymbol{\varphi})$ pour $\boldsymbol{\varphi} \in I(\tilde{G}'(s; F)) \otimes Mes(G'(F))$. Un raisonnement formel permet de s'affranchir de l'hypothèse ci-dessus et de définir en général un terme $S_{\mathbf{M}}^{\mathbf{G}'(s)}(\boldsymbol{\delta}, \boldsymbol{\varphi})$, pour $\boldsymbol{\varphi} \in I(\mathbf{G}'(s)) \otimes Mes(G'(F))$. Comme on va le voir, ce terme est stable en $\boldsymbol{\varphi}$, c'est-à-dire ne dépend que de l'image de $\boldsymbol{\varphi}$ dans $SI(\mathbf{G}'(s)) \otimes Mes(G'(F))$. On note $\mathbf{f}^{\mathbf{G}'(s)}$ le transfert de $\mathbf{f}$. C'est un élément de cet espace. Le terme $S_{\mathbf{M}}^{\mathbf{G}'(\tilde{s})}(\boldsymbol{\delta}, \mathbf{f}^{\mathbf{G}'(\tilde{s})})$ est donc bien défini.

La construction repose donc sur le théorème suivant.

Théorème 2.2. *Pour tout $\boldsymbol{\delta} \in D_{orb}^{st}(\tilde{M}(F)) \otimes Mes(M(F))^*$, la forme linéaire $\mathbf{f} \mapsto S_{\tilde{M}}^{\tilde{G}}(\boldsymbol{\delta}, \mathbf{f})$ est stable, c'est-à-dire qu'elle se descend en une forme linéaire sur l'espace $SI(\tilde{G}(F)) \otimes Mes(G(F))$.*

Variante. Supposons donné un système de fonctions B comme en 2.10. Il s'en déduit aisément pour tout s un tel système pour chaque $\tilde{G}'(s)$. On définit alors $S_{\tilde{M}}^{\tilde{G}}(\boldsymbol{\delta}, B, \mathbf{f})$ de la même façon que ci-dessus. Pour ce terme, le théorème est encore vérifié.

2.12. Intégrales orbitales pondérées endoscopiques. Supposons que F est non-archimédien, mais que $(G, \tilde{G}, \mathbf{a})$ est quelconque. Considérons une donnée endoscopique $\mathbf{G}' = (G', \mathcal{G}', \tilde{s})$ de $(G, \tilde{G}, \mathbf{a})$. Considérons un diagramme $(\epsilon, B', T', B, T, \eta)$, où $\epsilon \in \tilde{G}'(F)$ et $\eta \in \tilde{G}(F)$ sont des éléments semi-simples. Du diagramme se déduit un homomorphisme $\mathfrak{t}^\theta \to \mathfrak{t}'$ (où $\theta = ad_\eta$). Le tore $T^{\theta,0}$ est un sous-tore maximal de G_η. Notons $\Sigma^{G_\eta}(T^{\theta,0})$ et $\Sigma^{G'_\epsilon}(T')$ les ensembles de racines de $T^{\theta,0}$ dans $\mathfrak{g}_\eta$ et de T' dans $\mathfrak{g}'_\epsilon$. On peut considérer ces racines comme des formes linéaires sur $\mathfrak{t}^\theta$, resp. $\mathfrak{t}'$. Par l'isomorphisme précédent, $\Sigma^{G'_\epsilon}(T')$ ne s'identifie pas à un sous-ensemble de $\Sigma^{G_\eta}(T^{\theta,0})$. Mais il existe une unique fonction $B_\epsilon^{\tilde{G}} : \Sigma^{G'_\epsilon}(T') \to \mathbb{Q}_{>0}$ de sorte que, pour tout $\alpha \in \Sigma^{G'_\epsilon}(T')$, $\alpha / B_\epsilon^{\tilde{G}}(\alpha)$ soit un élément de $\Sigma^{G_\eta}(T^{\theta,0})$. Plus globalement, on peut définir un système de fonctions $B^{\tilde{G}}$ sur $\tilde{G}'$, au sens de

2.10, de sorte que, pour tout diagramme comme ci-dessus, la fonction $B_\epsilon^{\tilde{G}}$ soit celle associée à ce système.

Soient $\tilde{M}$ un espace de Levi de $\tilde{G}$ et $\mathbf{M}' = (M', \mathcal{M}', \tilde{\zeta})$ une donnée endoscopique elliptique et relevante pour $(M, \tilde{M}, \mathbf{a}_M)$. Soient $\boldsymbol{\delta} \in D_{orb}^{st}(\mathbf{M}') \otimes Mes(M'(F))^*$ et $\mathbf{f} \in I(\tilde{G}(F), \omega) \otimes Mes(G(F))$. On pose

$$I_{\tilde{M}}^{\tilde{G},\mathcal{E}}(\mathbf{M}', \boldsymbol{\delta}, \mathbf{f}) = \sum_{\tilde{s} \in \tilde{\zeta} Z(\hat{M})^{\Gamma_F, \hat{\theta}} / Z(\hat{G})^{\Gamma_F, \hat{\theta}}} i_{\tilde{M}'}(\tilde{G}, \tilde{G}(\tilde{s})) S_{\mathbf{M}'}^{\mathbf{G}'(\tilde{s})}(\boldsymbol{\delta}, B^{\tilde{G}}, \mathbf{f}^{\mathbf{G}'(\tilde{s})}),$$

cf. [8] section 5. Le sens de chaque terme s'explique comme dans le paragraphe précédent.

Soit $\boldsymbol{\gamma} \in D_{orb}(\tilde{M}(F), \omega) \otimes Mes(M(F))^*$. On montre qu'il existe une famille finie $(\mathbf{M}_i')_{i=1,\dots,n}$ de données endoscopiques elliptiques et relevantes de $(M, \tilde{M}, \mathbf{a}_M)$ et, pour chaque i, un élément $\boldsymbol{\delta}_i \in D_{orb}^{st}(\mathbf{M}_i') \otimes Mes(M_i'(F))^*$, de sorte que

$$\boldsymbol{\gamma} = \sum_{i=1,\dots,n} transfert(\boldsymbol{\delta}_i).$$

Pour $\mathbf{f} \in I(\tilde{G}(F), \omega) \otimes Mes(G(F))$, posons

$$I_{\tilde{M}}^{\tilde{G},\mathcal{E}}(\boldsymbol{\gamma}, \mathbf{f}) = \sum_{i=1,\dots,n} I_{\tilde{M}}^{\tilde{G},\mathcal{E}}(\mathbf{M}_i', \boldsymbol{\delta}_i, \mathbf{f}).$$

La décomposition ci-dessus de $\boldsymbol{\gamma}$ n'est pas unique mais on montre que $I_{\tilde{M}}^{\tilde{G},\mathcal{E}}(\boldsymbol{\gamma}, \mathbf{f})$ ne dépend pas de ce choix.

Théorème 2.3. *Pour tous $\boldsymbol{\gamma} \in D_{orb}(\tilde{M}(F), \omega) \otimes Mes(M(F))^*$ et $\mathbf{f} \in I(\tilde{G}(F), \omega) \otimes Mes(G(F))$, on a l'égalité*

$$I_{\tilde{M}}^{\tilde{G},\mathcal{E}}(\boldsymbol{\gamma}, \mathbf{f}) = I_{\tilde{M}}^{\tilde{G}}(\boldsymbol{\gamma}, \mathbf{f}).$$

2.13. Le cas *F* archimédien. Il y a des complications techniques lorsque F est archimédien. La première est que, pour obtenir des formules d'inversion satisfaisantes entre $\tilde{G}$ et ses données endoscopiques, on est parfois obligé d'adjoindre au couple $(G, \tilde{G})$ d'autres couples $(G_\sharp, \tilde{G}_\sharp)$, où $G_\sharp$ est une forme intérieure de G. On appelle K-espace la réunion disjointe (finie) de ces espaces $\tilde{G}_\sharp$ et, en général, on doit travailler avec de tels K-espaces, cf. [8] section 2. Cela ne modifie guère que les notations et ce n'est d'ailleurs pas utile dans le cas où G est quasi-déployé, $\tilde{G}$ est à torsion intérieure et $\mathbf{a} = 1$. Une difficulté plus sérieuse est que l'espace de distributions $D_{orb}(\tilde{G}(F), \omega) \otimes Mes(G(F))^*$ engendré par les intégrales orbitales se comporte mal par endoscopie. C'est-à-dire, considérons une donnée endoscopique $\mathbf{G}' = (G', \mathcal{G}', \tilde{s})$ de $(G, \tilde{G}, \mathbf{a})$, supposons pour simplifier que le recours à des données auxiliaires ne soit pas nécessaire et que l'on puisse définir un transfert $\mathbf{f} \mapsto \mathbf{f}^{\tilde{G}'}$ de $I(\tilde{G}(F), \omega) \otimes Mes(G(F))$ dans $SI(\tilde{G}'(F)) \otimes Mes(G'(F))$. Soit $\boldsymbol{\delta} \in D_{orb}^{st}(\tilde{G}'(F)) \otimes Mes(G'(F))^*$. Comme le montre un exemple dû à Magdy Assem, que m'a indiqué Kottwitz, il n'est pas vrai en général que l'application $\mathbf{f} \mapsto S^{\tilde{G}}(\boldsymbol{\delta}, \mathbf{f}^{\tilde{G}'})$ soit une combinaison linéaire d'intégrales orbitales. La construction de 2.12 s'évanouit si on se limite aux distributions qui sont des intégrales orbitales. La solution que l'on a retenue est de définir un espace de distributions $D_{tr-orb}(\tilde{G}(F), \omega)$ un peu plus gros que $D_{orb}(\tilde{G}(F), \omega)$, qui vérifie :

- dans la situation ci-dessus, le transfert envoie $D_{tr-orb}^{st}(\tilde{G}'(F)) \otimes Mes(G'(F))^*$ dans $D_{tr-orb}(\tilde{G}(F), \omega) \otimes Mes(G(F))^*$ (où $D_{tr-orb}^{st}(\tilde{G}'(F))$ est le sous-espace des éléments de $D_{tr-orb}(\tilde{G}'(F))$ qui sont stables) ;

- on peut définir les intégrales $I_{\tilde{M}}^{\tilde{G}}(\boldsymbol{\gamma}, \mathbf{f})$ pour $\boldsymbol{\gamma} \in D_{tr-orb}(\tilde{M}(F), \omega) \otimes Mes(M(F))^*$.

On n'en donne pas la construction. En utilisant cet espace, on peut adapter les définitions de 2.11 et de 2.12. Le théorème 2.11 reste valable. Une forme modifiée du théorème 2.12 aussi.

3. La théorie globale

3.1. Espaces tordus. Soit F un corps de nombres. On note $Val(F)$ l'ensemble des places de F et, pour $v \in Val(F)$, F_v le complété de F en v. On note $\mathbb{A}$ l'anneau des adèles de F. Les définitions de 2.1 et 2.3 valent en remplaçant le corps local de ce paragraphe par le corps de nombres F. La seule différence notable est qu'au lieu de fixer un élément $\mathbf{a} \in H^1(W_F; Z(\hat{G}))$, on fixe seulement un élément $\mathbf{a} \in H^1(W_F; Z(\hat{G}))/ker^1(F; Z(\hat{G}))$, où $ker^1(F; Z(\hat{G}))$ est le noyau fini de l'homomorphisme

$$H^1(W_F; Z(\hat{G})) \to \prod_{v \in Val(F)} H^1(W_{F_v}; Z(\hat{G})).$$

On fixe des données $(G, \tilde{G}, \mathbf{a})$. De $\mathbf{a}$ se déduit un homomorphisme continu $\omega : G(\mathbb{A}) \to \mathbb{C}^\times$, trivial sur $G(F)$. Pour tout $v \in Val(F)$, les données $(G, \tilde{G}, \mathbf{a})$ se localisent en des données $(G_v, \tilde{G}_v, \mathbf{a}_v)$ sur F_v. On fixe un espace de Levi minimal $\tilde{M}_0$ de $\tilde{G}$. On note $W^{\tilde{G}}$ le quotient du normalisateur de $\tilde{M}_0$ dans $G(F)$ par son sous-groupe $M_0(F)$. Pour tout espace de Levi $\tilde{M}$, on fixe une mesure de Haar sur $\mathcal{A}_{\tilde{M}} = X_*(A_{\tilde{M}}) \otimes \mathbb{R}$ (cf. 2.9), ces mesures étant soumises à certaines conditions de compatibilité.

On fixe un ensemble fini $V_{ram} \subset Val(F)$, contenant les places archimédiennes et tel que, pour $v \in Val(F) - V_{ram}$, les données $(G_v, \tilde{G}_v, \mathbf{a}_v)$ soient "non ramifiées". On ne précisera pas ici le sens de cette expression. Elle entraîne en tout cas que, pour $v \in Val(F) - V_{ram}$, on peut fixer un sous-groupe compact hyperspécial $K_v \subset G(F_v)$ et un espace hyperspécial associé $\tilde{K}_v \subset \tilde{G}(F_v)$. On entend par là que $\tilde{K}_v$ est un sous-ensemble non vide de $\tilde{G}(F_v)$ et que, pour tout $\gamma \in \tilde{K}_v$, on a les égalités $\tilde{K}_v = K_v\gamma = \gamma K_v$. On fixe de tels objets, auxquels on impose les conditions :

- pour tout $v \in Val(F) - V_{ram}$, K_v est en "bonne position" relativement à $\tilde{M}_0$;
- pour tout $\gamma \in \tilde{G}(F)$, γ appartient à $\tilde{K}_v$ pour presque tout $v \in Val(F) - V_{ram}$ ("presque tout" signifie "sauf pour un nombre fini").

3.2. Intégrales orbitales pondérées. Soit $V \subset Val(F)$ un ensemble fini de places de F. On pose $F_V = \prod_{v \in V} F_v$. Beaucoup d'objets définis dans le cas local ont des analogues définis sur l'anneau F_V. Ils sont obtenus par produit ou tensorisation des objets sur les corps F_v pour $v \in V$. On adapte la notation en conséquence. Par exemple, $\tilde{G}(F_V) = \prod_{v \in V} \tilde{G}(F_v)$ et $I(\tilde{G}(F_V), \omega) = \otimes_{v \in V} I(\tilde{G}(F_v), \omega_v)$.

Soit $\tilde{M}$ un espace de Levi de $\tilde{G}$. Pour $\boldsymbol{\gamma} \in D_{orb}(\tilde{M}(F_V), \omega) \otimes Mes(M(F_V))^*$ et $\mathbf{f} \in I(\tilde{G}(F_V), \omega) \otimes Mes(G(F_V))$, Arthur a défini l'intégrale pondérée ω-équivariante $I_{\tilde{M}}^{\tilde{G}}(\boldsymbol{\gamma}, \mathbf{f})$, cf. [6]. La définition ressemble à celle esquissée en 1.8, mais est de nature mi-locale, mi-globale. Elle est locale en ce sens que $\boldsymbol{\gamma}$ et $\mathbf{f}$ sont des produits d'objets locaux. Elle est globale parce que le poids $v_{\tilde{M}}$ et le processus rendant les intégrales ω-équivariantes ne font intervenir que des espaces de Levi définis sur F. Les termes obtenus sont toutefois reliés à

ceux de 1.8 par la relation suivante. On suppose $\boldsymbol{\gamma} = \otimes_{v\in V}\boldsymbol{\gamma}_v$, $\mathbf{f} = \otimes_{v\in V}\mathbf{f}_v$. D'après [6] théorème 8.1, on a

$$I_{\tilde{M}}^{\tilde{G}}(\boldsymbol{\gamma},\mathbf{f}) = \sum_{\tilde{L}^V\in\mathcal{L}(\tilde{M}_V)} d_{\tilde{M}_V}^{\tilde{G}}(\tilde{M},\tilde{L}^V)\prod_{v\in V} I_{\tilde{M}_v}^{\tilde{L}^v}(\boldsymbol{\gamma}_v,\mathbf{f}_{v,\tilde{L}^v}) \tag{3.1}$$

Expliquons cette formule. On a noté $\mathcal{L}(\tilde{M}_V)$ l'ensemble des familles $\tilde{L}^V = (\tilde{L}^v)_{v\in V}$ telles que, pour tout $v\in V$, $\tilde{L}^v$ est un espace de Levi de $\tilde{G}_v$ contenant $\tilde{M}_v$. Pour tout v, $\mathbf{f}_{v,\tilde{L}^v}$ est l'image de $\mathbf{f}_v$ dans $I(\tilde{L}^v(F_v),\omega_v)$ par l'application "terme constant" usuelle dans la théorie de l'induction. Soit $\tilde{L}^V\in\mathcal{L}(\tilde{M}_V)$. On introduit l'espace $\mathcal{A}_{\tilde{M}_V}^{\tilde{G}} = \oplus_{v\in V}(\mathcal{A}_{\tilde{M}_v}/\mathcal{A}_{\tilde{G}})$ et son sous-espace $\mathcal{A}_{\tilde{L}^V} = \oplus_{v\in V}(\mathcal{A}_{\tilde{L}^v}/\mathcal{A}_{\tilde{G}})$. L'espace $\mathcal{A}_{\tilde{M}}^{\tilde{G}} = \mathcal{A}_{\tilde{M}}/\mathcal{A}_{\tilde{G}}$ se plonge diagonalement dans $\mathcal{A}_{\tilde{M}_V}^{\tilde{G}}$, on note $\Delta_V(\mathcal{A}_{\tilde{M}}^{\tilde{G}})$ son image. Le terme $d_{\tilde{M}_V}^{\tilde{G}}(\tilde{M},\tilde{L}^V)$ est nul sauf si

$$\mathcal{A}_{\tilde{M}_V}^{\tilde{G}} = \Delta_V(\mathcal{A}_{\tilde{M}}^{\tilde{G}})\oplus\mathcal{A}_{\tilde{L}^V}^{\tilde{G}}.$$

Si cette égalité est vérifiée, $d_{\tilde{M}_V}^{\tilde{G}}(\tilde{M},\tilde{L}^V)$ est le rapport entre les mesures sur le membre de droite et celle sur le membre de gauche (ces mesures ont été fixées en 2.9 et 3.1).

3.3. La partie géométrique de la formule des traces tordue ω-équivariante. Pour tout $v\in Val(F)-V_{ram}$, notons $\mathbf{1}_{\tilde{K}_v}$ la fonction caractéristique de $\tilde{K}_v$. On note $C_c^\infty(\tilde{G}(\mathbb{A}))$ l'espace de fonctions sur $\tilde{G}(\mathbb{A})$ engendré par les fonctions $f=\otimes_{v\in Val(F)}f_v$, où $f_v\in C_c^\infty(\tilde{G}(F_v))$ pour tout v et $f_v = \mathbf{1}_{\tilde{K}_v}$ pour presque tout $v\notin V_{ram}$. Primitivement, la formule des traces tordue est une égalité $J_{géom}^{\tilde{G}}(f,\omega) = J_{spec}^{\tilde{G}}(f,\omega)$ pour $f\in C_c^\infty(\tilde{G}(\mathbb{A}))$, les deux termes dépendant d'une mesure de Haar sur $\tilde{G}(\mathbb{A})$. Elle a été établie dans [10], voir [15] pour une rédaction plus complète. Les normalisations différant selon les auteurs, nous utilisons précisément celle de [7]. On ne considère ici que la partie géométrique de cette formule. Comme toujours, nous préférons supprimer le choix de la mesure de Haar et remplacer f par $\mathbf{f}\in C_c^\infty(\tilde{G}(\mathbb{A}))\otimes Mes(G(\mathbb{A}))$. On obtient une expression $J_{géom}^{\tilde{G}}(\mathbf{f},\omega)$. Comme en 2.10, elle n'est pas ω-équivariante en $\mathbf{f}$. Fixons un ensemble fini $V\subset Val(F)$ contenant V_{ram}. On identifie $C_c^\infty(\tilde{G}(F_V))$ à un sous-espace de $C_c^\infty(\tilde{G}(\mathbb{A}))$ en identifiant $\mathbf{f}_V\in C_c^\infty(\tilde{G}(F_V))$ à $\mathbf{f}_V\otimes(\otimes_{v\notin V}\mathbf{1}_{\tilde{K}_v})$. Pour $v\notin V$, le groupe $G(F_v)$ est muni d'une mesure "canonique" pour laquelle la masse totale de K_v vaut 1. On identifie $Mes(G(F_V))$ à $Mes(G(\mathbb{A}))$ en tensorisant une mesure sur $G(F_V)$ par le produit de ces mesures canoniques pour $v\notin V$. On sait alors définir $J_{géom}^{\tilde{G}}(\mathbf{f}_V,\omega)$ pour $\mathbf{f}_V\in C_c^\infty(\tilde{G}(F_V))\otimes Mes(G(F_V))$. Arthur a transformé ce terme en une expression $I_{géom}^{\tilde{G}}(\mathbf{f}_V,\omega)$ qui est ω-équivariante, c'est-à-dire qui se descend en une forme linéaire sur $I(\tilde{G}(F_V),\omega)\otimes Mes(G(F_V))$, cf. [7] et [1] paragraphe 2. Décrivons cette expression.

Notons $\tilde{G}_{ss}$ l'ensemble des éléments semi-simples de $\tilde{G}$ et $\tilde{G}_{ss}(F)/conj$ l'ensemble des classes de conjugaison par $G(F)$ dans $\tilde{G}_{ss}(F)$ (une notation analogue sera utilisée plus loin avec F remplacé par F_V). Pour $\mathcal{O}\in\tilde{G}_{ss}(F)/conj$, on définit une certaine distribution $A^{\tilde{G}}(V,\mathcal{O},\omega)\in D_{orb}(\tilde{G}(F_V),\omega)\otimes Mes(G(F_V))^*$, qui vérifie les conditions suivantes

(i) c'est une combinaison linéaire finie d'intégrales orbitales associées aux images dans $\tilde{G}(F_V)$ d'éléments $\gamma\in\tilde{G}(F)$ dont la partie semi-simple appartient à $\mathcal{O}$;

(ii) $A^{\tilde{G}}(V,\mathcal{O},\omega) = 0$ sauf si, pour tout $v \notin V$, la classe de conjugaison dans $\tilde{G}(F_v)$ engendrée par $\mathcal{O}$ coupe $\tilde{K}_v$;

(iii) $A^{\tilde{G}}(V,\mathcal{O},\omega) = 0$ sauf si ω est trivial sur $Z(G;\mathbb{A})^\theta$ et sur $Z(G_\gamma;\mathbb{A})$ pour tout $\gamma \in \mathcal{O}$.

On note $\mathcal{L}(\tilde{M}_0)$ l'ensemble des espaces de Levi de $\tilde{G}$ contenant $\tilde{M}_0$. Pour une fonction $\mathbf{f}_V \in I(\tilde{G}(F_V),\omega) \otimes Mes(G(F_V))$, on a alors l'égalité

$$I^{\tilde{G}}_{géom}(\mathbf{f}_V,\omega) = \sum_{\tilde{M}\in\mathcal{L}(\tilde{M}_0)} |W^{\tilde{M}}||W^{\tilde{G}}|^{-1} \sum_{\mathcal{O}\in\tilde{M}_{ss}(F)/conj} I^{\tilde{G}}_{\tilde{M}}(A^{\tilde{M}}(V,\mathcal{O},\omega),\mathbf{f}_V) \qquad (3.2)$$

Pour $\mathbf{f}_V$ fixé, il n'y a qu'un nombre fini de termes non nuls. Soulignons que $I^{\tilde{G}}_{géom}(\mathbf{f}_V,\omega)$ et les distributions $A^{\tilde{M}}(V,\mathcal{O},\omega)$ dépendent des espaces $\tilde{K}_v$ pour $v \notin V$, bien que ceux-ci ne figurent pas dans la notation.

Donnons quelques précisions sur la distribution $A^{\tilde{G}}(V,\mathcal{O},\omega)$. Elle dépend de la classe de conjugaison $\mathcal{O} \in \tilde{G}_{ss}(F)/conj$ et de l'ensemble fini $V \supset V_{ram}$. Pour $\mathcal{O}$ fixé, on peut faire varier V. Pour $V \subset V'$, $A^{\tilde{G}}(V,\mathcal{O},\omega)$ et $A^{\tilde{G}}(V',\mathcal{O},\omega)$ sont reliés par une formule qui fait intervenir les intégrales orbitales pondérées (non ω-équivariantes) des fonctions $\mathbf{1}_{\tilde{K}_v}$ pour $v \in V' - V$. Considérons le cas particulier d'une classe $\mathcal{O}$ formée d'éléments fortement réguliers et elliptiques (c'est-à-dire que $\mathcal{O} \cap \tilde{M} = \emptyset$ pour tout espace de Levi $\tilde{M} \subsetneq \tilde{G}$). Supposons que cette classe vérifie les conditions (ii) et (iii). Fixons $\gamma \in \mathcal{O}$. Pour $v \notin V$, on peut d'après (ii) fixer $x_v \in G(F_v)$ tel que $x_v^{-1}\gamma x_v \in \tilde{K}_v$. On voit que l'on peut supposer $x_v = 1$ pour presque tout v. Notons x l'élement de $G(\mathbb{A})$ dont les composantes dans $G(F_v)$ sont x_v si $v \notin V$ et 1 si $v \in V$. Fixons aussi une mesure de Haar sur $G_\gamma(\mathbb{A})$. Par un procédé habituel, on définit un sous-groupe $\mathfrak{A}_{\tilde{G}} \subset A_{\tilde{G}}(\mathbb{A})$ isomorphe à $\mathcal{A}_{\tilde{G}}$ (si $F = \mathbb{Q}$, $\mathfrak{A}_{\tilde{G}}$ est la composante neutre de $A_{\tilde{G}}(\mathbb{R})$ pour la topologie réelle). Supposons V "assez grand", cette condition dépendant de $\mathcal{O}$. De même que ci-dessus, la mesure sur $G_\gamma(\mathbb{A})$ s'identifie à une mesure sur $G_\gamma(F_V)$. Soit dg une mesure de Haar sur $G(F_V)$ et $f_V \in C_c^\infty(\tilde{G}(F_V))$. Pour V assez grand, on a l'égalité

$$I^{\tilde{G}}(A^{\tilde{G}}(V,\mathcal{O},\omega), f_V \otimes dg) = [Z_G(\gamma;F) : G_\gamma(F)]^{-1}\omega(x) mes(\mathfrak{A}_{\tilde{G}}G_\gamma(F)\backslash G_\gamma(\mathbb{A}))$$
$$\int_{G_\gamma(F_V)\backslash G(F_V)} \omega(y) f_V(y^{-1}\gamma y)\, dy,$$

où dy se déduit des deux mesures fixées.

On a une application naturelle $\tilde{G}_{ss}(F)/conj \to \tilde{G}_{ss}(F_V)/conj$. Pour une classe de conjugaison $\mathcal{O}_V \in \tilde{G}_{ss}(F_V)/conj$, posons

$$A^{\tilde{G}}(\mathcal{O}_V,\omega) = \sum_{\mathcal{O}\in\tilde{G}_{ss}(F)/conj, \mathcal{O}\mapsto\mathcal{O}_V} A^{\tilde{G}}(V,\mathcal{O},\omega).$$

On peut reformuler l'égalité (3.2) en

$$I^{\tilde{G}}_{géom}(\mathbf{f}_V,\omega) = \sum_{\tilde{M}\in\mathcal{L}(\tilde{M}_0)} |W^{\tilde{M}}||W^{\tilde{G}}|^{-1} \sum_{\mathcal{O}_V\in\tilde{M}_{ss}(F_V)/conj} I^{\tilde{G}}_{\tilde{M}}(A^{\tilde{M}}(\mathcal{O}_V,\omega),\mathbf{f}_V).$$

3.4. Endoscopie. La notion de donnée endoscopique pour $(G,\tilde{G},\mathbf{a})$ se définit comme en 2.4. La seule différence est que l'on impose que le cocycle a de ce paragraphe a pour image la classe $\mathbf{a}$ dans $H^1(W_F;Z(\hat{G}))/ker^1(F;Z(\hat{G}))$. Soit $\mathbf{G}'=(G',\mathcal{G}',\tilde{s})$ une telle donnée endoscopique. On dit encore qu'elle est elliptique si $Z(\hat{G}')^{\Gamma_F,0}=Z(\hat{G})^{\Gamma_F,\hat{\theta},0}$. Il est associé à $\mathbf{G}'$ un espace tordu $\tilde{G}'$ comme en 2.5. On définit une constante $i(\tilde{G},\tilde{G}')$ de la façon suivante. Elle est nulle si $\mathbf{G}'$ n'est pas elliptique. Supposons $\mathbf{G}'$ elliptique. Notons $Aut(\mathbf{G}')$ le groupe des $x\in\hat{G}$ tels que $x\mathcal{G}'x^{-1}=\mathcal{G}'$ et $x\tilde{s}x^{-1}\in Z(\hat{G})\tilde{s}$. Notons

$$\tau(G)=|\pi_0(Z(\hat{G})^{\Gamma_F})||ker^1(F;Z(\hat{G}))|^{-1},$$

où π_0 désigne le groupe des composantes connexes. On pose

$$i(\tilde{G},\tilde{G}')=|det((1-\theta)_{|\mathcal{A}_G/\mathcal{A}_{\tilde{G}}})|^{-1}|\pi_0(Aut(\mathbf{G}'))|^{-1}\tau(G)\tau(G')^{-1}$$

$$|\pi_0(Z(\hat{G})^{\Gamma_F,0}\cap Z(\hat{G}'))|.$$

Pour tout $v\in Val(F)$, la donnée se localise en une donnée $\mathbf{G}'_v=(G'_v,\mathcal{G}'_v,\tilde{s})$ de $(G_v,\tilde{G}_v,\mathbf{a}_v)$, où $\mathbf{a}_v$ est l'image de $\mathbf{a}$ dans $H^1(W_{F_v};Z(\hat{G}))$. On dit que $\mathbf{G}'$ est relevante si $\tilde{G}'(F)\neq\emptyset$ et si, pour toute place $v\in Val(F)$, $\mathbf{G}'_v$ est relevante. Soit V un ensemble fini de places de F contenant V_{ram}. On dit que $\mathbf{G}'$ est non ramifiée hors de V si le sous-groupe d'inertie $I_v\subset W_{F_v}$ (qui est un sous-groupe de ${}^LG_v$) est contenu dans $\mathcal{G}'_v$. Si $\mathbf{G}'$ est non ramifiée hors de V, on montre que les conditions imposées à V_{ram} (que l'on n'a pas explicitées) valent aussi pour l'ensemble de places V et pour le couple $(G',\tilde{G}')$ (ou, si l'on préfère, pour le triplet obtenu en complétant ce couple par le cocycle $\mathbf{a}'$ trivial). Pour $v\in Val(F)-V$, le choix que l'on a fait de l'espace hyperspécial $\tilde{K}_v$ détermine un espace hyperspécial $\tilde{K}'_v\subset\tilde{G}'(F_v)$. Plus exactement, cet espace n'est déterminé qu'à conjugaison près par $G'_{AD}(F_v)$, où G'_{AD} est le groupe adjoint de G' mais les constructions ultérieures seront insensibles à une telle conjugaison. On fixe ainsi une famille $(\tilde{K}'_v)_{v\notin V}$, à laquelle on impose, comme il est loisible, la même condition de compatibilité globale qu'en 3.1.

Considérons une donnée endoscopique $\mathbf{G}'=(G',\mathcal{G}',\tilde{s})$ relevante et non ramifiée hors de V. On fixe des données auxiliaires G'_1, $\tilde{G}'_1$, C_1 et $\hat{\xi}_1$ comme en 2.7, ces données étant maintenant définies sur F. On leur impose, comme il est loisible, certaines conditions de non ramification hors de V. Ces conditions impliquent que l'on peut fixer pour tout $v\notin V$ un espace hyperspécial $\tilde{K}'_{1,v}\subset\tilde{G}'_1(F_v)$ qui se projette sur $\tilde{K}'_v$. On impose à ces données la même condition de compatibilité globale qu'en 3.1. En tensorisant les constructions de 2.7 sur les places $v\in V$, on définit des espaces $C^\infty_{c,\lambda_1}(\tilde{G}'_1(F_V))$, $I_{\lambda_1}(\tilde{G}'_1(F_V))$ etc..., ainsi que leurs avatars canoniques $C^\infty_c(\mathbf{G}'_V)$, $I(\mathbf{G}'_V)$ etc... Pour identifier par exemple $C^\infty_{c,\lambda_1}(\tilde{G}'_1(F_V))$ à $C^\infty_c(\mathbf{G}'_V)$, on doit choisir pour tout $v\in V$ un facteur de transfert $\Delta_{1,v}$. En fait, l'identification ne dépend que du produit $\Delta_{1,V}=\otimes_{v\in V}\Delta_{1,v}$. Un point important est que le choix que l'on vient de faire des espaces $\tilde{K}'_{1,v}$ pour $v\notin V$ détermine un tel facteur $\Delta_{1,V}$. En effet, pour tout $v\notin V$, le choix de $\tilde{K}'_{1,v}$ détermine un facteur de transfert $\Delta_{1,v}$. D'autre part, on peut définir canoniquement un facteur de transfert global, cf. [11] lemme 7.3A, [14] paragraphe IV.2. C'est-à-dire, considérons des éléments $\delta_1=(\delta_{1,v})_{v\in Val(F)}\in\tilde{G}'_1(\mathbb{A})$ et $\gamma=(\gamma_v)_{v\in Val(F)}\in\tilde{G}(\mathbb{A})$. Supposons que, pour tout v, γ_v soit fortement régulier et que $\delta_{1,v}$ et γ_v se correspondent. Imposons de plus à δ et γ une certaine condition de non ramification (impliquant que $\Delta_{1,v}(\delta_{1,v},\gamma_v)=1$ pour presque tout $v\notin V$). Alors on peut définir un facteur global $\Delta_1(\delta_1,\gamma)$. On normalise le facteur $\Delta_{1,V}$ de sorte que, pour de tels δ_1 et γ,

on ait l'égalité

$$\Delta_1(\delta_1,\gamma)=\Delta_{1,V}(\delta_{1,V},\gamma_V)\prod_{v\notin V}\Delta_{1,v}(\delta_{1,v},\gamma_v),$$

où $\delta_{1,V}=(\delta_{1,v})_{v\in V}$ et $\gamma_V=(\gamma_v)_{v\in V}$. Soit $\mathcal{O}'_V\in\tilde{G}'_{ss}(F_V)/conj$. Les constructions de 3.3 s'adaptent et on définit un élément $A^{\tilde{G}'_1}_{\lambda_1}(\mathcal{O}'_V)$. C'est une combinaison linéaire d'intégrales orbitales vues comme des formes linéaires sur $I_{\lambda_1}(\tilde{G}'_1(F_V))\otimes Mes(G'(F_V))$. A l'aide du facteur $\Delta_{1,V}$ ci-dessus, on l'identifie à un élément $A^{\mathbf{G}'}(\mathcal{O}'_V)\in D_{orb}(\mathbf{G}')\otimes Mes(G'(F))^*$. Le terme $A^{\tilde{G}'_1}_{\lambda_1}(\mathcal{O}'_V)$ dépend des choix des $\tilde{K}'_{1,v}$ mais le facteur $\Delta_{1,V}$ aussi. On voit alors que $A^{\mathbf{G}'}(\mathcal{O}'_V)$ ne dépend plus que des $\tilde{K}'_v$. On montre qu'il ne dépend pas du choix des données auxiliaires $G'_1,\dots,\hat{\xi}_1$.

L'ensemble des classes d'équivalence de données endoscopiques elliptiques, relevantes et non ramifiées hors de V est fini, on en fixe un ensemble de représentants $\mathcal{E}(\tilde{G},\mathbf{a},V)$.

3.5. Intégrales orbitales pondérées stables. On suppose G quasi-déployé, $\tilde{G}$ à torsion intérieure et $\mathbf{a}=1$. Soient $\tilde{M}$ un espace de Levi de $\tilde{G}$ et V un ensemble fini de places de F contenant V_{ram}. Pour une place archimédienne v de F, on introduit les espaces de distributions $D_{tr-orb}(\tilde{M}(F_v))$ et $D^{st}_{tr-orb}(\tilde{M}(F_v))$ évoqués en 2.13. Pour une place v non-archimédienne, on définit ces espaces comme étant simplement égaux à $D_{orb}(\tilde{M}(F_v))$, resp. $D^{st}_{orb}(\tilde{M}(F_v))$. On définit les produits tensoriels de ces espaces sur les places $v\in V$, que l'on note $D_{tr-orb}(\tilde{M}(F_V))$ et $D^{st}_{tr-orb}(\tilde{M}(F_V))$. La définition des intégrales orbitales pondérées invariantes $I^{\tilde{G}}_{\tilde{M}}(\boldsymbol{\gamma}_V,\mathbf{f}_V)$ de 3.2 s'étend au cas où $\boldsymbol{\gamma}_V$ appartient à $D_{tr-orb}(\tilde{M}(F_V))\otimes Mes(M(F_V))^*$. Cela étant, pour

$$\boldsymbol{\delta}_V\in D^{st}_{tr-orb}(\tilde{M}(F_V))\otimes Mes(M(F_V))^*\text{ et }\mathbf{f}_V\in I(\tilde{G}(F_V))\otimes Mes(G(F_V)),$$

on définit l'intégrale orbitale pondérée stable par la même formule qu'en 2.11 :

$$S^{\tilde{G}}_{\tilde{M}}(\boldsymbol{\delta}_V,\mathbf{f}_V)=I^{\tilde{G}}_{\tilde{M}}(\boldsymbol{\delta}_V,\mathbf{f}_V)-\sum_{s\in Z(\hat{M})^{\Gamma_F}/Z(\hat{G})^{\Gamma_F},s\neq 1}i_{\tilde{M}}(\tilde{G},\tilde{G}'(s))S^{\mathbf{G}'(s)}_{\mathbf{M}}(\boldsymbol{\delta}_V,\mathbf{f}^{\mathbf{G}'(s)}_V).$$

Comme dans ce paragraphe, cette définition n'est légitime que grâce au résultat suivant.

Proposition 3.1. *Pour tout élément $\boldsymbol{\delta}_V\in D^{st}_{tr-orb}(\tilde{M}(F_V))\otimes Mes(M(F_V))^*$, la forme linéaire $\mathbf{f}_V\mapsto S^{\tilde{G}}_{\tilde{M}}(\boldsymbol{\delta}_V,\mathbf{f}_V)$ est stable, c'est-à-dire se descend en une forme linéaire sur $SI(\tilde{G}(F_V))\otimes Mes(G(F_V))$.*

Cela se déduit du théorème 2.11 car on montre que les intégrales $S^{\tilde{G}}_{\tilde{M}}(\boldsymbol{\delta}_V,\mathbf{f}_V)$ s'expriment à l'aide des intégrales locales de ce paragraphe par une formule parallèle à (3.1).

3.6. Coefficients stables. On suppose G quasi-déployé, $\tilde{G}$ à torsion intérieure et $\mathbf{a}=1$. Soit V un ensemble fini de places de F contenant V_{ram}. Pour $\mathcal{O}_V\in\tilde{G}_{ss}(F_V)/conj$, on a défini en 3.3 la distribution $A^{\tilde{G}}(\mathcal{O}_V)\in D_{orb}(\tilde{G}(F_V))\otimes Mes(G(F_V))^*$. Pour une réunion finie $\mathcal{O}_V=\sqcup_{i=1,\dots,n}\mathcal{O}_{V,i}$ de telles classes, on pose $A^{\tilde{G}}(\mathcal{O}_V)=\sum_{i=1,\dots,n}A^{\tilde{G}}(\mathcal{O}_{V,i})$. Notons $\tilde{G}_{ss}(F_V)/st-conj$ l'ensemble des classes de conjugaison stable dans $\tilde{G}_{ss}(F_V)$. Pour un élément $\mathcal{O}_V$ de cet ensemble, ou pour une réunion finie de telles classes, on définit un

élément $SA^{\tilde{G}}(\mathcal{O}_V) \in D_{tr-orb}(\tilde{G}(F_V)) \otimes Mes(G(F_V))^*$ par la formule de récurrence

$$SA^{\tilde{G}}(\mathcal{O}_V) = A^{\tilde{G}}(\mathcal{O}_V) - \sum_{\mathbf{G}' \in \mathcal{E}(\tilde{G},\mathbf{a},V), G' \neq G} i(\tilde{G},\tilde{G}') transfert(SA^{\mathbf{G}'}(\mathcal{O}_V^{\tilde{G}'})).$$

Expliquons cette formule. Pour $\mathbf{G}' \in \mathcal{E}(\tilde{G},\mathbf{a},V)$, on note $\mathcal{O}_V^{\tilde{G}'}$ la réunion des classes de conjugaison stable dans $\tilde{G}'_{ss}(F_V)$ correspondant à une classe de conjugaison stable dans $\tilde{G}(F_V)$ contenue dans $\mathcal{O}_V$. Cette réunion est finie. Si $G' \neq G$, fixons des données auxiliaires G'_1,...,$(\tilde{K}'_{1,v})_{v \notin V}$ comme en 3.4. On peut supposer par récurrence sur $dim(G_{SC})$ que l'on a défini la variante $SA^{\tilde{G}'_1}_{\lambda_1}(\mathcal{O}_V^{\tilde{G}'})$ de notre distribution. Par le même procédé qu'en 3.4, elle s'identifie à un élément $SA^{\mathbf{G}'}(\mathcal{O}_V^{\tilde{G}'}) \in D_{tr-orb}(\mathbf{G}'_V) \otimes Mes(G'(F_V))^*$. On montre que cette distribution ne dépend plus des choix des espaces $\tilde{K}'_v$ pour $v \notin V$, mais seulement des $\tilde{K}_v$, lesquels sont fixés une fois pour toutes. Le théorème suivant montre que ces distributions sont stables, on peut donc les transférer.

Théorème 3.2. *Pour tout $\mathcal{O}_V \in \tilde{G}_{ss}(F_V)/st-conj$, la distribution $SA^{\tilde{G}}(\mathcal{O}_V)$ est stable.*

On voit par récurrence que la distribution $SA^{\tilde{G}}(\mathcal{O}_V)$ est supportée par les éléments de $\tilde{G}(F_V)$ dont la partie semi-simple appartient à $\mathcal{O}_V$.

3.7. La formule stable. On suppose G quasi-déployé, $\tilde{G}$ à torsion intérieure et $\mathbf{a} = 1$. Soit V un ensemble fini de places de F contenant V_{ram}. Pour $\mathbf{f}_V \in SI(\tilde{G}(F_V)) \otimes Mes(G(F_V))$, on pose

$$S^{\tilde{G}}_{géom}(\mathbf{f}_V) = \sum_{\tilde{M} \in \mathcal{L}(\tilde{M}_0)} |W^{\tilde{M}}||W^{\tilde{G}}|^{-1} \sum_{\mathcal{O}_V \in \tilde{M}_{ss}(F_V)/st-conj} S^{\tilde{G}}_{\tilde{M}}(SA^{\tilde{M}}(\mathcal{O}_V), \mathbf{f}_V).$$

On montre que, pour $\mathbf{f}_V$ fixé, il n'y a dans cette somme qu'un nombre fini de termes non nuls.

3.8. Le théorème principal. Le triplet $(G,\tilde{G},\mathbf{a})$ est ici quelconque. Soit V un ensemble fini de places contenant V_{ram}.

Théorème 3.3. *Pour tout $\mathbf{f}_V \in I(\tilde{G}(F_V),\omega) \otimes Mes(G(F_V))$, on a l'égalité*

$$I_{géom}(\mathbf{f}_V,\omega) = \sum_{\mathbf{G}' \in \mathcal{E}(\tilde{G},\mathbf{a},V)} i(\tilde{G},\tilde{G}') S^{\mathbf{G}'}_{géom}(\mathbf{f}_V^{\mathbf{G}'}).$$

La démonstration de ce théorème est très longue. En particulier, on doit utiliser la partie spectrale de la formule des traces, dont on n'a pas du tout parlé ici.

3.9. Endoscopie non standard. A plusieurs reprises, on utilise dans les preuves la méthode de descente d'Harish-Chandra. Dans le cas tordu, cette méthode appliquée à l'endoscopie fait apparaître des "triplets endoscopiques non standard". Plusieurs de nos assertions ont des contreparties pour de tels triplets. Indiquons-en une. Considérons deux groupes réductifs connexes G_1 et G_2 définis et quasi-déployés sur F. On les suppose simplement connexes. Pour $i = 1,2$, on fixe une paire de Borel (B_i,T_i) de G_i définie sur F, on note $\Sigma(T_i)$ l'ensemble des racines de T_i dans $\mathfrak{g}_i$ et $\check{\Sigma}(T_i)$ l'ensemble des coracines. On suppose donnés

un isomorphisme $j : \mathfrak{t}_1 \to \mathfrak{t}_2$ et une bijection $\tau : \Sigma(T_2) \to \Sigma(T_1)$ équivariants pour les actions galoisiennes. Il se déduit de τ une bijection $\check{\tau} : \check{\Sigma}(T_1) \to \check{\Sigma}(T_2)$ entre ensembles de coracines. On suppose que, pour tout $\check{\alpha} \in \check{\Sigma}(T_1)$, $j(\check{\alpha})$ est un multiple rationnel positif de $\check{\tau}(\check{\alpha})$ et que, pour tout $\alpha \in \Sigma(T_2)$, l'application duale j^* envoie α sur un multiple rationnel positif de $\tau(\alpha)$. L'exemple le plus frappant est le cas où $G_1 = Sp(2n)$, $G_2 = Spin(2n+1)$ et j envoie une coracine courte sur une coracine longue et une coracine longue sur deux fois une coracine courte .

Soit $v \in Val(F)$. L'isomorphisme j permet de définir une correspondance bijective entre classes de conjugaison stable semi-simples dans les algèbres de Lie $\mathfrak{g}_1(F_v)$ et $\mathfrak{g}_2(F_v)$. On peut alors définir un transfert similaire à celui de 2.7, mais au niveau des algèbres de Lie. L'analogue du "facteur de transfert" vaut 1 sur deux éléments qui se correspondent. Par l'exponentielle, on peut remonter le transfert aux groupes si on se limite à des fonctions ou des distributions à support assez proche de l'élément neutre. Pour $i = 1, 2$, on s'intéresse particulièrement à l'espace des distributions stables sur $\tilde{G}_i(F_v)$ qui sont à support unipotent. On le note $D^{st}_{unip}(\tilde{G}_i(F_v))$. Pour tout ensemble fini V de places de F, le transfert se restreint en un isomorphisme

$$D^{st}_{unip}(\tilde{G}_1(F_V)) \otimes Mes(G_1(F_V))^* \simeq D^{st}_{unip}(\tilde{G}_2(F_V)) \otimes Mes(G_2(F_V))^* \tag{3.3}$$

Soit V un ensemble fini de places de $Val(F)$, contenant les places archimédiennes et assez grand pour que, pour $v \notin V$, le triplet localisé $(G_{1,v}, G_{2,v}, j)$ vérifie une certaine condition de non ramification. Pour $i = 1, 2$, on applique les définitions des paragraphes précédents en prenant $G = G_i$, $\tilde{G} = G_i$ et $\mathbf{a} = 1$. Ainsi, pour $\mathcal{O}_V \in G_{i,ss}(F_V)/st - conj$, on dispose d'une distribution $SA^{G_i}(\mathcal{O}_V)$. Il s'avère qu'elle ne dépend pas des choix des sous-groupes hyperspéciaux hors de V (ni des espaces hyperspéciaux, qui, ici, sont forcément égaux à ces groupes). Pour $\mathcal{O}_V = \{1\}$, on note plutôt $SA^{G_i}_{unip}(V)$ cette distribution. C'est un élément de $D^{st}_{unip}(\tilde{G}_i(F_V)) \otimes Mes(G_i(F_V))^*$.

Théorème 3.4. *Les éléments $SA^{G_1}_{unip}(V)$ et $SA^{G_2}_{unip}(V)$ se correspondent par l'isomorphisme* (3.3).

Translation invariance, exponential sums, and Waring's problem

Trevor D. Wooley

Abstract. We describe mean value estimates for exponential sums of degree exceeding 2 that approach those conjectured to be best possible. The vehicle for this recent progress is the *efficient congruencing method*, which iteratively exploits the translation invariance of associated systems of Diophantine equations to derive powerful congruence constraints on the underlying variables. There are applications to Weyl sums, the distribution of polynomials modulo 1, and other Diophantine problems such as Waring's problem.

Mathematics Subject Classification (2010). Primary 11L15; Secondary 11P05.

Keywords. Exponential sums, Waring's problem, Hardy-Littlewood method.

1. Introduction

Although pivotal to the development of vast swathes of analytic number theory in the twentieth century, the differencing methods devised by Weyl [54] and van der Corput [15] are in many respects unsatisfactory. In particular, they improve on the trivial estimate for an exponential sum by a margin exponentially small in terms of its degree. The method introduced by Vinogradov [50, 51] in 1935, based on mean values, is rightly celebrated as a great leap forward, replacing this exponentially weak margin by one polynomial in the degree. Nonetheless, Vinogradov's methods yield bounds removed from the sharpest conjectured to hold by a margin at least logarithmic in the degree, a defect that has endured for six decades since the era in which these ideas were comprehensively analysed. In this report, we describe progress since 2010 that eliminates this defect, placing us within a whisker of establishing in full the main conjecture of the subject.

When $k, s \in \mathbb{N}$ and $\boldsymbol{\alpha} \in \mathbb{R}^k$, consider the exponential sum

$$f_k(\boldsymbol{\alpha}; X) = \sum_{1 \le x \le X} e(\alpha_1 x + \ldots + \alpha_k x^k) \tag{1.1}$$

and the mean value

$$J_{s,k}(X) = \oint |f_k(\boldsymbol{\alpha}; X)|^{2s} \, \mathrm{d}\boldsymbol{\alpha}. \tag{1.2}$$

Here, as usual, we write $e(z)$ for $e^{2\pi i z}$. Also, to save clutter, when $G : [0,1)^k \to \mathbb{C}$ is integrable, we write $\oint G(\boldsymbol{\alpha}) \, \mathrm{d}\boldsymbol{\alpha} = \int_{[0,1]^k} G(\boldsymbol{\alpha}) \, \mathrm{d}\boldsymbol{\alpha}$. By orthogonality, one sees that $J_{s,k}(X)$

Proceedings of the International Congress of Mathematicians, Seoul, 2014

counts the number of integral solutions of the system of equations

$$x_1^j + \ldots + x_s^j = y_1^j + \ldots + y_s^j \quad (1 \le j \le k), \tag{1.3}$$

with $1 \le x_i, y_i \le X$ $(1 \le i \le s)$. Upper bounds for $J_{s,k}(X)$ are known collectively as *Vinogradov's mean value theorem*. We now focus discussion by recording the classical version of this theorem that emerged from the first half-century of refinements following Vinogradov's seminal paper [50] (see in particular [27, 33, 51]), culminating in the papers of Karatsuba [29] and Stechkin [42].

Theorem 1.1. *There is an absolute constant $A > 0$ having the property that, whenever s, r and k are natural numbers with $s \ge rk$, then*

$$J_{s,k}(X) \le C(k,r)X^{2s-k(k+1)/2+\Delta_{s,k}}, \tag{1.4}$$

where $\Delta_{s,k} = \frac{1}{2}k^2(1-1/k)^r$ and $C(k,r) = \min\{k^{Ask}, k^{Ak^3}\}$.

We will not concern ourselves with the dependence on s and k of constants such as $C(k,r)$ appearing in bounds for $J_{s,k}(X)$ and its allies (but see [57] for improvements in this direction). Although significant in applications to the zero-free region of the Riemann zeta function, this is not relevant to those central to this paper. Thus, implicit constants in the notation of Landau and Vinogradov will depend at most on s, k and ε, unless otherwise indicated[1].

When $k \ge 2$, the exponent $\Delta_{s,k}$ of Theorem 1.1 satisfies $\Delta_{s,k} \le k^2e^{-s/k^2}$, and so $\Delta_{s,k} = O(1/\log k)$ for $s \ge k^2(2\log k + \log\log k)$. One can refine (1.4) to obtain an asymptotic formula when s is slightly larger (see [2, Theorem 3.9], for example).

Theorem 1.2. *Let $k, s \in \mathbb{N}$ and suppose that $s \ge k^2(2\log k + \log\log k + 5)$. Then there exists a positive number $\mathfrak{C}(s,k)$ with $J_{s,k}(X) \sim \mathfrak{C}(s,k)X^{2s-k(k+1)/2}$.*

With these theorems in hand, we consider the motivation for investigating the sums $f_k(\boldsymbol{\alpha}; X)$. Many number-theoretic functions may be estimated in terms of such sums. Thus, when $\mathrm{Re}(s)$ is close to 1, estimates for the Riemann zeta function $\zeta(s)$ stem from partial summation and Taylor expansions for $\log(1+x/N)$, since

$$\sum_{N<n\le N+X} n^{-it} = N^{-it} \sum_{1\le x\le X} e\Big(-\frac{t}{2\pi}\log(1+x/N)\Big).$$

On the other hand, specialisations of $f_k(\boldsymbol{\alpha}; X)$ arise naturally in applications of interest. Indeed, work on the asymptotic formula in Waring's problem depends on the sum obtained by setting $\alpha_1 = \ldots = \alpha_{k-1} = 0$ and $\alpha_k = \beta$, namely

$$g_k(\beta; X) = \sum_{1\le x\le X} e(\beta x^k). \tag{1.5}$$

[1]Given a complex-valued function $f(t)$ and positive function $g(t)$, we use Vinogradov's notation $f(t) \ll g(t)$, or Landau's notation $f(t) = O(g(t))$, to mean that there is a positive number C for which $f(t) \le Cg(t)$ for all large enough values of t. Also, we write $f(t) \gg g(t)$ when $g(t) \ll f(t)$. If C depends on certain parameters, then we indicate this by appending these as subscripts to the notation. Also, we write $f(t) = o(g(t))$ when $f(t)/g(t) \to 0$ as $t \to \infty$. Finally, we use the convention that whenever ε occurs in a statement, then the statement holds for each fixed $\varepsilon > 0$.

Writing $R_{s,k}(n)$ for the number of representations of n as the sum of s positive integral kth powers, one finds by orthogonality that

$$R_{s,k}(n) = \int_0^1 g_k(\beta; n^{1/k})^s e(-\beta n)\,\mathrm{d}\beta.$$

The uninitiated reader will wonder why one should focus on estimates for the mean value $J_{s,k}(X)$ when many applications depend on pointwise estimates for $f_k(\boldsymbol{\alpha}; X)$. Vinogradov observed that mean value estimates suffice to obtain useful pointwise estimates for $f_k(\boldsymbol{\alpha}; X)$. To see why this is the case, note first that $|f_k(\boldsymbol{\beta}; X)|$ differs little from $|f_k(\boldsymbol{\alpha}; X)|$ provided that the latter is large, and in addition $|\beta_j - \alpha_j|$ is rather smaller than X^{-j} for each j, so that $\boldsymbol{\beta}$ lies in a small neighbourhood of $\boldsymbol{\alpha}$ having measure of order $X^{-k(k+1)/2}$. Second, one sees from (1.1) that for each integer h the sum $f_k(\boldsymbol{\alpha}; X)$ may be rewritten in the form

$$f_k(\boldsymbol{\alpha}; X) = \sum_{1-h \le x \le X-h} e\big(\alpha_1(x+h) + \ldots + \alpha_k(x+h)^k\big).$$

By estimating the tails of this sum and applying the binomial theorem to identify the coefficient of each monomial x^j, one obtains new k-tuples $\boldsymbol{\alpha}^{(h)}$ for which $f_k(\boldsymbol{\alpha}; X) = f_k(\boldsymbol{\alpha}^{(h)}; X) + O(|h|)$. These ideas combine to show that one large value $|f_k(\boldsymbol{\alpha}; X)|$ generates a collection of neighbourhoods $\mathfrak{B}(h)$, with the property that whenever $\boldsymbol{\beta} \in \mathfrak{B}(h)$, then $|f_k(\boldsymbol{\beta}; X)|$ is almost as large as $|f_k(\boldsymbol{\alpha}; X)|$. Given N disjoint such neighbourhoods over which to integrate $|f_k(\boldsymbol{\beta}; X)|^{2s}$, non-trivial estimates for $|f_k(\boldsymbol{\alpha}; X)|$ follow from the relation

$$NX^{-k(k+1)/2}|f_k(\boldsymbol{\alpha}; X)|^{2s} \ll J_{s,k}(X).$$

This circle of ideas leads to the following theorem (see [11] and [47, Theorem 5.2]).

Theorem 1.3. *Let k be an integer with $k \ge 2$, and let $\boldsymbol{\alpha} \in \mathbb{R}^k$. Suppose that there exists a natural number j with $2 \le j \le k$ such that, for some $a \in \mathbb{Z}$ and $q \in \mathbb{N}$ with $(a,q) = 1$, one has $|\alpha_j - a/q| \le q^{-2}$. Then one has*

$$f_k(\boldsymbol{\alpha}; X) \ll \Big(X^{k(k-1)/2} J_{s,k-1}(2X)(q^{-1} + X^{-1} + qX^{-j})\Big)^{1/(2s)} \log(2X).$$

To illustrate the power of this theorem, suppose that k is large, and β satisfies the condition that, whenever $b \in \mathbb{Z}$ and $q \in \mathbb{N}$ satisfy $(b,q) = 1$ and $|q\beta - b| \le X^{1-k}$, then $q > X$. By substituting the conclusion of Theorem 1.1 into Theorem 1.3, one finds that $g_k(\beta; X) \ll X^{1-\sigma(k)}$, where $\sigma(k)^{-1} = (4 + o(1))k^2 \log k$.

2. Translation invariance and a congruencing idea

A key feature of the system of equations (1.3) is *translation-dilation invariance*. Thus, the pair $\boldsymbol{x}, \boldsymbol{y}$ is an integral solution of the system

$$x_1^j + \ldots + x_t^j = y_1^j + \ldots + y_t^j \quad (1 \le j \le k), \tag{2.1}$$

if and only if, for any $\xi \in \mathbb{Z}$ and $q \in \mathbb{N}$, the pair $\boldsymbol{x}, \boldsymbol{y}$ satisfies the system

$$(qx_1 + \xi)^j + \ldots + (qx_t + \xi)^j = (qy_1 + \xi)^j + \ldots + (qy_t + \xi)^j \quad (1 \le j \le k). \tag{2.2}$$

This property ensures that $J_t(X)$ is homogeneous with respect to restriction to arithmetic progressions[2]. Let $M = X^\theta$ be a parameter to be chosen later, consider a set $\mathcal{P}$ of $\lceil k^2/\theta \rceil$ primes p with $M < p \le 2M$, and fix some $p \in \mathcal{P}$. Also, define

$$\mathfrak{f}_c(\boldsymbol{\alpha};\xi) = \sum_{\substack{1\le x\le X\\ x\equiv \xi \pmod{p^c}}} e(\alpha_1 x + \ldots + \alpha_k x^k).$$

Since $\oint |\mathfrak{f}_c(\boldsymbol{\alpha};\xi)|^{2t}\,\mathrm{d}\boldsymbol{\alpha}$ counts the number of solutions of (2.2), with $q = p^c$, for which[3] $(1-\xi)/q \le \boldsymbol{x}, \boldsymbol{y} \le (X-\xi)/q$, by translation-dilation invariance, it counts solutions of (2.1) under the same conditions on $\boldsymbol{x}$ and $\boldsymbol{y}$. Thus

$$\max_{1\le \xi\le p^c} \oint |\mathfrak{f}_c(\boldsymbol{\alpha};\xi)|^{2t}\,\mathrm{d}\boldsymbol{\alpha} \ll 1 + J_t(X/M^c). \tag{2.3}$$

Translation invariance also generates useful auxiliary congruences. Let $t = s + k$, and consider the solutions of (2.1) with $1 \le \boldsymbol{x}, \boldsymbol{y} \le X$. The number of solutions T_0 in which $x_i = x_j$ for some $1 \le i < j \le k$ may be bounded via orthogonality and Hölder's inequality, giving $T_0 \ll J_t(X)^{1-1/(2t)}$. Given a *conditioned* solution with $x_i \ne x_j$ for $1 \le i < j \le k$, there exists a prime $p \in \mathcal{P}$ with $x_i \not\equiv x_j \pmod p$ for $1 \le i < j \le k$. Let $\Xi_c(\xi)$ denote the set of k-tuples $(\xi_1, \ldots, \xi_k)$, with $1 \le \boldsymbol{\xi} \le p^{c+1}$ and $\boldsymbol{\xi} \equiv \xi \pmod{p^c}$, and satisfying the property that $\xi_i \not\equiv \xi_j \pmod{p^{c+1}}$ for $i \ne j$. Also, put

$$\mathfrak{F}_c(\boldsymbol{\alpha};\xi) = \sum_{\boldsymbol{\xi}\in \Xi_c(\xi)} \mathfrak{f}_{c+1}(\boldsymbol{\alpha};\xi_1)\ldots\mathfrak{f}_{c+1}(\boldsymbol{\alpha};\xi_k),$$

and define

$$I_{a,b}(X) = \max_{\xi,\eta} \oint |\mathfrak{F}_a(\boldsymbol{\alpha};\xi)^2 \mathfrak{f}_b(\boldsymbol{\alpha};\eta)^{2s}|\,\mathrm{d}\boldsymbol{\alpha}. \tag{2.4}$$

Then for some $p \in \mathcal{P}$, which we now fix, the number T_1 of conditioned solutions satisfies

$$T_1 \ll \oint \mathfrak{F}_0(\boldsymbol{\alpha};0) f(\boldsymbol{\alpha};X)^s f(-\boldsymbol{\alpha};X)^{s+k}\,\mathrm{d}\boldsymbol{\alpha}. \tag{2.5}$$

Thus, by Schwarz's inequality and orthogonality, one has $T_1 \ll I_{0,0}(X)^{1/2} J_t(X)^{1/2}$. By combining the above estimates for T_0 and T_1, we derive the upper bound

$$J_t(X) \ll J_t(X)^{1-1/(2t)} + I_{0,0}(X)^{1/2} J_t(X)^{1/2},$$

whence $J_t(X) \ll I_{0,0}(X)$.

By Hölder's inequality, one finds that

$$|f(\boldsymbol{\alpha};X)|^{2s} = \Big|\sum_{\eta=1}^{p} \sum_{\substack{1\le x\le X\\ x\equiv \eta \pmod p}} e(\alpha_1 x + \ldots + \alpha_k x^k)\Big|^{2s} \le p^{2s-1} \sum_{\eta=1}^{p} |\mathfrak{f}_1(\boldsymbol{\alpha};\eta)|^{2s}.$$

[2] In this section we consider k to be fixed, and hence we drop mention of k from our notations.

[3] Here we make use of slightly unconventional vector notation. Thus, we write $\boldsymbol{z} \equiv \xi \pmod q$ when $z_i \equiv \xi \pmod q$ for $1 \le i \le t$, or $a \le \boldsymbol{z} \le b$ when $a \le z_i \le b$ $(1 \le i \le t)$, and so on.

Thus, on noting the trivial relation $f(\boldsymbol{\alpha};X)=\mathfrak{f}_0(\boldsymbol{\alpha};\eta)$, one sees from (2.4) that

$$J_t(X)\ll I_{0,0}(X)\ll M^{2s}\max_{\xi,\eta}\oint|\mathfrak{F}_0(\boldsymbol{\alpha};\xi)^2\mathfrak{f}_1(\boldsymbol{\alpha};\eta)^{2s}|\,\mathrm{d}\boldsymbol{\alpha}=M^{2s}I_{0,1}(X). \tag{2.6}$$

The mean value underlying $I_{0,1}(X)$ counts the number of integral solutions of

$$\sum_{i=1}^k(x_i^j-y_i^j)=\sum_{l=1}^s\big((pu_l+\eta)^j-(pv_l+\eta)^j\big)\quad(1\le j\le k),$$

with $1\le\boldsymbol{x},\boldsymbol{y}\le X$ and $1\le p\boldsymbol{u}+\eta,p\boldsymbol{v}+\eta\le X$, in which $x_i\not\equiv x_j\pmod p$ for $i\ne j$, and similarly for $\boldsymbol{y}$. Translation invariance leads from these equations to

$$\sum_{i=1}^k\big((x_i-\eta)^j-(y_i-\eta)^j\big)=p^j\sum_{l=1}^s(u_l^j-v_l^j)\quad(1\le j\le k),$$

and hence

$$(x_1-\eta)^j+\ldots+(x_k-\eta)^j\equiv(y_1-\eta)^j+\ldots+(y_k-\eta)^j\pmod{p^j}\quad(1\le j\le k). \tag{2.7}$$

Since the x_i are distinct modulo p, Hensel's lemma shows that, for each fixed choice of $\boldsymbol{y}$, there are at most $k!p^{k(k-1)/2}$ choices for $\boldsymbol{x}\pmod{p^k}$ satisfying (2.7). An application of Cauchy's inequality shows from here that

$$I_{0,1}(X)\ll M^{k(k-1)/2}\max_{\eta}\oint\bigg(\sum_{\nu=1}^{p^k}|\mathfrak{f}_k(\boldsymbol{\alpha};\nu)|^2\bigg)^k|\mathfrak{f}_1(\boldsymbol{\alpha};\eta)|^{2s}\,\mathrm{d}\boldsymbol{\alpha}. \tag{2.8}$$

Although our notation has been crafted for later discussion of efficient congruencing, the classical approach remains visible. One applies (2.8) with $\theta=1/k$, so that $p^k>X$. Thus $|\mathfrak{f}_k(\boldsymbol{\alpha};\nu)|\le1$, and it follows from (2.6) and (2.8) that

$$J_t(X)\ll M^{2s}I_{0,1}(X)\ll M^{2s+k(k-1)/2}(M^k)^k\max_{\eta}\oint|\mathfrak{f}_1(\boldsymbol{\alpha};\eta)|^{2s}\,\mathrm{d}\boldsymbol{\alpha}.$$

It therefore follows from (2.3) that

$$J_{s+k}(X)\ll M^{2s+k(k-1)/2}X^kJ_s(X/M)\ll X^{2k}(X^{1/k})^{2s-k(k+1)/2}J_s(X^{1-1/k}).$$

This iterative relation leads from the bound $J_{k,k}(X)\ll X^k$ to the estimate presented in Theorem 1.1. Early authors, such as Vinogradov and Hua, made use of short real intervals in place of congruences, the modern shift to congruences merely adjusting the point of view from the infinite place to a finite place.

3. Lower bounds and the main conjecture

Write $T_s(X)$ for the number of diagonal solutions of (1.3) with $1\le\boldsymbol{x},\boldsymbol{y}\le X$ and $\{x_1,\ldots,x_s\}=\{y_1,\ldots,y_s\}$. Then $J_{s,k}(X)\ge T_s(X)=s!X^s+O_s(X^{s-1})$. Meanwhile, when $1\le\boldsymbol{x},\boldsymbol{y}\le X$, one has $|(x_1^j-y_1^j)+\ldots+(x_s^j-y_s^j)|\le sX^j$. Hence

$$[X]^{2s}=\sum_{|h_1|\le sX}\ldots\sum_{|h_k|\le sX^k}\oint|f_k(\boldsymbol{\alpha};X)|^{2s}e(-\alpha_1h_1-\ldots-\alpha_kh_k)\,\mathrm{d}\boldsymbol{\alpha},$$

and we deduce from the triangle inequality in combination with (1.2) that

$$X^{2s} \ll \sum_{|h_1|\le sX} \dots \sum_{|h_k|\le sX^k} J_{s,k}(X) \ll X^{k(k+1)/2} J_{s,k}(X).$$

Thus we conclude that $J_{s,k}(X) \gg X^s + X^{2s-k(k+1)/2}$, a lower bound that guides a heuristic application of the circle method towards the following conjecture.

Conjecture 3.1 (The Main Conjecture). *Suppose that s and k are natural numbers. Then for each $\varepsilon > 0$, one has $J_{s,k}(X) \ll X^{\varepsilon}(X^s + X^{2s-k(k+1)/2})$.*

We emphasise that the implicit constant here may depend on ε, s and k. The critical case of the Main Conjecture with $s = k(k+1)/2$ has special significance.

Conjecture 3.2. *When $k \in \mathbb{N}$ and $\varepsilon > 0$, one has $J_{k(k+1)/2,k}(X) \ll X^{k(k+1)/2+\varepsilon}$.*

Suppose temporarily that this critical case of the Main Conjecture holds. Then, when $s \ge k(k+1)/2$, one may apply a trivial estimate for $f_k(\boldsymbol{\alpha}; X)$ to show that

$$J_{s,k}(X) \le X^{2s-k(k+1)} \oint |f_k(\boldsymbol{\alpha}; X)|^{k(k+1)}\, \mathrm{d}\boldsymbol{\alpha} \ll X^{2s-k(k+1)/2+\varepsilon},$$

and when $s < k(k+1)/2$, one may instead apply Hölder's inequality to obtain

$$J_{s,k}(X) \le \biggl(\oint |f_k(\boldsymbol{\alpha}; X)|^{k(k+1)}\, \mathrm{d}\boldsymbol{\alpha} \biggr)^{\frac{2s}{k(k+1)}} \ll X^{s+\varepsilon}.$$

In both cases, therefore, the Main Conjecture is recovered from the critical case.

Until 2014, the critical case of the Main Conjecture was known to hold in only two cases. The case $k = 1$ is trivial. The case $k = 2$, on the other hand, depends on bounds for the number of integral solutions of the simultaneous equations

$$\left.\begin{aligned} x_1^2 + x_2^2 + x_3^2 &= y_1^2 + y_2^2 + y_3^2 \\ x_1 + x_2 + x_3 &= y_1 + y_2 + y_3 \end{aligned}\right\}, \tag{3.1}$$

with $1 \le x_i, y_i \le X$. From the identity $(a+b-c)^2 - (a^2+b^2-c^2) = 2(a-c)(b-c)$, one finds that the solutions of (3.1) satisfy $(x_1 - y_3)(x_2 - y_3) = (y_1 - x_3)(y_2 - x_3)$. From here, elementary estimates for the divisor function convey us to the bound $J_{3,2}(X) \ll X^{3+\varepsilon}$, so that Conjecture 3.2 and the Main Conjecture hold when $k = 2$. In fact, improving on earlier work of Rogovskaya [41], it was shown by Blomer and Brüdern [10] that

$$J_{3,2}(X) = \frac{18}{\pi^2} X^3 \log X + \frac{3}{\pi^2} \biggl(12\gamma - 6\frac{\zeta'(2)}{\zeta(2)} - 5 \biggr) X^3 + O(X^{5/2} \log X).$$

In particular, the factor X^{ε} cannot be removed from the statements of Conjectures 3.1 and 3.2. However, a careful heuristic analysis of the circle method reveals that when $(s,k) \ne (3,2)$, the Main Conjecture should hold with $\varepsilon = 0$. See [47, equation (7.5)] for a discussion that records precisely such a conjecture.

The classical picture of the Main Conjecture splits naturally into two parts: small s and large s. When $1 \le s \le k$, the relation $J_{s,k}(X) = T_s(X) \sim s! X^s$ is immediate

from Newton's formulae concerning roots of polynomials. Identities analogous to that above yield multiplicative relations amongst variables in the system (1.3) when $s = k + 1$. In this way, Hua [26] confirmed the Main Conjecture for $s \leq k + 1$ by obtaining the bound $J_{k+1,k}(X) \ll X^{k+1+\varepsilon}$. Vaughan and Wooley have since obtained the asymptotic formula $J_{k+1,k}(X) = T_{k+1}(X) + O(X^{\theta_k+\varepsilon})$, where $\theta_3 = \frac{10}{3}$ [48, Theorem 1.5] and $\theta_k = \sqrt{4k+5}$ $(k \geq 4)$ [49, Theorem 1]. Approximations to the Main Conjecture of the type $J_{s,k}(X) \ll X^{s+\delta_{s,k}}$, with $\delta_{s,k}$ small, can be obtained for larger values of s. Thus, on writing $\gamma = s/k$, the work of Arkhipov and Karatsuba [3] shows that permissible exponents $\delta_{s,k}$ exist with $\delta_{s,k} \ll \gamma^{3/2}k^{1/2}$, Tyrina [43] gets $\delta_{s,k} \ll \gamma^2$, and Wooley [58, Theorem 1] obtains $\delta_{s,k} = \exp(-Ak/\gamma^2)$, when $s \leq k^{3/2}(\log k)^{-1}$, for a certain positive constant A.

We turn next to large values of s. When $k \in \mathbb{N}$, denote by $H(k)$ the least integer for which the Main Conjecture for $J_{s,k}(X)$ holds whenever $s \geq H(k)$. Theorem 1.2 gives $H(k) \leq (2 + o(1))k^2 \log k$, a consequence of the classical estimate (1.4) with permissible exponent $\Delta_{s,k} = k^2e^{-s/k^2}$. In 1992, the author [56] found a means of combining Vinogradov's methods with the *efficient differencing method* (see [55], and the author's previous ICM lecture [61]), obtaining $\Delta_{s,k} \approx k^2e^{-2s/k^2}$. This yields $H(k) \leq (1+o(1))k^2 \log k$ (see [60]), halving the previous bound. Meanwhile, Hua [26, Theorem 7] has applied Weyl differencing to bound $H(k)$ for small k. We summarise the classical status of the Main Conjecture in the following theorem.

Theorem 3.3. *The Main Conjecture holds for $J_{s,k}(X)$ when:*

(i) $k = 1$ *and* 2*;*

(ii) $k \geq 2$ *and* $1 \leq s \leq k + 1$*;*

(iii) $s \geq H(k)$*, where* $H(3) = 8$*,* $H(4) = 23$*,* $H(5) = 55$*,* $H(6) = 120$*, ..., and* $H(k) = k^2(\log k + 2 \log\log k + O(1))$.

4. The advent of efficient congruencing

The introduction of the *efficient congruencing method* [62] at the end of 2010 has transformed our understanding of the Main Conjecture. Incorporating subsequent developments [20, 64], and the multigrade enhancement of the method [65–67], we can summarise the current state of affairs in the form of a theorem.

Theorem 4.1. *The Main Conjecture holds for $J_{s,k}(X)$ when:*

(i) $k = 1$*,* 2 *and* 3*;*

(ii) $1 \leq s \leq D(k)$*, where* $D(4) = 8$*,* $D(5) = 10$*,* $D(6) = 17$*,* $D(7) = 20$*, ..., and* $D(k) = \frac{1}{2}k(k + 1) - \frac{1}{3}k + O(k^{2/3})$*;*

(iii) $k \geq 3$ *and* $s \geq H(k)$*, where* $H(k) = k(k - 1)$.

As compared to the classical situation, there are three principal advances:

(a) First, the Main Conjecture holds for $J_{s,k}(X)$ in the cubic case $k = 3$ (see [67, Theorem 1.1]), so that $J_{s,3}(X) \ll X^{\varepsilon}(X^s + X^{2s-6})$. This is the first occasion, for any polynomial Weyl sum of degree exceeding 2, that the conjectural mean value estimates have been established in full, even if the underlying variables are restricted to lie in such special sets as the smooth numbers.

(b) Second, the Main Conjecture holds in the form $J_{s,k}(X) \ll X^{s+\varepsilon}$ provided that $1 \le s \le \frac{1}{2}k(k+1) - \frac{1}{3}k + O(k^{2/3})$, which as $k \to \infty$ represents 100% of the critical interval $1 \le s \le k(k+1)/2$ (see [66, Theorem 1.3]). The classical result reported in Theorem 3.3(ii) only provides such a conclusion for $1 \le s \le k+1$, amounting to 0% of the critical interval. Here, the first substantial advance was achieved by Ford and Wooley [20, Theorem 1.1], giving the Main Conjecture for $1 \le s \le \frac{1}{4}(k+1)^2$. Although Theorem 4.1(ii) comes within $\big(\frac{1}{3} + o(1)\big)\, k$ variables of proving the critical case of the Main Conjecture, it seems that a new idea is required to replace this defect by $(c + o(1))k$, for some real number c with $c < \frac{1}{3}$.

(c) Third, the Main Conjecture holds in the form $J_{s,k}(X) \ll X^{2s-k(k+1)/2+\varepsilon}$ for $s \ge k(k-1)$. The classical result reported in Theorem 3.3(iii) provides such a conclusion for $s \ge (1 + o(1))k^2 \log k$, a constraint weaker by a factor $\log k$. So far as applications are concerned, this is by far the most significant advance thus far captured by the efficient congruencing method. The initial progress [62, Theorem 1.1] shows that the Main Conjecture holds for $s \ge k(k+1)$, already within a factor 2 of the critical exponent $s = k(k+1)/2$. Subsequently, this constraint was improved first to $s \ge k^2 - 1$, and then to $s \ge k^2 - k + 1$ (see [64, Theorem 1.1] and [65, Corollary 1.2]). The further modest progress reported in Theorem 4.1(iii) was announced in [67, Theorem 1.2], and will appear in a forthcoming paper.

Prior to the advent of efficient congruencing, much effort had been spent on refining estimates of the shape $J_{s,k}(X) \ll X^{2s-k(k+1)/2+\Delta_{s,k}}$, with the permissible exponent $\Delta_{s,k}$ as small as possible (see [9, 19, 56, 58]). Of great significance for applications, efficient congruencing permits substantially sharper bounds to be obtained for such exponents than were hitherto available. Such ideas feature in [64, Theorem 1.4], and the discussion following [20, Theorem 1.2] shows that when $\frac{1}{4} \le \alpha \le 1$ and $s = \alpha k^2$, then the exponent $\Delta_{s,k} = (1 - \sqrt{\alpha})^2 k^2 + O(k)$ is permissible. Thus, in particular, the critical exponent $\Delta_{k(k+1)/2,k} = (\frac{3}{2} - \sqrt{2})k^2$ is permissible. By combining [66, Theorem 1.5] and the discussion following [65, Corollary 1.2], one arrives at the following improvement.

Theorem 4.2. *When k is large, there is a positive number $C(s) \le \frac{1}{3}$ for which*

$$J_{s,k}(X) \ll X^{(C(s)+o(1))k}\big(X^s + X^{2s-k(k+1)/2}\big).$$

When $\alpha \in [\frac{5}{8}, 1]$, moreover, one may take $C(\alpha k^2) \le \big(2 - 3\alpha + (2\alpha - 1)^{3/2}\big)/(3\alpha)$.

We finish this section by noting that Theorem 4.1(iii) permits a substantial improvement in the conclusion of Theorem 1.2.

Theorem 4.3. *Let $k, s \in \mathbb{N}$ and suppose that $s \ge k^2 - k + 1$. Then there exists a positive number $\mathfrak{C}(s,k)$ with $J_{s,k}(X) \sim \mathfrak{C}(s,k)X^{2s-k(k+1)/2}$.*

5. A sketch of the efficient congruencing method

Although complicated in detail, the ideas underlying efficient congruencing are accessible given some simplifying assumptions. In this section, we consider k to be fixed, and drop

mention of k from our notation. Let $t = (u+1)k$, where $u \geq k$ is an integer, and put $s = uk$. We define

$$\lambda_t = \limsup_{X \to \infty} (\log J_t(X))/(\log X).$$

Thus, for each $\varepsilon > 0$, one has the bound $J_t(X) \ll X^{\lambda_t + \varepsilon}$. Our goal is to establish that $\lambda_t = 2t - k(k+1)/2$, as predicted by the Main Conjecture. Define Λ via the relation $\lambda_t = 2t - \frac{1}{2}k(k+1) + \Lambda$. We suppose that $\Lambda > 0$, and seek a contradiction in order to show that $\Lambda = 0$. Our method rests on an N-fold iteration related to the approach of §2, where N is sufficiently large in terms of u, k and Λ. Let $\theta = (16k)^{-2N}$, put $M = X^\theta$, and consider a prime number p with $M < p \leq 2M$. Also, let $\delta > 0$ be small in terms of all these parameters, so that $8\delta < N(k/u)^N \Lambda\theta$.

Define the mean value

$$K_{a,b}(X) = \max_{\xi,\eta} \oint |\mathfrak{F}_a(\boldsymbol{\alpha};\xi)^2 \mathfrak{F}_b(\boldsymbol{\alpha};\eta)^{2u}| \, \mathrm{d}\boldsymbol{\alpha},$$

and introduce the normalised mean values

$$[[K_{a,b}(X)]] = \frac{K_{a,b}(X)}{(X/M^a)^{2k-k(k+1)/2}(X/M^b)^{2s}} \quad \text{and} \quad [[J_t(X)]] = \frac{J_t(X)}{X^{2t-k(k+1)/2}}.$$

Then whenever X is sufficiently large in terms of the ambient parameters, one has $[[J_t(X)]] > X^{\Lambda - \delta}$ and, when $X^{1/2} \leq Y \leq X$, we have the bound $[[J_t(Y)]] \leq Y^{\Lambda+\delta}$.

We begin by observing that an elaboration of the argument delivering (2.5) can be fashioned to replace (2.6) with the well-conditioned relation

$$J_t(X) \ll M^{2s} \max_{\xi,\eta} \oint |\mathfrak{F}_0(\boldsymbol{\alpha};\xi)^2 \mathfrak{F}_1(\boldsymbol{\alpha};\eta)^{2u}| \, \mathrm{d}\boldsymbol{\alpha} = M^{2s} K_{0,1}(X).$$

Here we have exercised considerable expedience in ignoring controllable error terms. Moreover, one may need to replace $K_{0,1}(X)$ by the surrogate $K_{0,1+h}(X)$, for a suitable integer h. An analogue of the argument leading to (2.8) yields the bound

$$K_{0,1}(X) \ll M^{k(k-1)/2} \max_{\eta} \oint \Big(\sum_{\nu=1}^{p^k} |\mathfrak{f}_k(\boldsymbol{\alpha};\nu)|^2 \Big)^k |\mathfrak{F}_1(\boldsymbol{\alpha};\eta)|^{2u} \, \mathrm{d}\boldsymbol{\alpha}.$$

By Hölder's inequality, one finds first that

$$\Big(\sum_{\nu=1}^{p^k} |\mathfrak{f}_k(\boldsymbol{\alpha};\nu)|^2 \Big)^k \leq (p^k)^{k-1} \sum_{\nu=1}^{p^k} |\mathfrak{f}_k(\boldsymbol{\alpha};\nu)|^{2k},$$

and then

$$K_{0,1}(X) \ll M^{k(k-1)/2} (M^k)^k \max_{\eta,\nu} \Big(T_1(\eta)^{1-1/u} T_2(\eta,\nu)^{1/u} \Big),$$

where

$$T_1(\eta) = \oint |\mathfrak{F}_1(\boldsymbol{\alpha};\eta)|^{2u+2} \, \mathrm{d}\boldsymbol{\alpha} \quad \text{and} \quad T_2(\eta,\nu) = \oint |\mathfrak{F}_1(\boldsymbol{\alpha};\eta)^2 \mathfrak{f}_k(\boldsymbol{\alpha};\nu)^{2s}| \, \mathrm{d}\boldsymbol{\alpha}.$$

On considering the underlying Diophantine systems, one finds that $T_1(\eta)$ may be bounded via (2.3), while $T_2(\eta,\nu)$ may be bounded in terms of $K_{1,k}(X)$. Thus

$$J_t(X) \ll M^{2s+k(k-1)/2}(M^k)^k J_t(X/M)^{1-1/u} K_{1,k}(X)^{1/u}.$$

A modicum of computation therefore confirms that

$$[[J_t(X)]] \ll [[J_t(X/M)]]^{1-1/u}[[K_{1,k}(X)]]^{1/u}. \tag{5.1}$$

The mean value underlying $K_{1,k}(X)$ counts the number of integral solutions of

$$\sum_{i=1}^{k}(x_i^j - y_i^j) = \sum_{l=1}^{s}\big((p^k u_l+\eta)^j - (p^k v_l+\eta)^j\big) \quad (1\le j\le k),$$

with $1\le \boldsymbol{x},\boldsymbol{y}\le X$ and $1\le p^k\boldsymbol{u}+\eta, p^k\boldsymbol{v}+\eta\le X$ having suitably conditioned coordinates. In particular, one has $\boldsymbol{x}\equiv\boldsymbol{y}\equiv\xi \pmod p$ but $x_i\not\equiv x_j \pmod{p^2}$ for $i\ne j$, and similarly for $\boldsymbol{y}$. Translation invariance leads from these equations to

$$\sum_{i=1}^{k}\big((x_i-\eta)^j - (y_i-\eta)^j\big) = p^{jk}\sum_{l=1}^{s}(u_l^j - v_l^j) \quad (1\le j\le k),$$

and hence to the congruences

$$(x_1-\eta)^j+\ldots+(x_k-\eta)^j \equiv (y_1-\eta)^j+\ldots+(y_k-\eta)^j \pmod{p^{jk}} \quad (1\le j\le k). \tag{5.2}$$

Since the x_i are distinct modulo p^2, an application of Hensel's lemma shows that, for each fixed choice of $\boldsymbol{y}$, there are at most $k!(p^k)^{k(k-1)/2}\cdot p^{k(k-1)/2}$ choices for $\boldsymbol{x} \pmod{p^{k^2}}$ satisfying (5.2). Here, the factor $p^{k(k-1)/2}$ reflects the fact that, even though $x_i\not\equiv x_j \pmod{p^2}$ for $i\ne j$, one has $x_i\equiv x_j \pmod p$ for all i and j. This situation is entirely analogous to that delivering (2.8) above, and thus we obtain

$$K_{1,k}(X) \ll (M^{k+1})^{k(k-1)/2}\max_{\xi,\eta}\oint\Bigg(\sum_{\substack{\nu=1\\ \nu\equiv\xi \pmod p}}^{p^{k^2}}|\mathfrak{f}_{k^2}(\boldsymbol{\alpha};\nu)|^2\Bigg)^k|\mathfrak{F}_k(\boldsymbol{\alpha};\eta)|^{2u}\,\mathrm{d}\boldsymbol{\alpha}.$$

From here, as above, suitable applications of Hölder's inequality show that

$$[[K_{1,k}(X)]] \ll [[J_t(X/M^k)]]^{1-1/u}[[K_{k,k^2}(X)]]^{1/u}. \tag{5.3}$$

By substituting this estimate into (5.1), we obtain the new upper bound

$$[[J_t(X)]] \ll \big([[J_t(X/M)]][[J_t(X/M^k)]]^{1/u}\big)^{1-1/u}[[K_{k,k^2}(X)]]^{1/u^2}.$$

By iterating this process N times, one obtains the relation

$$[[J_t(X)]] \ll \Bigg(\prod_{r=0}^{N-1}[[J_t(X/M^{k^r})]]^{1/u^r}\Bigg)^{1-1/u}[[K_{k^{N-1},k^N}(X)]]^{1/u^N}. \tag{5.4}$$

While this is a vaste oversimplification of what is actually established, it correctly identifies the relationship which underpins the efficient congruencing method.

Since $M^{k^N} < X^{1/3}$, our earlier discussion ensures that

$$[[J_t(X)]] \gg X^{\Lambda-\delta} \quad \text{and} \quad [[J_t(X/M^{k^r})]] \ll (X/M^{k^r})^{\Lambda+\delta} \quad (0 \le r \le N).$$

Meanwhile, an application of Hölder's inequality provides the trivial bound

$$[[K_{k^{N-1},k^N}(X)]] \ll \big(M^{k(k+1)/2}\big)^{k^N} X^{\Lambda+\delta}.$$

By substituting these estimates into (5.4), we deduce that

$$X^{\Lambda-\delta} \ll \bigg(X^{1/u^N} \prod_{r=0}^{N-1} \big(X/M^{k^r}\big)^{(1-1/u)/u^r}\bigg)^{\Lambda+\delta} \Big(M^{k(k+1)/2}\Big)^{(k/u)^N},$$

and hence $X^{\Lambda-\delta} \ll X^{\Lambda+\delta}(M^{\Theta})^{(k/u)^N}$, where

$$\Theta = \tfrac{1}{2}k(k+1) - (1-1/u)(\Lambda+\delta)\sum_{r=1}^{N}(u/k)^r.$$

But we have $u \ge k$, and so our hypotheses concerning N and δ ensure that

$$\Theta \le \tfrac{1}{2}k(k+1) - N(1-1/u)(\Lambda+\delta) < -\tfrac{1}{2}N\Lambda < -3(u/k)^N\delta/\theta.$$

We therefore conclude that $X^{\Lambda-\delta} \ll X^{\Lambda+\delta}M^{-3\delta/\theta} \ll X^{\Lambda-2\delta}$. This relation yields the contradiction that establishes the desired conclusion $\Lambda = 0$. We may therefore conclude that whenever $t \ge k(k+1)$, one has $J_t(X) \ll X^{2t-k(k+1)/2+\varepsilon}$.

We have sketched the proof of the Main Conjecture for $J_t(X)$ when $t \ge k(k+1)$. Theorem 4.1, which represents the latest state of play in the efficient congruencing method, goes considerably further. Two ideas underpin these advances.

First, one may sacrifice some of the power potentially available from systems of congruences such as (2.7) or (5.2) in order that the efficient congruencing method be applicable when $t < k(k+1)$. Let r be a parameter with $2 \le r \le k$, and define the generating function $\mathfrak{F}_c^{(r)}(\boldsymbol{\alpha};\xi)$ by analogy with $\mathfrak{F}_c(\boldsymbol{\alpha};\xi)$, though with r (in place of k) underlying exponential sums $\mathfrak{f}_{c+1}(\boldsymbol{\alpha};\xi_i)$. One may imitate the basic argument sketched above, with $t = (u+1)r$, to bound the analogue $K_{a,b}^{(r)}(X)$ of the mean value $K_{a,b}(X)$. In place of (5.2) one now obtains the congruences

$$(x_1-\eta)^j + \ldots + (x_r-\eta)^j \equiv (y_1-\eta)^j + \ldots + (y_r-\eta)^j \pmod{p^{jb}} \quad (1 \le j \le k). \tag{5.5}$$

For simplicity, suppose that $r \le (k-1)/2$. Then by considering the r congruence relations of highest degree here, one finds from Hensel's lemma that, for each fixed choice of $\boldsymbol{y}$, there are at most $k!$ choices for $\boldsymbol{x} \pmod{p^{(k-r)b}}$ satisfying (5.5). Although this is a weaker congruence constraint than before on $\boldsymbol{x}$ and $\boldsymbol{y}$, the cost in terms of the number of choices is smaller, and so useful estimates may nonetheless be obtained for $J_t(X)$. Ideas along these lines underpin both the work [64] of the author, and in the sharper form sketched above, that of Ford and the author [20].

The second idea conveys us to the threshold of the Main Conjecture. Again we consider the mean values $K_{a,b}^{(r)}(X)$, and for simplicity put $r = k-1$. The congruences (5.5) yield a constraint on the variables tantamount to $x_i \equiv y_i \pmod{p^{2b}}$ at little cost. Encoding this

constraint using exponential sums, and applying Hölder's inequality, one bounds $K_{a,b}^{(k-1)}(X)$ in terms of $K_{a,b}^{(k-2)}(X)$ and $K_{b,2b}^{(k-1)}(X)$. Iterating this process to successively estimate $K_{a,b}^{(k-j)}(X)$ for $j = 1, 2, \dots, k-1$, we obtain a bound for $K_{a,b}^{(k-1)}(X)$ in terms of $K_{b,jb}^{(k-1)}(X)$ $(2 \le j \le k)$ and $J_t(X/M^b)$. The heuristic potential of this idea amounts to a relation of the shape

$$[[K_{a,b}^{(k-1)}(X)]] \ll \Big(\prod_{j=2}^{k} [[K_{b,jb}^{(k-1)}(X)]]^{\phi_j} \Big) [[J_t(X/M^b)]]^{1-(k-1)/s}, \tag{5.6}$$

where the exponents ϕ_j are approximately equal to $1/s$. Again, this substantially oversimplifies the situation, since non-negligible additional factors occur. However, one discerns a critical advantage over earlier relations such as (5.3). As one iterates (5.6), one bounds $[[K_{a,b}^{(k-1)}(X)]]$ in terms of new expressions $[[K_{b,b'}^{(k-1)}(X)]]$, where the ratio b'/b is on average about $\frac{1}{2}k + 1$, as opposed to the previous ratio k. The relation (5.6) may be converted into a substitute for (5.4) of the shape

$$[[J_t(X)]] \ll \Big(\prod_{r=0}^{N-1} [[J_t(X/M^{\rho^r})]]^{1/u^r} \Big)^{1-1/u} [[K_{\rho^{N-1},\rho^N}^{(k-1)}(X)]]^{1/u^N},$$

in which ρ is close to $\frac{1}{2}k + 1$ and $t = (u+1)(k-1)$. Thus, when $u \ge \rho$, we find as before that the lower bound $[[J_t(X)]] \gg X^{\Lambda-\delta}$ is tenable only when $\Lambda = 0$, and we have heuristically established the Main Conjecture when t is only slightly larger than $k(k+1)/2$. Of course, the relation (5.6) represents an idealised situation, and the proof in detail of the results in [65, 66] contains numerous complications requiring the resolution of considerable technical difficulties.

6. Waring's problem

Investigations concerning the validity of the anticipated asymptotic formula in Waring's problem have historically followed one of two paths, associated on the one hand with Weyl, and on the other with Vinogradov. We recall our earlier notation, writing $R_{s,k}(n)$ for the number of representations of the natural number n in the shape $n = x_1^k + \dots + x_s^k$, with $\boldsymbol{x} \in \mathbb{N}^s$. A heuristic application of the circle method suggests that for $k \ge 3$ and $s \ge k+1$, one should have

$$R_{s,k}(n) = \frac{\Gamma(1+1/k)^s}{\Gamma(s/k)} \mathfrak{S}_{s,k}(n) n^{s/k-1} + o(n^{s/k-1}), \tag{6.1}$$

where

$$\mathfrak{S}_{s,k}(n) = \sum_{q=1}^{\infty} \sum_{\substack{a=1 \\ (a,q)=1}}^{q} \Big(q^{-1} \sum_{r=1}^{q} e(ar^k/q) \Big)^s e(-na/q).$$

Under modest congruence conditions, one has $1 \ll \mathfrak{S}_{s,k}(n) \ll n^{\varepsilon}$, and thus the conjectural relation (6.1) may be seen as an honest asymptotic formula (see [47, §§4.3, 4.5 and 4.6] for details). Let $\widetilde{G}(k)$ denote the least integer t with the property that, whenever $s \ge t$, the asymptotic formula (6.1) holds for all large enough n.

Leaving aside the smallest exponents $k = 1$ and 2 accessible to classical methods, the first to obtain a bound for $\widetilde{G}(k)$ were Hardy and Littlewood [21], who devised a method based on Weyl differencing to show that $\widetilde{G}(k) \le (k-2)2^{k-1} + 5$. In 1938, Hua [24] obtained a refinement based on the estimate

$$\int_0^1 |g_k(\alpha; X)|^{2^k} \, \mathrm{d}\alpha \ll X^{2^k - k + \varepsilon}, \tag{6.2}$$

in which $g_k(\alpha; X)$ is defined via (1.5), showing that $\widetilde{G}(k) \le 2^k + 1$. For small values of k, this estimate remained the strongest known for nearly half a century. Finally, Vaughan [45, 46] succeeded in wielding Hooley's Δ-functions to deduce that $\widetilde{G}(k) \le 2^k$ for $k \ge 3$. For slightly larger exponents $k \ge 6$, this bound was improved by Heath-Brown [22] by combining Weyl differencing with a novel cubic mean value estimate. His bound $\widetilde{G}(k) \le \frac{7}{8}2^k + 1$ was, in turn, refined by Boklan [8], who exploited Hooley's Δ-functions in this new setting to deduce that $\widetilde{G}(k) \le \frac{7}{8}2^k$ for $k \ge 6$.

Turning now to large values of k, the story begins with Vinogradov [50], who showed that $\widetilde{G}(k) \le 183k^9(\log k + 1)^2$, reducing estimates previously exponential in k to polynomial bounds. As Vinogradov's mean value theorem progressed to the state essentially captured by Theorem 1.1, bounds were rapidly refined to the form $\widetilde{G}(k) \le (C + o(1))k^2 \log k$, culminating in 1949 with Hua's bound [27] of this shape with $C = 4$. The connection with Vinogradov's mean value theorem is simple to explain, for on considering the underlying Diophantine systems, one finds that

$$\int_0^1 |g_k(\alpha; X)|^{2s} \, \mathrm{d}\alpha = \sum_{\boldsymbol{h}} \oint |f_k(\boldsymbol{\alpha}; X)|^{2s} e(-h_1\alpha_1 - \ldots - h_{k-1}\alpha_{k-1}) \, \mathrm{d}\boldsymbol{\alpha},$$

where the summation is over $|h_j| \le sX^j$ $(1 \le j \le k-1)$. The bound (1.4) therefore leads via the triangle inequality and (1.2) to the estimate

$$\int_0^1 |g_k(\alpha; X)|^{2s} \, \mathrm{d}\alpha \ll X^{k(k-1)/2} J_{s,k}(X) \ll X^{2s - k + \Delta_{s,k}}, \tag{6.3}$$

which serves as a surrogate for (6.2). In 1992, the author reduced the permissible value of C from 4 to 2 by applying the repeated efficient differencing method [56]. A more efficient means of utilising Vinogradov's mean value theorem to bound $\widetilde{G}(k)$ was found by Ford [18] (see also [44]), showing that $C = 1$ is permissible. Refinements for smaller values of k show that this circle of ideas surpasses the above-cited bound $\widetilde{G}(k) \le \frac{7}{8}2^k$ when $k \ge 9$ (see Boklan and Wooley [9]).

We summarise the classical state of affairs in the following theorem.

Theorem 6.1 (Classical status of $\widetilde{G}(k)$). *One has:*

(i) $\widetilde{G}(k) \le 2^k$ $(k = 3, 4, 5)$ *and* $\widetilde{G}(k) \le \frac{7}{8}2^k$ $(k = 6, 7, 8)$*;*

(ii) $\widetilde{G}(9) \le 365$*,* $\widetilde{G}(10) \le 497$*,* $\widetilde{G}(11) \le 627$*,* $\widetilde{G}(12) \le 771$*, . . . ;*

(iii) $\widetilde{G}(k) \le (1 + o(1))k^2 \log k$ $(k$ *large*$)$.

The most immediate impact of the new efficient congruencing method in Vinogradov's mean value theorem [62] was the bound $\widetilde{G}(k) \le 2k^2 + 2k - 3$, valid for $k \ge 2$. This already

supersedes the previous work presented in Theorem 6.1 when $k \ge 7$. In particular, the obstinate factor of $\log k$ is definitively removed for large values of k. Subsequent refinements [20, 63–66] have delivered further progress, especially for smaller values of k, which we summarise as follows.

Theorem 6.2 (Status of $\widetilde{G}(k)$ after efficient congruencing). *One has:*

(i) $\widetilde{G}(k) \le 2^k$ $(k = 3, 4)$;

(ii) $\widetilde{G}(5) \le 28$, $\widetilde{G}(6) \le 43$, $\widetilde{G}(7) \le 61$, $\widetilde{G}(8) \le 83$, $\widetilde{G}(9) \le 107$, $\widetilde{G}(10) \le 134$, $\widetilde{G}(11) \le 165$, $\widetilde{G}(12) \le 199$, ...;

(iii) $\widetilde{G}(k) \le (C + o(1))k^2$ (k *large*), *where* $C = 1.54079$ *is an approximation to the number* $(5 + 6\xi - 3\xi^2)/(2 + 6\xi)$, *in which* ξ *is the real root of* $6\xi^3 + 3\xi^2 - 1$.

A comparison of Theorems 6.1 and 6.2 reveals that the classical Weyl-based bounds have now been superseded for $k \ge 5$. The latest developments [65, 67] hint, indeed, at further progress even when $k = 4$. These advances for smaller values of k stem in part, of course, from the substantial progress in our new bounds for $J_{s,k}(X)$, as outlined in Theorems 4.1 and 4.2. However, an important role is also played by a novel mean value estimate for moments of $g_k(\alpha; X)$. Define the minor arcs $\mathfrak{m} = \mathfrak{m}_k$ to be the set of real numbers $\alpha \in [0, 1)$ satisfying the property that, whenever $a \in \mathbb{Z}$ and $q \in \mathbb{N}$ satisfy $(a, q) = 1$ and $|q\alpha - a| \le X^{1-k}$, then $q > X$. The argument of the proof of [63, Theorem 2.1] yields the bound

$$\int_{\mathfrak{m}} |g_k(\alpha; X)|^{2s} \, \mathrm{d}\alpha \ll X^{\frac{1}{2}k(k-1)-1} (\log X)^{2s+1} J_{s,k}(X). \tag{6.4}$$

We thus infer from Theorem 4.1(iii) that whenever $k \ge 3$ and $s \ge k(k-1)$, then

$$\int_{\mathfrak{m}} |g_k(\alpha; X)|^{2s} \, \mathrm{d}\alpha \ll X^{2s-k-1+\varepsilon}.$$

As compared to the classical approach embodied in (6.3), an additional factor X has been saved in these estimates at no cost in terms of the number of variables, and for smaller values of k this is a very substantial gain.

For large values of k, the enhancement of Ford [18] given by Ford and Wooley [20, Theorem 8.5] remains of value. When $k, s \in \mathbb{N}$, denote by $\eta(s, k)$ the least number η with the property that, whenever X is sufficiently large in terms of s and k, one has

$$J_{s,k}(X) \ll_\varepsilon X^{2s-k(k+1)/2+\eta+\varepsilon}.$$

Let $r \in \mathbb{N}$ satisfy $1 \le r \le k-1$. Then [20, Theorem 8.5] shows that whenever $s \ge r(r-1)/2$, one has

$$\int_0^1 |g_k(\alpha; X)|^{2s} \, \mathrm{d}\alpha \ll X^{2s-k+\varepsilon} \big(X^{\eta_r^*(s,k)-1/r} + X^{\eta_r^*(s,k-1)} \big),$$

where $\eta_r^*(s, w) = r^{-1}\eta(s - r(r-1)/2, w)$ for $w = k-1, k$.

Finally, we note that familiar conjectures concerning mean values of the exponential sum $g_k(\alpha; X)$ imply that one should have $\widetilde{G}(k) \le 2k + 1$ for each $k \ge 3$, and indeed it may even be the case that $\widetilde{G}(k) = k + 1$.

7. Estimates of Weyl-type, and distribution mod 1

Pointwise estimates for exponential sums appear already in the work of Weyl [54] in 1916. By applying $k-1$ Weyl-differencing steps, one bounds the exponential sum $f_k(\boldsymbol{\alpha};X)$ in terms of a new exponential sum over a linear polynomial, and this may be estimated by summing what is, after all, a geometric progression. In this way, one obtains the classical version of Weyl's inequality (see [47, Lemma 2.4]).

Theorem 7.1 (Weyl's inequality). *Let $\boldsymbol{\alpha} \in \mathbb{R}^k$, and suppose that $a \in \mathbb{Z}$ and $q \in \mathbb{N}$ satisfy $(a,q)=1$ and $|\alpha_k - a/q| \le q^{-2}$. Then one has*

$$|f_k(\boldsymbol{\alpha};X)| \ll X^{1+\varepsilon}\left(q^{-1}+X^{-1}+qX^{-k}\right)^{2^{1-k}}. \tag{7.1}$$

This provides a non-trivial estimate for $f_k(\boldsymbol{\alpha};X)$ when the leading coefficient α_k is not well-approximated by rational numbers. Consider, for example, the set $\mathfrak{m}=\mathfrak{m}_k$ defined in the preamble to (6.4). When $\alpha_k \in \mathfrak{m}$, an application of Dirichlet's theorem on Diophantine approximation shows that there exist $a \in \mathbb{Z}$ and $q \in \mathbb{N}$ with $(a,q)=1$ such that $q \le X^{k-1}$ and $|q\alpha - a| \le X^{1-k}$. The definition of $\mathfrak{m}$ then implies that $q > X$, and so Theorem 7.1 delivers the bound

$$\sup_{\alpha_k \in \mathfrak{m}} |f_k(\boldsymbol{\alpha};X)| \ll X^{1-\sigma(k)+\varepsilon}, \tag{7.2}$$

in which $\sigma(k)=2^{1-k}$. Heath-Brown's variant [22, Theorem 1] of Weyl's inequality applies mean value estimates for certain cubic exponential sums that, for $k \ge 6$, give bounds superior to (7.1) when q lies in the range $X^{5/2} < q < X^{k-5/2}$. By making use of the cubic case of the Main Conjecture in Vinogradov's mean value theorem [67], the author [68] has extended this range to $X^2 < q < X^{k-2}$.

Theorem 7.2. *Let $k \ge 6$, and suppose that $\alpha \in \mathbb{R}$, $a \in \mathbb{Z}$ and $q \in \mathbb{N}$ satisfy $(a,q)=1$ and $|\alpha - a/q| \le q^{-2}$. Then one has*

$$|g_k(\alpha;X)| \ll X^{1+\varepsilon}\Theta^{2^{-k}} + X^{1+\varepsilon}(\Theta/X)^{\frac{2}{3}2^{-k}},$$

where $\Theta = q^{-1}+X^{-3}+qX^{-k}$.

For comparison, we note that Heath-Brown [22, Theorem 1] obtains the bound

$$|g_k(\alpha;X)| \ll X^{1+\varepsilon}(X\Theta)^{\frac{4}{3}2^{-k}}.$$

Robert and Sargos [40, Théorème 4 et Lemme 7] extend these ideas when $k \ge 8$ to show that $|g_k(\alpha;X)| \ll X^{1+\varepsilon}\big(X^{17/8}\Theta'\big)^{\frac{8}{5}2^{-k}}$, in which $\Theta' = q^{-1}+X^{-4}+qX^{-k}$. See Parsell [37] for a refinement when $k=8$.

The above methods yield exponents exponentially small in k. By substituting estimates for $J_{s,k}(X)$ into the conclusion of Theorem 1.3, one obtains analogous bounds polynomial in k. Classical versions of Vinogradov's mean value theorem yield estimates of the shape (7.2) with $\sigma(k)^{-1} = (C+o(1))k^2\log k$. Thus, Linnik [33] obtained the permissible value $C = 22\,400$, and Hua [27] obtained $C=4$ in 1949. This was improved via efficient differencing [56] in 1992 to $C=2$, and subsequently the author [59] obtained $C=3/2$ by incorporating some ideas of Bombieri [11]. The latest developments in efficient congruencing yield the new exponent $\sigma(k)^{-1} = 2(k-1)(k-2)$ for $k \ge 3$, a conclusion that removes the factor $\log k$ from earlier estimates, and improves on Weyl's inequality for $k \ge 7$.

Theorem 7.3. *Let k be an integer with $k \geq 3$, and let $\boldsymbol{\alpha} \in \mathbb{R}^k$. Suppose that there exists a natural number j with $2 \leq j \leq k$ such that, for some $a \in \mathbb{Z}$ and $q \in \mathbb{N}$ with $(a,q) = 1$, one has $|\alpha_j - a/q| \leq q^{-2}$. Then one has*

$$|f_k(\boldsymbol{\alpha}; X)| \ll X^{1+\varepsilon}(q^{-1} + X^{-1} + qX^{-j})^{\sigma(k)},$$

where $\sigma(k)^{-1} = 2(k-1)(k-2)$.

This conclusion makes use of Theorem 4.1(iii), and improves slightly on [65, Theorem 11.1]. When $k \geq 6$ and α lies on a suitable subset of $\mathbb{R}$, the above-cited work of Heath-Brown may deliver estimates for $|g_k(\alpha; X)|$ superior to those stemming from Weyl's inequality, and similar comments apply to the work of Robert and Sargos, and of Parsell, when $k \geq 8$. However, Theorem 7.3 proves superior in all circumstances to the estimates of Heath-Brown when $k > 7$, and to the estimates of Robert and Sargos for all exponents k.

In many applications, it is desirable to have available estimates for $|f_k(\boldsymbol{\alpha}; X)|$ that depend on simultaneous approximations to $\alpha_1, \dots, \alpha_k$ of a given height. This is a subject to which R. C. Baker and W. M. Schmidt have made significant contributions. By exploiting such methods in combination with our new estimates for $J_{s,k}(X)$, one obtains the following conclusion (compare [65, Theorem 11.2]).

Theorem 7.4. *Let k be an integer with $k \geq 3$, and let τ and δ be real numbers with $\tau^{-1} > 4(k-1)(k-2)$ and $\delta > k\tau$. Suppose that X is sufficiently large in terms of k, δ and τ, and further that $|f_k(\boldsymbol{\alpha}; X)| > X^{1-\tau}$. Then there exist integers $q, a_1, \dots, a_k$ such that $1 \leq q \leq X^{\delta}$ and $|q\alpha_j - a_j| \leq X^{\delta - j}$ $(1 \leq j \leq k)$.*

Here, the constraint $\tau^{-1} > 4(k-1)(k-2)$ may be compared with the corresponding hypothesis $\tau^{-1} > (8 + o(1))k^2 \log k$ to be found in [5, Theorem 4.5], and the Weyl-based bound $\tau^{-1} > 2^{k-1}$ obtained in [5, Theorem 5.2] (see also [6]). The conclusion of Theorem 7.4 is superior to the latter for $k > 8$.

Bounds for exponential sums of Weyl-type may be converted into equidistribution results for polynomials modulo 1 by applying estimates of Erdős-Turán type. Write $\|\theta\|$ for the least value of $|\theta - n|$ for $n \in \mathbb{Z}$, and consider a sequence $(x_n)_{n=1}^{\infty}$ of real numbers . Then it follows from [5, Theorem 2.2], for example, that whenever $\|x_n\| \geq M^{-1}$ for $1 \leq n \leq N$, then

$$\sum_{1 \leq m \leq M} \left| \sum_{n=1}^{N} e(mx_n) \right| > \tfrac{1}{6}N.$$

By carefully exploiting this result using the methods of Baker [5], one deduces from Theorem 7.4 the following conclusion (compare [65, Theorem 11.3]).

Theorem 7.5. *When $k \geq 3$, put $\tau(k) = 1/\left(4(k-1)(k-2)\right)$. Then whenever $\boldsymbol{\alpha} \in \mathbb{R}^k$ and N is sufficiently large in terms of k and ε, one has*

$$\min_{1 \leq n \leq N} \|\alpha_1 n + \alpha_2 n^2 + \ldots + \alpha_k n^k\| < N^{\varepsilon - \tau(k)}.$$

8. Further applications

Vinogradov's mean value theorem finds application in numerous number-theoretic problems, besides those discussed in the previous two sections. We take the opportunity now to outline several applications, emphasising recent developments.

(i) *Tarry's problem.* When h, k and s are positive integers with $h \geq 2$, consider the Diophantine system

$$\sum_{i=1}^{s} x_{i1}^j = \sum_{i=1}^{s} x_{i2}^j = \ldots = \sum_{i=1}^{s} x_{ih}^j \quad (1 \leq j \leq k). \tag{8.1}$$

Let $W(k,h)$ denote the least natural number s having the property that the simultaneous equations (8.1) possess an integral solution $\boldsymbol{x}$ with

$$\sum_{i=1}^{s} x_{iu}^{k+1} \neq \sum_{i=1}^{s} x_{iv}^{k+1} \quad (1 \leq u < v \leq h).$$

The problem of estimating $W(k,h)$ was intensely investigated by E. M. Wright and L.-K. Hua (see [25, 28, 69]), the latter obtaining $W(k,h) \leq k^2(\log k + O(1))$ for $h \geq 2$. The argument of the proof of [62, Theorem 1.3] shows that $W(k,h) \leq s$ whenever one can establish the estimate $J_{s,k+1}(X) = o(X^{2s-k(k+1)/2})$. By using this criterion together with the estimates for $J_{s,k+1}(X)$ obtained via the latest efficient congruencing methods, one obtains substantial improvements in these earlier conclusions (see [65, Theorem 12.1] and [66, Theorem 12.1]).

Theorem 8.1. *When h and k are natural numbers with $h \geq 2$ and $k \geq 3$, one has $W(k,h) \leq \frac{5}{8}(k+1)^2$. Moreover, when k is large, one has $W(k,h) \leq \frac{1}{2}k(k+1)+1$.*

Although the last of these conclusions achieves the limit of current analytic approaches to bounding $W(k,h)$, explicit numerical examples are available[4] which may be applied to show that $W(k,2) = k+1$ for $1 \leq k \leq 9$ and $k = 11$.

(ii) *Sum-product theorems.* When A is a finite set of real numbers, define the sets $A + A = \{x + y : x, y \in A\}$ and $A \cdot A = \{xy : x, y \in A\}$, and more generally

$$hA = \{x_1 + \ldots + x_h : \boldsymbol{x} \in A^h\} \quad \text{and} \quad A^{(h)} = \{x_1 \ldots x_h : \boldsymbol{x} \in A^h\}.$$

A conjecture of Erdős and Szemerédi [17] asserts that for any finite set of integers A, one has $|A+A| + |A \cdot A| \gg_\varepsilon |A|^{2-\varepsilon}$. It is also conjectured that whenever A is a finite set of *real* numbers, then for each $h \in \mathbb{N}$, one should have $|hA| + |A^{(h)}| \gg_{\varepsilon,h} |A|^{h-\varepsilon}$. Chang [13] has made progress towards this conjecture by showing that when A is a finite set of integers, and $|A.A| < |A|^{1+\varepsilon}$, then $|hA| \gg_{\varepsilon,h} |A|^{h-\delta}$, where $\delta \to 0$ as $\varepsilon \to 0$. Subsequently, Bourgain and Chang [12] showed that for any $b \geq 1$, there exists $h \geq 1$ with the property that $|hA| + |A^{(h)}| \gg |A|^b$. By exploiting bounds for $W(k,h)$ of the type given by Theorem 8.1, Croot and Hart [16] have made progress toward an analogue of such conclusions for sets of real numbers.

Theorem 8.2. *Suppose that $\varepsilon > 0$ and $|A \cdot A| \leq |A|^{1+\varepsilon}$. Then there exists a number $\lambda > 0$ such that, when h is large enough in terms of ε, one has $|h(A \cdot A)| > |A|^{\lambda h^{1/3}}$.*

This conclusion (see [64, Theorem 11.5]) improves on [16, Theorem 2], where a similar result is obtained with $(h/\log h)^{1/3}$ in place of the exponent $h^{1/3}$.

(iii) *The Hilbert-Kamke problem and its brethren.* Hilbert [23] considered an extension of Waring's problem related to Vinogradov's mean value theorem. When $n_1, \ldots, n_k \in \mathbb{N}$, let $R_{s,k}(\boldsymbol{n})$ denote the number of solutions of the system

$$x_1^j + \ldots + x_s^j = n_j \quad (1 \leq j \leq k), \tag{8.2}$$

[4] See the website http://euler.free.fr/eslp/eslp.htm.

with $\boldsymbol{x} \in \mathbb{N}^s$. Put $X = \max_{1 \le j \le k} n_j^{1/j}$, and then write

$$\mathcal{J}_{s,k}(\boldsymbol{n}) = \int_{\mathbb{R}^k} \bigg(\int_0^1 e(\beta_1 \gamma + \ldots + \beta_k \gamma^k)\, \mathrm{d}\gamma \bigg)^s e(-\beta_1 n_1/X - \ldots - \beta_k n_k/X^k)\, \mathrm{d}\boldsymbol{\beta}$$

and

$$\mathcal{S}_{s,k}(\boldsymbol{n}) = \sum_{q=1}^{\infty} \sum_{\substack{1 \le a_1, \ldots, a_k \le q \\ (q, a_1, \ldots, a_k) = 1}} \big(q^{-1} f_k(\boldsymbol{a}/q; q) \big)^s\, e\left(-(a_1 n_1 + \ldots + a_k n_k)/q \right).$$

See [1, 34, 35] for an account of the analysis of this problem, and in particular for a discussion of the conditions under which real and p-adic solutions exist for the system (8.2). While the conditions $n_k^{j/k} \le n_j \le s^{1-j/k} n_k^{j/k}$ $(1 \le j \le k)$ are plainly necessary, one finds that p-adic solubility is not assured when $s < 2^k$. This classical technology gives an asymptotic formula for $R_{s,k}(\boldsymbol{n})$ provided that $s \ge (4 + o(1))k^2 \log k$. Efficient congruencing methods lead to considerable progress. The following result improves on [62, Theorem 9.2] using Theorem 4.1(iii).

Theorem 8.3. *Let $s, k \in \mathbb{N}$ and $\boldsymbol{n} \in \mathbb{N}^k$. Suppose that $X = \max n_j^{1/j}$ is sufficiently large in terms of s and k, and that the system (8.2) has non-singular real and p-adic solutions. Then whenever $k \ge 3$ and $s \ge 2k^2 - 2k + 1$, one has*

$$R_{s,k}(\boldsymbol{n}) = \mathcal{J}_{s,k}(\boldsymbol{n}) \mathcal{S}_{s,k}(\boldsymbol{n}) X^{s-k(k+1)/2} + o(X^{s-k(k+1)/2}).$$

Similar arguments apply to more general Diophantine systems. Let $k_1, \ldots, k_t$ be distinct positive integers. Suppose that $s, k \in \mathbb{N}$, and that $a_{ij} \in \mathbb{Z}$ for $1 \le i \le t$ and $1 \le j \le s$. Write

$$\phi_i(\boldsymbol{x}) = a_{i1} x_1^{k_i} + \ldots + a_{is} x_s^{k_i} \quad (1 \le i \le t),$$

and consider the Diophantine system $\phi_i(\boldsymbol{x}) = 0$ $(1 \le i \le t)$. We write $N(B; \boldsymbol{\phi})$ for the number of integral solutions of this system with $|\boldsymbol{x}| \le B$. When $L > 0$, define

$$\sigma_\infty = \lim_{L \to \infty} \int_{|\boldsymbol{\xi}| \le 1} \prod_{i=1}^{t} \max\left\{0, L(1 - L|\phi_i(\boldsymbol{\xi})|)\right\}\, \mathrm{d}\boldsymbol{\xi}.$$

Also, for each prime number p, put

$$\sigma_p = \lim_{H \to \infty} p^{H(t-s)} \mathrm{card}\{\boldsymbol{x} \in (\mathbb{Z}/p^H\mathbb{Z})^s : \phi_i(\boldsymbol{x}) \equiv 0 \pmod{p^H}\ (1 \le i \le t)\}.$$

By applying the Hardy-Littlewood method, a fairly routine application of Theorem 4.1(iii) delivers the following conclusion (compare [62, Theorem 9.1]).

Theorem 8.4. *Let s and k be natural numbers with $k \ge 3$ and $s \ge 2k^2 - 2k + 1$. Suppose that $\max k_i \le k$, and that a_{ij} $(1 \le i \le t, 1 \le j \le s)$ are non-zero integers. Suppose in addition that the system of equations $\phi_i(\boldsymbol{x}) = 0$ $(1 \le i \le t)$ has non-singular real and p-adic solutions, for each prime number p. Then*

$$N(B; \boldsymbol{\phi}) \sim \sigma_\infty \bigg(\prod_p \sigma_p \bigg) B^{s - k_1 - \ldots - k_t}.$$

(iv) *Solutions of polynomial congruences in short intervals.* There has been much activity in recent years concerning the solubility of polynomial congruences in short intervals, some of which makes use of estimates associated with Vinogradov's mean value theorem. Let $f \in \mathbb{F}_p[X]$ have degree $m \geq 3$, and let M be a positive integer with $M < p$. Denote by $I_f(M; R, S)$ the number of solutions of the congruence $y^2 \equiv f(x) \pmod p$, with $(x, y) \in [R+1, R+M] \times [S+1, S+M]$. Weil's bounds for exponential sums yield the estimate $I_f(M; R, S) = M^2 p^{-1} + O(p^{1/2}(\log p)^2)$, one that is worse than trivial for $M \leq p^{1/2}(\log p)^2$. The work of Chang et al. [14] gives estimates that remain non-trivial for significantly smaller values of M.

Theorem 8.5. *Let $f \in \mathbb{F}_p[X]$ be any polynomial of degree $m \geq 4$. Then whenever M is a positive integer with $1 \leq M < p$, we have*

$$I_f(M; R, S) \ll M^{1+\varepsilon} \left(M^3 p^{-1} + M^{3-m}\right)^{1/(2m(m-1))}.$$

This follows from [14, Theorem 4] on applying Theorem 4.1(iii). In particular, for any $\varepsilon > 0$, one finds that there exists a $\delta > 0$, depending only on ε and $\deg(f)$, such that whenever $M < p^{1/3-\varepsilon}$ and $\deg(f) \geq 4$, then $I_f(M; R, S) \ll M^{1-\delta}$.

(v) *The zero-free region for the Riemann zeta function.* We would be remiss not to mention the role of Vinogradov's mean value theorem in the proof of the widest available zero-free region for the Riemann zeta function. The sharpest estimates date from work of Vinogradov [52] and Korobov [31] in 1958 (see also [53]). Thus, there is a positive constant c_1 with the property that $\zeta(s) \neq 0$ when $s = \sigma + it$, with $\sigma, t \in \mathbb{R}$, whenever $|t| \geq 3$ and $\sigma \geq 1 - c_1(\log|t|)^{-2/3}(\log\log|t|)^{-1/3}$. More recently, Ford [19] has shown that one may take $c_1 = 1/57.54$. This, in turn leads to an effective version of the prime number theorem of the shape

$$\pi(x) = \int_2^x \frac{\mathrm{d}t}{\log t} + O\left(x \exp\left(-c_2(\log x)^{3/5}(\log\log x)^{-1/5}\right)\right),$$

where $c_2 = 0.2098$. Using currently available methods, the nature of the constant $C(k, r)$ in estimates of the shape (1.4) is significant for estimates of this type, while the precise nature of the defect in the exponent $\Delta_{s,k}$ less so. Thus, although the new estimates for $J_{s,k}(X)$ stemming from efficient congruencing have the potential to impact the numerical constants c_1 and c_2, the dependence on t and x, respectively, in the above estimates has not been affected.

9. Generalisations

Thus far, we have focused on estimates for $J_{s,k}(X)$, the number of solutions (over the ring $\mathbb{Z}$) of the translation-dilation invariant system (1.3) with $1 \leq \boldsymbol{x}, \boldsymbol{y} \leq X$. Previous authors have considered generalisations in which either the ring, or else the translation-dilation invariant system, is varied.

(i) *Algebraic number fields.* The arguments underlying the proof of Theorem 4.1 change little when the setting is shifted from $\mathbb{Z}$ to the ring of integers of a number field. When $s \geq k(k-1)$, the ensuing estimates are at most a factor X^{ε} away from the upper bound predicted by a heuristic application of the circle method. In common with Birch's use of Hua's lemma in number fields [7], our estimates are therefore robust to variation in the degree of the field extension, since Weyl-type estimates for exponential sums no longer play a significant role in applications. In forthcoming work we apply such ideas to establish the following result.

Theorem 9.1. *Let $L/\mathbb{Q}$ be a field extension of finite degree. Suppose that $d \geq 3$, $s > 2d(d-1)$ and $\boldsymbol{a} \in (L^\times)^s$. Then the hypersurface defined by $a_1x_1^d + \ldots + a_sx_s^d = 0$ satisfies weak approximation and the Hasse principle over L.*

For comparison, Birch [7, Theorem 3] gives such a conclusion only for $s > 2^d$, while the work of Körner [30] yields analogous conclusions in which the number of variables is larger, and depends also on the degree of the field extension $L/\mathbb{Q}$.

(ii) *Function fields.* Consider a finite field $\mathbb{F}_q$ of characteristic p. Let $B \in \mathbb{N}$ be large enough in terms of q, k and s, and denote by $J_{s,k}(B;q)$ the number of solutions of (1.3) with $x_i, y_i \in \mathbb{F}_q[t]$ $(1 \leq i \leq s)$ having degree at most B. When $p < k$, one can reduce (1.3) to a minimal translation-invariant system in which certain equations are omitted. We write K for the sum of the degrees of this minimal system, so that $K = k(k+1)/2$ when $p > k$, and $K < k(k+1)/2$ when $p < k$. Then, when $s \geq k(k+1)$, the efficient congruencing method adapts to give the upper bound $J_{s,k}(B;q) \ll (q^B)^{2s-K+\varepsilon}$. This and much more is contained in forthcoming work of the author joint with Y.-R. Liu, generalisations of which are described in [32].

(iii) *Multidimensional analogues.* Vinogradov's methods have been generalised to multidimensional settings by Arkhipov, Chubarikov and Karatsuba [2, 4], Parsell [36] and Prendiville [39]. Variants of the efficient congruencing method deliver much sharper conclusions in far greater generality. Let $r, s, d \in \mathbb{N}$, and consider a linearly independent system of homogeneous polynomials $\boldsymbol{F} = (F_1, \ldots, F_r)$, where $F_j(\boldsymbol{z}) \in \mathbb{Z}[z_1, \ldots, z_d]$. Suppose that for $1 \leq j \leq r$ and $1 \leq l \leq d$, the polynomial $\partial F_j/\partial z_l$ lies in $\mathrm{span}(1, F_1, \ldots, F_r)$. Such a *reduced translation-dilation invariant* system is said to have *rank* r, *dimension* d, *degree* $k = \max \deg F_j$, and *weight* $K = \sum_1^r \deg F_j$. Denote by $J_s(X;\boldsymbol{F})$ the number of integral solutions of the system of equations

$$\sum_{i=1}^{s} (F_j(\boldsymbol{x}_i) - F_j(\boldsymbol{y}_i)) = 0 \quad (1 \leq j \leq r),$$

with $1 \leq \boldsymbol{x}_i, \boldsymbol{y}_i \leq X$ $(1 \leq i \leq s)$. The work of Parsell, Prendiville and the author [38, Theorem 2.1] provides a general estimate for $J_s(X;\boldsymbol{F})$ matching the predictions of the appropriate analogue of the Main Conjecture.

Theorem 9.2. *Let $\boldsymbol{F}$ be a reduced translation-dilation invariant system of rank r, dimension d, degree k and weight K. Then $J_s(X;\boldsymbol{F}) \ll X^{2sd-K+\varepsilon}$ for $s \geq r(k+1)$.*

Reduced translation-dilation invariant systems are easy to generate by taking successive partial derivatives and reducing to a linearly independent spanning set. Thus, for example, the initial seed $x^5 + 3x^2y^3$ gives rise to just such a system

$$\boldsymbol{F} = \{x^5 + 3x^2y^3, 5x^4 + 6xy^3, x^2y^2, 10x^3 + 3y^3, xy^2, x^2y, x^2, xy, y^2, x, y\},$$

with $d = 2$, $r = 11$, $k = 5$, $K = 30$. We therefore see from Theorem 9.2 that $J_s(X;\boldsymbol{F}) \ll X^{4s-30+\varepsilon}$ for $s \geq 66$. Theorem 9.2 should be susceptible to improvement by using the ideas underlying multigrade efficient congruencing [65–67].

10. Challenges

The remarkable success of the efficient congruencing method encourages ambitious speculation concerning other potential applications, a topic we briefly explore.

(i) (*The Main Conjecture for larger s*). In Theorem 4.1, one sees that the upper bound $J_{s,k}(X) \ll X^{s+\varepsilon}$ predicted by the Main Conjecture is now known to hold for $1 \le s \le \frac{1}{2}k(k+1) - t_k$, where $t_k = \frac{1}{3}k + O(k^{2/3})$. In striking contrast, on the other side of the critical value $s = \frac{1}{2}k(k+1)$, the upper bound $J_{s,k}(X) \ll X^{2s-k(k+1)/2+\varepsilon}$ is known to hold only when $s \ge \frac{1}{2}k(k+1) + u_k$, where $u_k = \frac{1}{2}k(k-3)$. Plainly, the value of u_k is substantially larger than t_k, and an intriguing possibility is that a hitherto unseen refinement of the method might reduce u_k to a size more similar to that of t_k. This would have great significance in numerous applications.

(ii) (*Paucity*). When $k \ge 3$ and $1 \le s < \frac{1}{2}k(k+1)$, we have precise asymptotics for $J_{s,k}(X)$ only when $s \le k+1$. Since the formula $J_{s,k}(X) = T_s(X) \sim s!X^s$ is trivial for $1 \le s \le k$, the case $s = k+1$ is the only one with content. It is tempting to speculate that a suitable adaptation of efficient congruencing might confirm that $J_{s,k}(X) = T_s(X) + O(X^{s-\delta})$, for some $\delta > 0$, for some exponent $s \ge k+2$.

(iii) (*Minor arc bounds*). When $q \in \mathbb{N}$ and $\boldsymbol{a} \in \mathbb{Z}^k$, denote by $\mathfrak{M}(q,\boldsymbol{a})$ the set of points $\boldsymbol{\alpha} \in [0,1)^k$ such that $|q\alpha_j - a_j| \le X^{1-j}$ $(1 \le j \le k)$. Write $\mathfrak{M}$ for the union of the boxes $\mathfrak{M}(q,\boldsymbol{a})$ with $0 \le a_j \le q \le X$ $(1 \le j \le k)$ and $(q,a_1,\dots,a_k) = 1$, and put $\mathfrak{m} = [0,1)^k \setminus \mathfrak{M}$. The methods of §7 provide estimates of the shape $|f_k(\boldsymbol{\alpha};X)| \ll X^{1-\sigma_k+\varepsilon}$ for $\boldsymbol{\alpha} \in \mathfrak{m}$. However, when $s = k(k-1)+t$ and $t \ge 1$, our most efficient means of estimating moments of $f_k(\boldsymbol{\alpha};X)$ of order $2s$, restricted to minor arcs, proceeds by applying Theorem 4.1(iii) via the trivial bound

$$\begin{aligned}\int_{\mathfrak{m}} |f_k(\boldsymbol{\alpha};X)|^{2s}\,\mathrm{d}\boldsymbol{\alpha} &\ll \Big(\sup_{\boldsymbol{\alpha}\in\mathfrak{m}} |f_k(\boldsymbol{\alpha};X)|\Big)^{2t} \oint |f_k(\boldsymbol{\alpha};X)|^{2k(k-1)}\,\mathrm{d}\boldsymbol{\alpha}\\ &\ll X^{2s-\frac{1}{2}k(k+1)-2t\sigma_k+\varepsilon}.\end{aligned}$$

This bound is relatively weak, even when t is large. Efficient congruencing provides a possible means of deriving estimates directly for such moments, and might even lead to improvements in our lower bounds for permissible exponents σ_k.

(iv) (*Non-translation invariant systems*). The system (1.3) is translation-dilation invariant. A major desideratum is to apply a variant of efficient congruencing to systems of equations that are *not* translation invariant. The author has forthcoming work applicable to systems that are only approximately translation invariant.

Elementary integration of differentials in families and conjectures of Pink

Umberto Zannier

Abstract. In this short survey paper we shall consider, in particular, indefinite integrals of differentials on algebraic curves, trying to express them in *elementary terms*. This is an old-fashioned issue, for which Liouville gave an explicit criterion that may be considered a primordial example of differential algebra. Before presenting some connections with more recent topics, we shall start with an overview of the classical facts, recalling some criteria for elementary integration and relating this with issues of torsion in abelian varieties. Then we shall turn to differentials in 1-parameter algebraic families, asking for which values of the parameter we can have an elementary integral. (This had been considered already in the 80s by J. Davenport.) The mentioned torsion issues provide a connection of this with a conjecture of R. Pink in the realm of the so-called *Unlikely Intersections*. In joint work in collaboration with David Masser (still partly in progress), we have proved finiteness of the set of relevant values, under suitable necessary conditions. Here we shall give a brief account of the whole context, pointing out at the end possible links with other problems.

Mathematics Subject Classification (2010). 11G10, 11G50

Keywords. Integration, abelian varieties, torsion points, unlikely intersections, conjecture of Pink.

1. Integration in finite terms

Since the invention of integral calculus and the realization of indefinite integration as a process inverse to differentiation, a development occurred towards an 'algebra' for 'explicit' calculations in this direction. Some basic functions, like polynomials and rational functions, the exponential function e^z and its inverse $\log z$, as well as the basic trigonometric functions $\sin z, \cos z, \tan z$ and their inverses, admit indefinite integrals (i.e. a primitive)[1]which again may be expressed 'in terms of these functions'. The application of a few rules (derived from corresponding rules for differentiation) allows expressions of the same kind for other functions obtained from the former ones by rational operations and by composition. Then, a (rough) question that arose naturally, and still today presents itself very soon, already to freshmen, is: *Which other functions, constructed from the above mentioned ones (for instance), do admit an indefinite integral expressed again in similar fashion?*

To give more precise meaning to this, we may define the class of *elementary functions* as those obtained from the rational functions over $\mathbb{C}$ by a finite number of operations of the following three kinds:

(a) Algebraic operations; namely, if $f_1(z), \dots, f_d(z)$ have been already obtained, we al-

Proceedings of the International Congress of Mathematicians, Seoul, 2014

low in our class all rational functions in them and a solution $y = y(z)$ of

$$y^d + f_1(z)y^{d-1} + \ldots + f_d(z) = 0.$$

(b) Exponentiation: if $f(z)$ has been obtained, we allow $\exp f(z)$.

(c) Taking a logarithm: we allow $\log f(z)$.

Of course (b), (c) lead to trigonometrical functions as well. Some care is needed concerning e.g. the domain of definition, and also, in (a) and (c), which branch of the functions has to be taken. For instance, one may agree to consider open disks in $\mathbb{C}$ as domains, restricting possibly the disk each time an operation is performed, and choosing an arbitrary branch. In considering finite sets of functions, this procedure is legitimate, and we can even assume that our functions are meromorphic in a sufficiently small disk, so that in particular they form a field, which is moreover closed under differentiation.[2]

Needless to say, one could start with a larger class of functions, or allow other kinds of operations, like solutions of differential equations of prescribed type; however, this rapidly lead to subtle issues in differential Galois theory, and here we shall stick to the above basic special case (except for a few comments in the last section). We refer to Rosenlicht's article [29] for a self-contained detailed and clear account of this, to Risch's paper [25] for a more formal and general treatment, to Hardy's book [7] for a somewhat general treatment, however often based on examples and with few proofs, and to Ritt's [27] book for further and rather more involved issues, in several directions, and for other references.[3]

Once we have decided which is our class of elementary functions, we can say that a primitive of one such function may be expressed in *finite terms* (or in *elementary terms*, or in *closed form*) if it belongs itself to the class in question. In spite of the many indefinite integrals which can be likewise obtained, sometimes at the cost of some ingenious trick, a freshman shall soon be faced with some other ones, of quite simple functions, which he can not express in simple terms. Let us now see a few of these explicit instances which seem to defeat every attempt:

The integral $\int \frac{\mathrm{d}z}{\log z}$ is an example (coming also from Prime Number Theory); it is transformed into $\int e^z \frac{\mathrm{d}z}{z}$ by replacing z with e^z. Another one which very soon appears is the Gaussian $\int e^{-z^2}\mathrm{d}z$, coming from Probability Theory; the substitution $z^2 \leftrightarrow z$ reduces it to $\int e^{-z}\frac{\mathrm{d}z}{\sqrt{z}}$.

Integrals of algebraic differentials also are puzzling, and indeed lead to quite important issues; let us see some examples, the simplest ones coming with rational functions. It is usually explained in undergraduate courses that such a function $R(z) \in \mathbb{C}(z)$ can be integrated in finite terms, actually as a sum of a rational function and a linear combination of functions $\log(z-a)$ (at least provided we allow complex numbers). This is obtained on decomposing $R(z)$ in *partial fractions*, that is expressing it as a $\mathbb{C}$-linear combination of terms z^m and $(z-a)^{-m}$ ($m \in \mathbb{N}$).

---

[1] In fact, it would be more sensible to speak of integral, or primitive, of a *differential* $f(z)\mathrm{d}z$ rather than 'integral of a function', but we shall use also the latter terminology when it causes no confusion.

[2] This is for instance the viewpoint adopted in [29]; it is to be mentioned that this does not suffice for more abstract investigations of algebraic differential equations. In the sequel we shall not pause on such precision.

[3] Some other rather classical references in Differential Algebra are Kolchin's [10] and Kaplanski's [8] books, the latter being short but giving a very clear and useful account; a further recent and more advanced one is van der Put and Singer's treatise [24]. We point out that these books touch especially differential Galois theory and are not directly involved with our more basic context, which, in Rosenlicht's words, is in a sense 'pre-Galois'.

The same happens when we integrate a differential on a curve of genus zero, because we may parametrize the curve (and hence the differential) rationally. The best-known examples probably occur with conic curves; so, any integral $\int R(z, \sqrt{1-z^2}) \cdot \mathrm{d}z$, where $R \in \mathbb{C}(u, v)$, may be reduced to the case of rational functions through the parametrization $w = \frac{2t}{1+t^2}$, $z = \frac{1-t^2}{1+t^2}$ of the circle $w^2 + z^2 = 1$ (with inverse $t = (1-z)/w$). In particular, we find (up to a constant and up to a choice of $i = \sqrt{-1}$) the formula $\int \frac{\mathrm{d}z}{\sqrt{1-z^2}} = -i \log \frac{i+2t-it^2}{1+t^2} = -i \cdot \log(iz + \sqrt{1-z^2}) = \arcsin z$.

On the contrary, if we consider curves of higher genus, often any attempt shall fail; for instance, trying to compute the length of a lemniscate[4] leads to an integral of the form $\int \frac{\mathrm{d}z}{\sqrt{1-z^4}}$, similar only in shape to the previous one. Indeed, it seems that Fagnano tried unsuccessfuly to rationalize the integrand, on imitating the case of the circle; this failure however eventually led him to important formulae, which were subsequently recognized as duplication formulae for elliptic functions (or for points on an elliptic curve). In fact, the integral (locally) represents essentially an inverse to a Weierstrass function $\wp(z)$ associated to the elliptic curve $w^2 = 1 - z^4$ (in the same way that the former integral represents an inverse to $\sin z$). Some thirty years later Euler, with closely related investigations, arrived to general addition formulae (see the discussion in Siegel's book [33], Ch. 1). This elliptic instance (and other ones in higher genus) shall be quite relevant below.

Now, in all of these cases, the question arises on *how to prove the impossibility of an integration in finite terms?* How to convince ourselves that the failure is not merely due to a lack of ingenuity on our part?

In a sense, a fairly complete answer to this was given by Liouville, who presented a theory of integration in finite terms between 1833 and 1841. This is illustrated (in particular) in [27], but here we shall follow [29], which contains an algebraic proof of a generalization by Ostrowski (1946) of a theorem proved by Liouville's in 1835, giving a most useful criterion.

To explain this, we first recall that a differential field F is a field equipped with a derivation denoted $a \to a'$, such that $(a+b)' = a' + b'$ and $(ab)' = a'b + ab'$. The *constants* are defined as the elements $c \in F$ with $c' = 0$; they form a subfield containing 1. We agree to call a an *exponential* of b, or b a *logarithm* of a, if $b' = a'/a$.

In agreement with the above notion, we define an *elementary (differential) extension of* F to be a differential field obtained from F by a finite sequence of adjunctions of elements which are either algebraic, or exponentials or logarithms, i.e. a field $F(t_1, \ldots, t_n)$, where for each $i = 1, \ldots, n$, the element t_i is either algebraic over $F(t_1, \ldots, t_{i-1})$, or the exponential or the logarithm of an element of $F(t_1, \ldots, t_{i-1})$. We find back the previously sketched concept in case F is the field of meromorphic functions on a given disk, provided we restrict possibly the disk each time we add a new element.

With these definitions, following again [29] (see also [28]), let us state the alluded result:

Theorem 1.1 ([28, 29]). *Let F be a differential field of characteristic zero and let $\alpha \in F$. If the equation $y' = \alpha$ has a solution in some elementary differential extension field of F having the same subfield of constants, then there are constants $c_1, \ldots, c_n \in F$ and elements $u_1, \ldots, u_n, v \in F$ such that*

$$\alpha = v' + \sum_{i=1}^{n} c_i \frac{u_i'}{u_i}.$$

[4] This is the set of points in the plane such that the product of the distances from two given points has a given product; it is expressed by an equation of degree 4.

Remark 1.2.

(i) We immediately point out that the assumption about the subfield of constants is automatic in the cases of the fields of meromorphic functions mentioned above.[5] In any case, in the first place one can apply the result after appropriate enlargement of the constants, and actually the proof can be modified to show that the result remains true assuming only that the field of constants of F is algebraically closed. We omit details in this brief account; a corresponding sharper form of the theorem can be found in [25].

(ii) Note that there is an obvious converse: if α has the stated shape, then $\alpha = \beta'$, where $\beta = v + \sum c_i \log u_i$ and where 'log' is to be interpreted in the above 'differential' sense, which of course coincides with the usual one in the said context of meromorphic functions, when the derivation is $\mathrm{d}/\mathrm{d}z$; in that case $\int \alpha \cdot \mathrm{d}z = \beta$. Clearly β lies in an elementary extension of F.

In [29] one finds some nice applications of this criterion. One concerns $f(z)e^{g(z)}$ for rational functions f, g. As proved by Liouville himself, $\int f(z)e^{g(z)}\mathrm{d}z$ *is elementary if and only if there is a rational function* $a \in \mathbb{C}(z)$ *such that* $f = a' + ag'$; a proof is not too difficult starting from the theorem (with $F = \mathbb{C}(z, e^{g(z)})$). In turn, one may readily check that $\int e^{-z^2}\mathrm{d}z$ is not elementary (we find the equation $1 = a' - 2az$, with no rational function solutions: a could not have poles and would then be constant) and similarly for $\int (e^z/z)\mathrm{d}z$. Certain substitutions, e.g. as in the above examples, or integrations by parts, lead to other impossibilities. With a bit more effort, in [29] it is checked that $\int (\sin z/z)\mathrm{d}z$ is non-elementary as well; more generally, partial fraction decompositions often allows to apply the last criterion to obtain either an explicit elementary integral or an impossibility proof.

We want now to concentrate on algebraic differentials, which shall be done in the next section. Before this, let us remark that a natural question, after Liouville's theorem, is: *How to decide algorithmically if a given function has an elementary primitive? And, in the affirmative case, how to compute it?* Of course, one must give first a suitable meaning of 'given function' and 'compute'; this may be done in a reasonable way. As remarked in the book [7], at Hardy's time a general algorithm was not known, and was first announced (with some details) in Risch's short paper [26]. It is to be observed that the steps of this procedure which are probably the most subtle arise with algebraic differentials, and are related to the main context of the present article. The whole matter is discussed in detail in [6], which also raises issues which motivated part of the work with Masser considered below.

2. Integration of some algebraic differentials and a Pell equation in polynomials

In this section we shall illustrate the previous result to analyze some 'concrete' special cases of elementary integrability of algebraic differentials. (We stress that this kind of analysis is by no means new, and our contributions to the topic shall appear later.)

We have mentioned above some integrals on curves of genus zero, and also Fagnano's and Euler's attempts with integrals of the shape $\int \frac{\mathrm{d}z}{\sqrt{1-z^4}}$, which correspond to work with

[5] Note that this need not hold for instance in the case when the original field of constants is not algebraically closed; a simple example comes from $\int (z^2+1)^{-1}\mathrm{d}z$ if we work over $\mathbb{R}$, not $\mathbb{C}$.

rational differentials $\mathrm{d}z/w$ on the elliptic curve $w^2 = 1 - z^4$. Let us then consider, more generally, differentials

$$\omega = \frac{h(z)\mathrm{d}z}{w}, \qquad w^2 = f(z), \tag{2.1}$$

where $f(z)$ is a polynomial of degree $2d$, without multiple zeros, and where $h(z) \neq 0$ is a polynomial, say of degree e. For brevity, here we shall stick to these special cases.

The curve so defined is hyperelliptic. We have given for it an equation in the affine (z, w)-plane; the closure in $\mathbb{P}_2$ of such affine curve is singular (only) at infinity (for $d > 1$), but it admits a smooth projective model, which we shall denote by H; it has genus $g = d-1$.

The shape of ω is somewhat natural, also because (as we shall check) for $0 \leq e \leq d-2$ we obtain the *regular* differentials on H. Note that the Fagnano-Euler differential corresponds to $d = 2, g = 1, e = 0$. Similarly to that case, the vector-integral of a $\mathbb{C}$-basis for the regular differentials locally gives an embedding of the curve in a torus $\mathbb{C}^g/\Lambda$, corresponding to its Jacobian variety J_H; the integrals are usually called *Abelian functions*. (See for instance [11], especially Ch. 4.)

As mentioned above, H is defined by $w^2 = f(z)$ on the whole affine plane; above each point $z = \alpha \in \mathbb{C}$ it has two points $(\alpha, \pm\sqrt{f(\alpha)})$, except when $f(\alpha) = 0$, in which case the said point of the z-line is branched with index 2. Above the point $z = \infty \in \mathbb{P}_1(\mathbb{C})$, H has again two points, denoted $\infty_\pm$, corresponding to the (Laurent-Puiseux) expansions $w = \pm a_d z^d +$lower order terms, where a_d^2 is the leading coefficient of f.

Let us denote by $F = \mathbb{C}(H) = \mathbb{C}(z, w)$ the function field of H over $\mathbb{C}$. It is a differential field with respect to the derivation $\mathrm{d}/\mathrm{d}z$; note that the equation for H yields $2w\mathrm{d}w = f'(z)\mathrm{d}z$, or $2ww' = f'(z)$, which determines the derivation on the whole F. By Theorem 1.1 we find that $\int \omega$ *is an elementary function if and only if there are* $v, u_1, \ldots, u_n \in F$ *and* $c_1, \ldots, c_n \in \mathbb{C}$ *such that*

$$\omega = \mathrm{d}v + \sum_{i=1}^{n} c_i \frac{\mathrm{d}u_i}{u_i}. \tag{2.2}$$

We now want to derive from (2.2) some necessary conditions; in particular, this shall prove some cases of impossibility of the integration of ω in finite terms, and shall yield explicit integral formulae in some other cases.

Let us notice at once that in (2.2) we may assume that n is minimal, and then $c_1, \ldots, c_n$ shall be linearly independent over $\mathbb{Q}$; if not, then, by taking a suitable $\mathbb{Q}$-basis $c'_1, \ldots, c'_m$ for $\sum \mathbb{Q}c_i$, with $m < n$, we may write $c_i = \sum_j b_{ij} c'_j$ with integers b_{ij}. Hence, recalling that logarithmic differentiation $u \mapsto \mathrm{d}u/u$ sends products to sums, we find $\sum_{i=1}^n c_i \mathrm{d}u_i/u_i = \sum_{j=1}^m c'_j \mathrm{d}v_j/v_j$, where $v_j = \prod_i u_i^{b_{ij}} \in F$. However, this contradicts minimality of n.

To analyze (2.2) we study the poles of ω. We view z, w as rational functions on H. Let $p \in H(\mathbb{C})$ and suppose first that $z(p) \in \mathbb{C}$ is finite. If $f(z(p)) \neq 0$, then $w(p) \neq 0$, $z - z(p)$ is a local parameter at p, and so certainly ω is regular at p. If $f(z(p)) = 0$, then w is a local parameter at p. As noted above, we have $2w\mathrm{d}w = f'(z)\mathrm{d}z$, whence $\omega = 2h(z)\mathrm{d}w/f'(z)$. Now, f has no multiple roots, hence $f'(z(p)) \neq 0$, proving that ω is again regular at p. Hence the only possible poles of ω are $\infty_\pm$. At each of these points, $\zeta := 1/z$ is a local parameter, and we have $\mathrm{d}z = -\mathrm{d}\zeta/\zeta^2$. Hence $\omega = h(z)\mathrm{d}\zeta/w\zeta^2$. The order of z at each point at infinity is -1, and the order of w is $-d$, whence the order of ω at each such point is $d - e - 2$. In particular, we find the previous assertion that ω is everywhere regular if and

only if $e \leq d-2$.[6] (A binomial expansion for w at infinity easily shows that the residues of ω at these poles are given by certain polynomials in the coefficients of f, h, linear in the last ones.)

Now, let us first suppose that $n = 0$, i.e. no u_i appears in (2.2), so $\omega = \mathrm{d}v$ is an *exact* differential already in F. (A necessary condition for this is that ω has no residues, but if $g > 0$ this is not sufficient.) Then, since ω has no finite poles, v cannot have finite poles as well, and hence is regular on the affine part of H; since the plane equation $w^2 = f(z)$ is nonsingular at finite points, we infer that $v = a(z) + wb(z)$ with polynomials a, b. This yields $\omega = (a' + (2w)^{-1}(2fb' + f'b))\mathrm{d}z$, so $a \in \mathbb{C}$ and $2h(z) = 2f(z)b'(z) + f'(z)b(z)$. This implies also in particular $e \geq 2d-1$.

Remark 2.1. The conclusion so obtained may be rephrased by saying that the image on polynomials of the linear differential operator of the first order $\Phi := 2f(z)\frac{\mathrm{d}}{\mathrm{d}z} + f'(z)$ contains $2h(z)$. Note that, although the kernel of Φ is trivial on the said space, Φ sends a polynomial of degree m to one of degree $m + 2d - 1$, hence certainly it is not surjective and it is 'unlikely' that a 'randomly' chosen $h(z)$ lies in the image.

Now suppose that $n \geq 1$. Note that if u_i has multiplicity $m_i \in \mathbb{Z}$ at $p \in H$, then $\mathrm{d}u_i/u_i$ has a simple pole at p, with residue m_i. In particular, no differential $\mathrm{d}u_i/u_i$ can have finite zeros or poles. In fact, any $p \in H$ is (at most) a simple pole of $\sum c_i \mathrm{d}u_i/u_i$, with residue $\sum c_i m_i$. But the m_i are integers and the c_i are linearly independent over $\mathbb{Q}$, hence the residue would not be zero as soon as some $m_i \neq 0$. On the other hand, $\mathrm{d}v$ has residue 0 at p, so p is certainly a pole of ω if some $m_i \neq 0$. Since ω has no finite poles, this proves the claim. (This also proves that if ω is regular then no u_i can appear, and the previous analysis then shows that regular differentials cannot be integrated in the sought way.)

Hence each u_i which appears has divisor supported at $\{\infty_+, \infty_-\}$; however, since the divisor of a function has degree 0, we infer that each u_i which appears has divisor of the shape $m_i(\infty_+ - \infty_-)$, for an $m_i \in \mathbb{Z}$. If some u_i appears, this implies in particular that the divisor class of $\infty_+ - \infty_-$ is torsion on the Jacobian J_H of H. Let m be the exact order of torsion; then m is the minimal integer > 0 such that there is a rational function $u \in F$ with $\mathrm{div}(u) = m(\infty_+ - \infty_-)$, and it is easy to see that in this case each u_i is, up to a constant factor, an integral power of u, so that in fact we may suppose that $n = 1$, $u_1 = u$.

Remark 2.2. The equation $\omega = \mathrm{d}u/u$, with algebraic ω, to be solved with an algebraic function u, appears for instance in Baldassarri and Dwork's paper [3], where algebraic solutions of second order linear differential equations are studied, also from the algorithmic viewpoint. (See e.g. pp. 69–70, where conclusions similar to those appearing below are mentioned.)

Let us draw some consequences from these last deductions. First, the function u is regular at finite points, so is of the shape $u = x(z) + wy(z)$, for $x, y \in \mathbb{C}[z]$, $y \neq 0$. We may suppose that u has a pole of order $m > 0$ at ∞_- and no other poles, so the conjugate function (over $\mathbb{C}(z)$), denoted u^σ, has a pole of order m at ∞_+ and no other poles. This easily yields $\deg x = m, \deg y = m - d$, and the norm to $\mathbb{C}(z)$ given by uu^σ must be constant (it has no poles), hence may be assumed to be 1 upon division. So we find

$$x(z)^2 - f(z)y(z)^2 = 1, \qquad y(z) \neq 0, \tag{2.3}$$

[6] Note that this never happens when $g = 0$, but includes the Fagnano-Euler differential when $g = 1$.

namely (x, y) is a nontrivial solution of the Pell's equation $X^2 - fY^2 = 1$ over the polynomial ring $\mathbb{C}[z]$.

The relevance of the numerical Pell's equation over $\mathbb{Z}$ is well known, and we shall not pause on it here, except by recalling that the equation has always nontrivial solutions (i.e. $y \neq 0$) provided f is a positive integer, not a square. The Pell's equation over a polynomial ring is partly analogous, but rather less known, although it has also been studied since long ago, for instance in 1826 by Abel [1], just in the context of elementary integrability of certain differentials. These integrals indeed became special cases of *Abelian integrals*, in more modern terminology; so it appears that the present context is quite related to some of Abel's motivations for his most important discoveries. Here we shall describe only in small part Abel's results on this and we refer to van der Poorten and Tran's article [23] for more, and further to the writer's survey [35] (related to the content of the present article) for a description of other contexts where this equation appears.

Coming back to the above, it is readily checked that some of the steps may be reversed, and that the solvability of (2.3) amounts to $\infty_+ - \infty_-$ being torsion on J_H. It also turns out that, contrary to the numerical case, this solvability is rather 'exceptional': see Example 2.4 below and especially [35] for a detailed illustration of the meaning of this.

In general, if $(x, y) \in \mathbb{C}[z]^2$ is a solution of (2.3), let us put $u := x + wy$. After a few calculations, we find $2\mathrm{d}u/u = (2xx' - f'y^2 - 2fyy') + w((f'yx/f) + 2xy' - 2x'y)$. Differentiation of (2.3) yields $2xx' = 2fyy' + f'y^2$. On the one hand, since x, y must be coprime polynomials, this implies that y divides x', so $x' = qy$ for a $q \in \mathbb{C}[z]$, of degree $d - 1$. On the other hand, plugging into the previous formula gives $2xq = 2fy' + f'y$ and $\mathrm{d}u/u = q/w$. In particular, we find an elementary integral from a solution to the Pell's equation, a result due to Abel:

$$\int \frac{x'(z)\mathrm{d}z}{y(z)\sqrt{f(z)}} = \log\left(x(z) + \sqrt{f(z)} \cdot y(z)\right). \tag{2.4}$$

Conversely, as is easily checked, this identity (with $y \neq 0$) implies that $x(z)^2 - f(z)y(z)^2$ is constant, hence if $x, y \in \mathbb{C}[z]$, the Pell's equation (2.3) is solvable. (Also, it then turns out automatically that x'/y has to be a polynomial.)

Coming back to our previous setting, similarly to the first case we find that $\omega - \mathrm{d}v = (2w)^{-1}(2h - 2fb' - f'b))\mathrm{d}z + a'\mathrm{d}z$. If this is to be equal to $c \cdot \mathrm{d}u/u = cq/w$ for a $c \in \mathbb{C}^*$, we must have $a =$constant and $2fb' + f'b = 2h - 2cq$.

We may resume the analysis in the following criterion (see also the paper [19] with Masser):

Proposition 2.3. *Suppose that the (nonzero) differential* (2.1) *may be integrated in finite terms. Then (at least) one of the following occurs:*

(i) *The differential equation* $2\varphi' f + \varphi f' = 2h$ *has a polynomial solution* $b \in \mathbb{C}[z]$*, and then* $\deg h \geq 2d - 1$*. In this case indeed we have* $\int \omega = bw$*.*

(ii) *The Pell's equation* (2.3) *has a solution* $(x, y) \in \mathbb{C}[z]^2$*, and then the ratio* $q := x'/y$ *is a polynomial of degree* $d - 1$*; also, for some* $c \in \mathbb{C}$*, the differential equation* $2\varphi' f + \varphi f' = 2h - 2cq$ *has a polynomial solution* $b \in \mathbb{C}[z]$*, and either* h/q *is constant or again* $\deg h \geq 2d - 1$*. Now we have* $\int \omega = bw + c\log(x + wy)$*.*

Note that the Pell's equation is solvable in the Fagnano-Euler case: $(z^2)^2 - \sqrt{-1}^2(1 - z^4) = 1$, however the differential $\mathrm{d}z/w$ has no elementary integral: it is regular on H, and such differentials always escape, e.g. since $\deg h \leq d - 2$ in those cases.

We have seen that the solvability of the Pell's equation corresponds to a certain point being torsion on the Jacobian J_H; to decide whether this holds in concrete cases historically proved to be a subtle question. Although there are nowadays standard algorithms to check whether a given point on an abelian variety is torsion or not, and to find the possible torsion order[7], this matter had not been clarified until ≈1970 (see [26], [6]). In this way, if $f(z), h(z)$ are given 'explicitly', we may check effectively by the above criterion whether $\int \omega$ is elementary or not, and we may exhibit an elementary primitive when this exists: indeed, once the torsion order is known (if there is torsion), we may compute suitable x, y as in (2.3), and then (i) or (ii) gives a linear differential equation to be solved in a polynomial $b(z)$ (and a constant c in case (ii)). But the degree of a possible $b(z)$ is bounded by $\max(0, \deg h + 1 - 2d)$ and then all of this amounts to solve a given system of linear equations.

As alluded above, there are considerations showing that for a 'random' polynomial $f(z)$ of even degree ≥ 4, the Pell's equation shall have no nontrivial solutions.[8] The randomness is intended in the sense of dimensions: *The 'Pellian' polynomials of a given degree fall into a denumerable union of (algebraic) families of lower dimension compared to the family of all polynomials of that degree*.

See [35] for some details and illustrations; here we restrict to the following examples, providing evidence in this direction already for pencils of polynomials (where we remark that (ii) below is rather harder to prove than the general assertion just stated):

Example 2.4.

(i) Consider the pencil of polynomials $f_\lambda(z) = z^4 + z + \lambda$, so $H_\lambda : w^2 = f_\lambda(z)$ has genus 1. It may be proved that the Pell's equation for $f_\lambda(z)$ cannot be solved identically in λ, but that, nevertheless, the Pell's equation for f_l has nontrivial solutions for infinitely many $l \in \mathbb{C}$.[9] The ls in question appear as poles of the coordinates z, w of multiples of $\infty_+ - \infty_-$ on the elliptic curve obtained from H_λ after choosing ∞_- as an origin (note that such coordinates are algebraic functions of λ); some explicit values leading to solutions are $l = 0, 1/2, (-1 - i\sqrt{3})/4$, with minimal degree of $x(z)$ being resp. $3, 4, 4$.

In particular, all of these ls are algebraic numbers (which may be seen also on observing that otherwise the identical Pell's equation would be solvable) and moreover with bounded Weil height (as follows from a theorem of Silverman) so they are rather 'sparse'; for instance, this implies that there are only finitely many of them which are rational, or even of any fixed degree over $\mathbb{Q}$. (See [34] and the references therein for proofs of these facts.)

(ii) Consider now the pencil $f_\lambda(z) = z^6 + z + \lambda$, giving H_λ of genus 2. As in (i), it is not too difficult to prove that (2.3), with $f = f_\lambda$, cannot be solved identically. But now we have an assertion stronger than before about the 'exceptional' values l: though there are some, like $l = 0$ (one has the 'Pellian' identity $(2z^5 + 1)^2 - f_0(z)(2z^2)^2 = 1$)[10], we proved with

[7] Of course, we must work with *finitely presented* objects, for instance varieties and points defined over $\overline{\mathbb{Q}}$ and given by explicit equations over $\mathbb{Z}$. In this case suitable algorithms come e.g. from reduction modulo two distinct primes. This method is quoted also in [3].

[8] It is easy to see that for $\deg f = 2$ there are always solutions of (2.3) with $x, y \in \mathbb{C}[z]$. This corresponds to a curve H of genus 0, and in fact we have already noted that then any differential can be integrated in finite terms.

[9] This fact, though not difficult, seems not completely obvious to us; a proof comes on using the above described correspondence with torsion on an elliptic curve; see [34], especially p. 92.

[10] The previous values were communicated to me by Masser's student Merkert, whereas this one was found by Masser; both of them used continued fractions.

Masser in [18] that the Pell's equation for $f_l(z)$ is solvable only for finitely many $l \in \mathbb{C}$.[11]

Correspondingly, there are only finitely many $l \in \mathbb{C}$ for which an elementary integral $\int h(z)\mathrm{d}z/\sqrt{f_l(z)}$ exists with $h \in \mathbb{C}[z]$ of degree ≤ 4. One of them, derived from the above identity for $l = 0$, is $\int 5z^2\mathrm{d}z/\sqrt{z^6+z} = \log(1 + 2z^5 + 2z^2\sqrt{z^6+z})$.

In the sequel we shall again consider families depending on a parameter.

3. Differentials and integrals depending on a parameter

In the last Example 2.4, we have met parametric families of Pell's equations in polynomials, illustrating in particular that a nontrivial solution is quite an exceptional phenomenon. The link provided by Proposition 2.3 then shows that an elementary abelian integral as in (2.4), in such parametric families of differentials, is also quite uncommon.

Then, one may ask what happens for parametric families more general than the above ones. From another viewpoint, it is also natural to ask the above questions also for (functions and) differential forms depending on several variables, and to consider the problem of finding an elementary primitive with respect to some derivation of the relevant field.

Here we shall consider such problems, and stick to the case of two variables z, λ, and again to differentiation with respect to z, so that λ may be seen as a parameter for a pencil, not depending on z (we may also think of λ as a point on an algebraic curve).

We shall soon come back to examples of the previous kind, but first let us briefly pause, as before, on some cases with transcendental functions, which seem puzzling. For instance, let us consider $(\log z)^\lambda \mathrm{d}z$, which we may also write as $e^{\lambda \log\log z}\mathrm{d}z$; to integrate it we may also use the substitution $z \mapsto e^z$, which sends it to $z^\lambda e^z \mathrm{d}z$, and then a *definite* integral relates to the Gamma function. We view λ as a constant, and so we start with a ground field $\mathbb{C}(\lambda)$, or even $L := \overline{\mathbb{C}(\lambda)}$, in place of $\mathbb{C}$. Then we may try to apply Theorem 1.1 to $F = L(z, \log z, \psi)$, where ψ is thought of as $(\log z)^\lambda$, and may be given a meaning as an element whose derivative ψ' equals $\lambda\psi(z\log z)^{-1}$.[12] This field is certainly closed under differentiation with respect to z. Taking into account that $z, \log z, \psi$ may be shown to be algebraically independent over L, one may also show that F has L as field of constants for $\mathrm{d}/\mathrm{d}z$, and after some work, we shall find that $\int \psi \cdot \mathrm{d}z$ is not elementary.[13]

In fact, already thinking of special values of λ yields non elementary integrals, as we have seen to happen with $\lambda = -1$, and actually this continues to hold for λ equal to any negative integer, since substitution $z \mapsto e^z$ and integration by parts reduces this to $\lambda = -1$. But for $\lambda \in \mathbb{N}$ we find elementary integrals as is immediately verified by the same steps. This sort of ambiguous behaviour inspires further research.

Actually, this matter of specialization may raise issues already at the moment of giving an exact definition; for instance, for special values of λ we could find poles of some coefficients introduced along the process of constructing an elementary extension. However, if we argue (as above) with algebraic functions of λ, and since in each elementary extension only finitely many functions are involved, these poles may occur only at finitely many points, and we may

[11] As in Example (i), only the algebraic l are of interest for this case.

[12] One has to use here basic notions of differential algebra, as presented for instance in [29].

[13] Here we should add the condition that also the extension field has L as a field of constants, but in fact this may be dispensed with, see Remark 1.2(i) above. Or else, if we want to avoid this point, we can also look at λ as a 'generic' complex number itself and look at F as a field of meromorphic functions in some region, as before, so that $\mathbb{C}$ remains the field of constants.

specialize without ado outside this set. Hence, for instance, we may immediately deduce that if an integral is 'generically' elementary (i.e., if it is elementary over the constant field $\overline{\mathbb{C}(\lambda)}$) then it remains elementary for all but finitely many complex values of λ.[14] It is the converse issue which is (at least for us) much less clear, and much more interesting: *If an integral is not 'generically' elementary, for 'which' values of the parameter can it become elementary?*

Let us call 'exceptional' these values. Of course, by 'which' we may mean several things; for instance we may aim to prove that the exceptional values are in some sense 'sparse', or even that they form a finite set, or at least that their set has infinite complement, depending on the case. Note that the above example shows that in general there is no finiteness assertion for them.[15]

Such a kind of problem was actually raised explicitly by J. Davenport in the already quoted book [6]; he considered throughout especially differentials on an algebraic curve, and in Ch. 3.6 he allowed dependence on a parameter, also varying algebraically. We may view these data as a pencil of (curve+differential)s, or else as a single differential on a curve, both defined over the function field of a(nother) curve. In the sequel we shall tacitly switch between these viewpoints.

Notation. For later convenience, once the differential ω_λ is given (assumed not to have an elementary primitive identically in λ), let us denote by $\mathcal{E}$ the set of the 'exceptional' values of the parameter for which the specialized differential admits an elementary primitive . (It shall be clear from the context whether we consider any complex value or only algebraic ones.)

The said book considers, among others, the problem of proving that *if such a differential does not admit an elementary primitive, then the set of values of the parameter for which the specialized differential admits such a primitive is finite* (i.e., $\mathcal{E}$ is finite). So, for instance we have already noted that this fails for the above example of $(\log z)^\lambda$, but now we are confined to algebraic differentials.

The book contains a Theorem 7 in this direction; however there seems not to be a complete proof of all the stated assertions. In particular, a difficulty which that treatment does not overcome concerns torsion on a Jacobian (similarly to what we have seen in §2 in connection to the Pell's equation). It would be much easier to prove the weaker assertion that *the differential admits an elementary primitive if and only if the specialized one admits such a primitive for all but finitely many values of the parameter*.[16] Such a result may remind of the Hilbert's irreducibility theorem. But here we shall be concerned with the more delicate question of the *finiteness* of the set $\mathcal{E}$ of exceptional values.

---

[14] This yields another proof that $(\log z)^\lambda \mathrm{d}z$ is not elementary, because, as noted above, it is not such for λ equal to any negative integer.

[15] Through Theorem 1.1 it may be proved that we find an elementary integral of $(\log z)^\lambda$ precisely for $\lambda \in \mathbb{N}$.

[16] This amounts to $\mathcal{E}$ having infinite complement. Even this kind of assertion contains different levels of subtlety, depending on whether we allow 'generic' specializations, or merely algebraic ones. For instance, the assertion of the above Example 2.4(ii) may be weakened either to '*there are infinitely many values of* $\lambda \in \mathbb{C}$ *for which the Pell is not solvable for* f_λ' or to the same statement with $\mathbb{C}$ replaced by $\overline{\mathbb{Q}}$ or even $\mathbb{Q}$. Now, we had already noted that the first assertion amounts to the fact that (2.3) is not solvable identically in λ; actually (even limiting to a single transcendental value of λ), this is almost tautological, which is not the case for the second claim. This last, at any rate in the 'non-constant' cases, follows from a general result by Silverman predicting bounded Weil height for the exceptional points, or also from suitable applications of Hilbert's irreducibility Theorem, as in work by Néron.

A link with Unlikely Intersections. In a series of papers in collaboration with Masser [14]–[19] we had considered problems involving torsion on pencils of abelian varieties. These papers actually prove, under suitable conditions, general finiteness theorems for the set of specializations where a non-torsion section for a pencil of abelian surfaces may become torsion.[17] (We analyzed separately the cases when the abelian surface is isogenous to a product of elliptic curves, or is simple, because the arguments present some differences.) Such an issue may be considered a 'relative' case of the celebrated Manin-Mumford conjecture (a theorem of Raynaud since the 80s), and is a special case of a general conjecture of Pink [22]. The general topic is often referred to as 'Unlikely Intersections', because the specializations in question are 'unexpected' (mainly for dimensional reasons) and should be hard to come by. See [34] and [35] for a discussion.

Now, we have already pointed out in §2 that the solvability of the Pell's equation is related to torsion on a suitable Jacobian variety, and this simple observation (well known since long ago) provides the link of the said context with the present one.

Indeed, at some point Masser noticed the book [6] and eventually, especially through the role of the Pell's equation, we realized that the finiteness questions raised therein could have been obtained as a consequence of our methods. As will be seen in some examples below, the present context shall involve other algebraic groups beyond abelian varieties; these arise as generalized Jacobians of suitable curves, and, for the cases of interest here, are extensions of abelian varieties by additive groups $\mathbb{G}_{\mathrm{a}}^{r}$. (See what follows for more; see also [35], §4, for another link of generalized Jacobians with certain 'degenerate' Pell's equations.)

The proof of a full finiteness statement for any pencil of differentials on a curve is in the course of being written down. Here we shall merely give some examples, collected in the next section, illustrating the mentioned connection; the examples should also isolate the main issues which appear in a general finiteness proof. (In a subsequent section we shall say more on this general case.)

Remark 3.1. In this context λ shall indicate a generic point of a given curve over $\overline{\mathbb{Q}}$; the arguments are not affected by the structure of this curve, and hence for simplicity in the sequel we shall work mainly with $\mathbb{P}_1$, i.e. letting λ be an indeterminate.

Also, we shall let throughout $\overline{\mathbb{Q}}$ be a ground field for the coefficients involved in our functions and curves. The case when arbitrary complex coefficients appear may be treated in a completely similar way, but requires a corresponding extension of the said auxiliary results obtained with Masser; such an extension, which seems more involved than may be expected, has been carried out partly in [16] and [17], but the general case is still in progress (in joint work also with Corvaja).

4. Some examples of finiteness of the set of exceptional specializations

To better illustrate the alluded finiteness problem in this article, and keep continuity with the above, we start by analyzing the hyperelliptic differentials already considered in (2.1), actually for the particular pencils which appear in a previous example. For these cases, we shall sketch a deduction of finiteness of the set denoted $\mathcal{E}$ above, relying on the mentioned results with Masser and related ones.

[17] On the contrary, except for some degenerate 'constant' cases which may be classified, there are infinitely many torsion specializations on a pencil of elliptic curves, as happens in connection with Example 2.4(i) above.

Example 4.1. We shall refer to differentials and curves as in (2.1), but depending on a parameter λ, so we take therein $h(z) = h_\lambda(z)$, $f(z) = f_\lambda(z)$, polynomials in $\overline{\mathbb{Q}}(\lambda)[z]$, and we consider a corresponding $\omega_\lambda = h_\lambda/w$. Let us discuss the specialization issue in some detail, using the pencils appearing in Example 2.4. We shall presently reverse the order of the two instances therein, because the second one leads more rapidly to a connection with our context.

(i) Let us choose $f_\lambda(z) = z^6 + z + \lambda$, as in 2.4(ii); now the curve $H = H_\lambda$ is given by $w^2 = z^6 + z + \lambda$, and has (generically) genus 2.

Let us suppose that ω_λ is not identically integrable in finite terms (i.e. considered over the field $\overline{\mathbb{Q}(\lambda)}$) and let us pick $l \in \overline{\mathbb{Q}}$ such that ω_l is integrable in finite terms; as above, we denote by $\mathcal{E}$ the set of these 'exceptional' numbers. (We tacitly disregard the finitely many l such that f_l has a double root, so that H_l shall have also genus 2.)

We shall use Proposition 2.3. Take first the case when Pell's equation (2.3) for f_l does not have a solution. Then, we infer that the differential equation $2\varphi' f_l + \varphi f_l' = 2h_l$ has a polynomial solution. This solvability amounts to the one of a (inhomogeneous) system of $\leq \deg h_l + 1$ linear equations, where the unknowns are the coefficients of φ (which must have degree $\leq \deg h_l - \deg f_l + 1 \leq \deg h_\lambda - 5$) and where the entries of the system are expressed linearly in l and the coefficients of h_l. By Capelli's criterion, the solvability may be controlled through the vanishing of suitable minors of the matrix of the system. Now, we have a similar matrix with l replaced by λ, with a corresponding solvability condition. Each minor which is not identically zero in λ may become zero only for finitely many algebraic numbers l; hence, if l is taken outside this finite set (for any of the minors) we cannot have solvability (because we are assuming that the system is not identically solvable).

On the other hand, we have already remarked that the Pell's equation may have solutions only for finitely many l, as is proved in [18]. (It should be noted that this second finiteness, contrary to the elementary nature of the arguments for the former case, requires much more effort and the use of rather deep tools.)

In conclusion, combination of these remarks yields finiteness for the set $\mathcal{E}$.

(ii) Let us now choose $f_\lambda(z) = z^4 + z + \lambda$, as in 2.4(i); now H_λ has genus 1 (and is isomorphic to the curve with Weierstrass equation $y^2 = x^3 - \lambda x + 1/4$). We again suppose that ω_λ is not identically integrable in finite terms and analyze the set $\mathcal{E}$, assuming by contradiction that it is infinite.

Arguing as in part (i), we obtain finiteness of the set of those $l \in \mathcal{E}$ such that the Pell's equation for f_l is not solvable.

Suppose now that the Pell's equation for f_l has a solution; we have remarked in Example 2.4 that for the present f_λ, of degree 4, this set is infinite (forgetting that $l \in \mathcal{E}$), so we cannot argue as in (i) and have to find supplementary arguments.

Say that $l \in \mathcal{E}$ and that (x_l, y_l) is a Pell's solution with minimal degrees. Now the differential equation of Proposition 2.3 is $2\varphi' f_l + \varphi f_l' = 2h_l - 2cq_l$, where c is any constant and $q_l = x_l'/y_l$ has degree 1. One problem in carrying out the previous analysis is that we have little information on q_l; for instance it shall follow that not even its zero can be expressed algebraically in l (restricting to the numbers $l \in \mathcal{E}$ in question). Still less we know x_l, y_l; note that they are polynomials of minimal degree so that $u_l := x_l + w_l y_l$ has divisor $m_l(\infty_+ - \infty_-)$, where $m_l \neq 0$ is an integer depending on l, and $|m_l| = \deg x_l$. Certainly $|m_l|$ shall tend to infinity (for otherwise, as is very easy to see, the Pell's equation would be identically solvable). All of this suggests that the quantities appearing in the specialized

system are not part of an algebraic (continuous) family.

We may cope with this serious difficulty in some steps, as follows. Since the differential equation $2\varphi' f_l + \varphi f_l' = 2h_l - 2cq_l$ has (for some constant c) a polynomial solution $\varphi = \varphi_l$, say, and since $\deg q_l = 1$, we see that for infinitely many l the polynomial $2h_l$ is in the image, *modulo linear polynomials*, of the differential operator $2f_l \mathrm{d}/\mathrm{d}z + f_l'$. But then, by elementary arguments of linear algebra very similar to those in the first part, we deduce the same for $2h_\lambda$, namely that there exists a polynomial $\varphi_\lambda \in \overline{\mathbb{Q}}(\lambda)[z]$ such that $2\varphi_\lambda' f_\lambda + \varphi_\lambda f_\lambda' - 2h_\lambda$ has degree ≤ 1.

This amounts to the fact that $\omega_\lambda - \mathrm{d}(\varphi_\lambda w)$ is of the shape $Q_\lambda(z)\mathrm{d}z/w$, for a polynomial $Q_\lambda \in \overline{\mathbb{Q}}(\lambda)[z]$, linear in z, and on subtracting $\mathrm{d}(\varphi_\lambda w)$ we may directly assume that $\omega_\lambda = Q_\lambda(z)\mathrm{d}z/w$. In turn, this yields that ω_λ has at most simple poles at ∞_+, ∞_- and no other poles.[18]

Then for infinitely many $l \in \mathcal{E}$ we obtain that $\omega_l = c_l \mathrm{d}u_l/u_l$, for a constant c_l, which we may assume $\neq 0$, for otherwise we fall in the previous case (and ω_λ would be identically integrable in finite terms).

Now, looking at poles shall not yield further information, and then let us look at zeros of these differentials. Let $\zeta_\lambda \in \overline{\mathbb{Q}}(\lambda)$ be the unique zero of Q_λ. Then we may specialize it at almost all $l \in \overline{\mathbb{Q}}$, obtaining a zero denoted ζ_l, and we deduce that both points above $z = \zeta_l$ on H_l, i.e. both points $\xi_l^\pm \in H_l$ such that $z(\xi_l^\pm) = \zeta_l$, are zeros of $\mathrm{d}u_l$.

Hence, for these $l \in \mathcal{E}$ there is a rational function on H_l having divisor of the shape $m_l(\infty_+ - \infty_-)$ and such that its differential vanishes at both points above ζ_l, so vanishes at ξ_l^+. Now, while the first condition says that $\infty_+ - \infty_-$ is torsion on the Jacobian of H_l (which is essentially H_l), adding the second condition says that $\infty_+ - \infty_-$ *is torsion on the generalized Jacobian of* H_l *with respect to the modulus* $2\xi_l^+$.

For notions related to generalized Jacobians we refer to Serre's book [32], and, for the present case, also to the recent paper [5] by Corvaja, Masser and the writer. Here, we merely mention that this generalized Jacobian, denoted here Γ_l, is an extension of the elliptic curve H_l (for instance with ∞_- as origin), by the additive algebraic group $\mathbb{G}_\mathrm{a}$; i.e., there is an exact sequence of algebraic groups $0 \to \mathbb{G}_\mathrm{a} \to \Gamma_l \to H_l \to 0$. It may be described in several ways; one of them, especially relevant here, uses a 'strong' equivalence of divisors on a curve H: two such divisors D, D' are *strongly equivalent* if their difference is in the first place a principal divisor, i.e. $D - D' = \mathrm{div}(u)$ for some rational function u on H (which is usual equivalence); it is then required that the differential $\mathrm{d}u$ vanishes at a prescribed point. So, this is precisely what happens in the above situation, where $H = H_l$ and ξ_l^+ is the point in question.

Naturally, we may consider the 'generic' extension Γ_λ of H_λ by $\mathbb{G}_\mathrm{a}$, corresponding to the modulus $2\xi_\lambda^+$.[19] And we find that for the relevant $l \in \mathcal{E}$, the image in Γ_l of the divisor $\infty_+ - \infty_-$ is torsion. Now, Γ_λ is an algebraic group (e.g., over $\overline{\mathbb{Q}(\lambda)}$) of dimension 2; also, the divisor $\infty_+ - \infty_-$ is not identically torsion therein, for otherwise this would imply in particular that it is torsion on H_λ.

Moreover, it turns out that the extension Γ_λ is *not trivial* (also said *not split*), i.e. not isomorphic to $\mathbb{G}_\mathrm{a} \times H_\lambda$. This fact, proved for instance in [32] (see Ch. VII, Prop. 15), does not appear to be obvious, and is absolutely crucial for the sought finiteness: indeed, for a

[18] We observe that in more general cases these steps may be replaced by a simple use of the Riemann-Roch theorem.

[19] This involves a choice of the sign; indeed, it would be more precise to work with the base curve with function field $\mathbb{C}(\lambda, \sqrt{f(\zeta_\lambda)})$, rather than with the λ-line. However, for brevity we skip such precisions.

split extension, a point could lie in $\{0\} \times H_\lambda$ and could then yield infinitely many torsion specializations (as nothing would change compared to H_λ itself).

At this stage, an analogue of the joint results with Masser, obtained by Masser's student Schmidt [31], asserts that the above torsion-degeneracy in fact may happen only for finitely many values l of λ.

This contradiction concludes the analysis of the present cases.

Note that this implies the previous assertion that the (unique) zero of the polynomial q_l does not vary algebraically in l (for the infinitely many l for which (2.3) is solvable). (Observe also that the leading coefficient of q_l is $\pm m_l$, whose absolute value tends to infinity.)

Remark on effectivity. We note that, though we may calculate the exceptional numbers $l \in \mathcal{E}$ for which the Pell's equation is not solvable, our proof methods do not presently allow to list the finitely many remaining ones. However the mentioned theorem of Silverman giving the boundedness of the Weil height $h(l)$ is effective and can be used to list the relevant l with degree bounded by a prescribed number. Also, there is good hope that the structure of the proofs can be suitably analyzed so to be made completely effective.

Example 4.2. We now present an example, taken from [5], when the curve is 'constant' (i.e. not depending on λ) but instead the differential is variable. Suppose that $f \in \mathbb{C}[z]$ has degree 3 and no multiple roots and consider the projective smooth curve H of genus 1 with affine equation $w^2 = f(z)$. This curve has a unique point O at infinity (i.e. where z has a pole). Take now the differential

$$\omega_\lambda := \frac{\mathrm{d}z}{(z-\lambda)w},$$

where λ is a variable, that is we consider (H and) this differential as defined over $\mathbb{Q}(\lambda)$. This may be easily checked to have a double zero at O and two poles at the points $P_\lambda^\pm$ where $z = \lambda$, with residues $\pm 1/\sqrt{f(\lambda)}$. Theorem 1.1 then easily implies that, if $l \in \mathbb{C}$, $\int \omega_l$ is elementary if and only if there are a nonzero constant c_l and a rational function u_l on H such that $\omega_l = c_l \mathrm{d}u_l/u_l$. Similarly to Example 4.1(ii), this implies that, for some nonzero integer m_l, the class of the divisor $m_l(P_l^+ - P_l^-)$ with respect to the modulus $2O$ is zero; in turn, this yields that $P_l^+ - P_l^-$ is torsion of the corresponding (nontrivial) extension Γ of $J_H(\cong H)$ by $\mathbb{G}_\mathrm{a}$. As in the previous example, though $P_l^+ - P_l^-$ is torsion on J_H for infinitely many l, it may be proved that this stronger torsion condition may be verified only for finitely many $l \in \mathbb{C}$.

In this example actually the double zero of ω at O would imply that the class of $m_l(P_l^+ - P_l^-)$ is zero with respect to the modulus $3O$, which is a condition even stronger than needed. If for instance we replace the present cubic $f(z)$ with, e.g., the quartic z^4+z+1, the corresponding ω_λ has two simple zeros at the two points at infinity. This gives just what is needed, and choosing any of the zeros suffices for the above argument to work.

It is to be noted that this proof can be carried out without appealing to the method used in the above quoted papers with Masser; this is because H is constant, and hence a generalization of Raynaud's theorem obtained by Hindry, or else the method of [5], suffices.[20] See [5] also for references.

[20] In fact, the divisor in question describes, as λ varies, a curve in Γ, and no such curve can contain infinitely many torsion points: otherwise the curve would have to be a translate of an algebraic subgroup, by the cited works. But the only algebraic subgroup of dimension 1 of Γ is $\mathbb{G}_\mathrm{a}$, and each translate of it has at most one torsion point.

5. Some considerations towards a general case

A general criterion. For the analysis of the general case of algebraic differentials over a curve one argues similarly, using a criterion easily derived from Theorem 1.1 and which has been implicit in the above examples. (This appears, e.g., in [26].) Let us describe the essentials.

We let X be an algebraic curve, with function field $k(X)$ (where k is algebraically closed of characteristic zero) and let ω be a (rational) differential on X admitting an elementary integral. Then, by Theorem 1.1 (or at any rate by the mentioned more precise version regarding the constants) ω can be written as in (2.2), with $v, u_1, \ldots, u_n \in k(X)$ and $c_i \in k$, namely $\omega = \mathrm{d}v + \sum_{i=1}^{n} c_i \mathrm{d}u_i/u_i$. As in a previous proof, we can assume that n is minimal, and then the c_i are linearly independent over $\mathbb{Q}$. Any differential $\mathrm{d}u_i/u_i$ has poles of order 1, at the zeros and poles of u_i, with residues given by the respective multiplicities; also, $\mathrm{d}v$ has no residues. Hence, at each point $p \in X$, we have an equation

$$\mathrm{res}_p\, \omega = e_{1p}c_1 + \ldots + e_{np}c_n, \tag{5.1}$$

with integers $e_{ip} = \mathrm{ord}_p(u_i)$. Of course, if we are given in advance only ω, we do not know the possible u_i; however the argument may be partially reversed; let us see how.

In the first place, we may *let $c_1, \ldots, c_n$ be a basis for the vector space spanned over $\mathbb{Q}$ by the residues of ω*, and then for any $p \in X$ we have (uniquely) an equation (5.1), where the e_{ip} are rationals; but in fact (since only finitely many points p are involved) they can be assumed to be integers after rescaling the c_i by a suitable rational. At this stage we have to check whether an equation (2.2) holds, however for some possibly different constants c_i^* (and possibly another n). In this case, by the above remarks, the $\mathbb{Q}$-space spanned by the c_i has to be the same as for the c_i^*. Hence, on expressing the c_i^* linearly in terms of the c_i, with rational coefficients, and using the additive property of the logarithmic derivative, at the cost of multiplying ω by a suitable integer $m \neq 0$, we may assume that $c_i^* = c_i$, and that $m\omega = \mathrm{d}v + \sum c_i \mathrm{d}u_i/u_i$. Hence, we arrive at the previous conclusion, 'only' at the cost of multiplying by m. Necessarily,

$$m \sum_{p \in X} e_{ip} \cdot p = \mathrm{div}(u_i), \qquad i = 1, \ldots, n. \tag{5.2}$$

Note that in this argument the divisors $D_i := \sum_{p \in X} e_{ip} \cdot p \in \mathrm{div}(X)$ are determined in terms only of ω, and have degree zero, because of the $\mathbb{Q}$-independence of the c_i and the sum-formula for residues (see [32], Prop. 6). They may be also shown to be linearly independent over $\mathbb{Z}$. A nonzero integer m as in (5.2) is *a priori* not given (or bounded) in terms of ω (which shall be the main point); in any case, (5.2) yields the following strong necessary condition:

Criterion. *If ω admits an elementary integral, there is a nonzero integer m such that the mD_i are principal divisors, i.e., for $i = 1, \ldots, n$, the class of D_i in the Jacobian J_X of X is torsion.*

So, we see that the torsion condition that we had previously found in connection with the Pell's equation appears indeed generally.

When we have a pencil of differentials, to be specialized, we may compare the 'generic' criterion with the 'special' one, as we have done in the above examples. Through this comparison, in the mentioned joint work with Masser we have very recently obtained the sought

finiteness for the exceptional set $\mathcal{E}$; as in the above simple examples, this heavily relies on the said finiteness results with Masser towards Pink's conjecture (or else on Schmidt's thesis).

However, it is to be remarked that in the course of these applications several new issues appear along the way, apparently with different levels of difficulty. We briefly list some of them, the simplest of which we already met in the examples; we shall not go in detail of how overcoming them (which may be indeed done, and shall appear in a forthcoming paper).

We let X_λ denote a pencil of curves over a(nother) 'base' curve B over $\overline{\mathbb{Q}}$, where λ is a generic point of B (and X_λ is defined over $\overline{\mathbb{Q}}(\lambda)$).[21] We let ω_λ a differential on X_λ and denote by X_l, ω_l, specializations of them, where $l \in B(\overline{\mathbb{Q}})$. We assume that ω_λ is not identically integrable in elementary terms and want to prove the finiteness of the above defined set $\mathcal{E}$.

(a) About the Criterion. We have observed that the condition provided by the 'Criterion' is only necessary for integrability in finite terms, not sufficient. Indeed, in the first place Theorem 1.1 involves also the function v and its differential, not taken into account in the Criterion. However, it is a matter of linear algebra (using the Riemann-Roch theorem) that if $\omega_l - \mathrm{d}v_l$ has only poles of order ≤ 1 for an infinity of special values l and rational functions v_l on X_l, then there exists a function v_λ such that $\omega_\lambda - \mathrm{d}v_\lambda$ has the same property.[22] In this way we may directly assume such a pole structure for ω_λ, and then the same will hold for ω_l, so we may assume $v = 0$ in the application of Theorem 1.1.

However, even with this hypothesis on a differential ω, the condition in the Criterion does not become sufficient. In fact, that condition only ensures that there are rational functions $u_1, \dots, u_n$ such that $m\omega - \sum c_i \mathrm{d}u_i/u_i$ has no poles. But on a curve genus g there are independent g differentials of this sort, so for $g > 0$ we cannot conclude that $m\omega = \sum c_i \mathrm{d}u_i/u_i$. Hence, concerning our purposes, we cannot hope to extract all the needed information from the Criterion. (To supplement this, one has to consider generalized Jacobians.)

(b) About rational dependence of coefficients. Then, there is the question of linear independence over $\mathbb{Q}$ of the c_i. For our purposes we must consider not merely the $c_i = c_i(\lambda)$, which are certain algebraic functions of λ, but also their specializations $c_i(l)$ at exceptional points $l \in \mathcal{E}$, and of course it may happen that the $\mathbb{Q}$-linear independence is destroyed at l. However this may occur at most for a set of algebraic points l of bounded degree over $\mathbb{Q}$ (in fact, when the dimension drops we have a nontrivial equation $\sum \rho_i c_i(l) = 0$ with $\rho_i \in \mathbb{Q}$). Now, the main point here is that, when dealing with torsion, the already mentioned results by Silverman gives boundedness of the height for the special values when a non-torsion section of an abelian family becomes torsion (at least provided the family has no 'constant' factors of dimension > 0); and then Northcott's finiteness theorem may be applied, which yields the sought finiteness. (On the other hand, concerning constant factors, we remark that Silverman's argument still may be partially restored to give sufficient information. See also Masser's Appendix C to [34]; we omit details here.)

Remark 5.1. The book [6] by J. Davenport raises some of these issues, and proposes methods to solve them, which sometimes indeed may work. (See pp. 89–91). However, for instance heights do not appear and a complete treatment is not clarified. In any case, there

[21] For simplicity we had previously considered only the case where $B = \mathbb{P}_1$, and λ is a variable, which causes no real conceptual difference in our arguments.

[22] Here we may have to use also good reduction at the relevant l, which however holds with only finitely many exceptions.

are delicate points still to be mentioned, and we go ahead to illustrate some of them.

(c) About torsion specializations. A major point concerns torsion, and actually this itself turns into several different issues, as we shall now try to illustrate.

The divisors which arise (i.e., the ones called D_i in the Criterion) define points in the Jacobian J_λ of X_λ, or, rather, sections $D_i = D_{i\lambda} : B \to J_\lambda$; indeed, J_λ is a pencil of Jacobians over B. For instance, if all the $D_{i\lambda}$ would be identically torsion, say of order m, then (as in (a) above) we would find suitable functions $u_{i\lambda}$ such that $\delta_\lambda := m\omega_\lambda - \sum c_i \mathrm{d}u_{i\lambda}/u_{i\lambda}$ would be regular. But then we could replace ω_λ with the regular δ_λ and conclude easily; indeed (as in the calculations of §2), $\delta_\lambda \neq 0$ (since ω_λ is not identically integrable in finite terms), hence $\delta_l \neq 0$ for almost all l, finishing the argument because a nonzero regular differential cannot be integrated in finite terms.

We conclude that it suffices to work with the assumption that some $D_{i\lambda}$ is not a torsion section, and one main step in proving finiteness of $\mathcal{E}$ is to show that D_{il} may become a torsion point on J_l only finitely many times.

Actually, such a clear-cut assertion is not always true: if J_λ is an elliptic pencil, then this kind of 'degeneracy' usually happens in an infinite (though sparse) set of $l \in B(\overline{\mathbb{Q}})$; we have found concrete instances of this behaviour in Examples 2.4(i) and 4.1(ii) above. For the assertion to hold, it turns out that we need at least that J_λ has relative (i.e., over B)) dimension ≥ 2, but still this does not suffice. For relative dimension $= 2$, the required finiteness of torsion specializations has been proved in the quoted joint papers with Masser, provided however that the non-torsion section does not map in a proper algebraic subgroup; for instance, this is automatic if J_λ is generically simple. We see that already in this case of surfaces some supplementary hypotheses are needed, and in fact, checking them for the sought application may happen to present difficulties.

Anyway, a first point in this direction has been to generalize [16]–[18] to any relative dimension ≥ 2; this extension is only in part similar to the former case, for instance because the abelian pencils which occur cannot always be represented as Jacobians (so one has to use the Siegel space). Also, one has to look at simple factors of J_λ (after an isogeny), and let A_λ be a typical one; it may happen that A_l becomes non-simple for $l \in \mathcal{E}$, and then to deal with other aspects of the proof (of which we shall say a little more in the next section) one needs for instance results by Masser and Wüstholz (see [13]) to control polarizations.

(d) About splitting of generalized Jacobians. Once such a more general result has been established under the appropriate hypotheses, we have still to deal with the cases when the relevant section does not meet such assumptions, as happens for instance when a nonzero multiple of it lies in some elliptic pencil inside the Jacobian pencil. In these cases, like for Example 4.1(ii), we have to take advantage of a generalized Jacobian, arising from zeros of a suitable differential.

The discussion of all the possibilities which may arise is not brief, and involves further obstacles. Therefore we do not pause further on this, except by pointing out that one such difficulty is related to the possible triviality of the relevant generalized Jacobian (by which we mean that the relevant $\mathbb{G}_{\mathrm{a}}^s$ is a direct factor). For basic cases like in Example 4.1, the triviality never occurs, as we have remarked; but this is not the only possibility. We offer a last example to illustrate this point.

Example 5.2. Let us consider the hyperelliptic curve H_λ of genus 2 with equation $w^2 = z^6 + z^4 + \lambda z^2 + 1$. We have an obvious map $\phi(z, w) = (z^2, w)$ to the curve of genus 1

defined by $v^2 = u^3 + u^2 + \lambda u + 1$. Let us take the point $\xi = \xi_\lambda := (0, 1)$ on H_λ. Then, as in Example 4.1(ii), we may construct the generalized Jacobian $\Gamma_{2\xi}$ of H_λ with respect to the modulus 2ξ; it is an extension of the usual Jacobian $J = J_\lambda$ by $\mathbb{G}_{\mathrm{a}}$:

$$0 \to \mathbb{G}_{\mathrm{a}} \to \Gamma_{2\xi} \xrightarrow{\pi} J \to 0.$$

As before, this extension is not split (as proved in [32]), in the sense that there is no section for π, or, equivalently, $\Gamma_{2\xi}$ is not isomorphic to $\mathbb{G}_{\mathrm{a}} \times J$.

However, it can be shown that there is a section if one restricts above a suitable elliptic curve $\tilde{E} \subset J$, namely there is a map $\eta : \tilde{E} \to \Gamma_{2\xi}$ with $\pi \circ \eta =$ identity of $\tilde{E}$. (One can exhibit $\tilde{E}$; in the first place, there is an isogeny ι from J to $E \times F$, where F is the curve of genus 1 defined by $y^2 = x^3 + \lambda x^2 + x + 1$, and one may put $\tilde{E} = \iota^{-1}(E \times \{0\})$.)

Hence, restricting $\Gamma_{2\xi}$ above $\tilde{E}$ yields a splitting, and this might heavily affect the finiteness proof, for reasons that we have outlined above. However, if we happen to meet such an instance in the course of the above analysis, there is a further information that can be used, and this concerns ramification of the map ϕ at ξ, which may be seen to be indeed related to this splitting. In the present case we find that the ramification index $e_\phi(\xi)$ is 2. But then, it turns out that for our purposes we could consider the extension of J determined by the modulus 3ξ, denoted $\Gamma_{3\xi}$; this is now an extension of J by $\mathbb{G}_{\mathrm{a}}^2$. And it would suffice that this extension, restricted above $E \times \{0\}$, is not totally split (i.e. not isomorphic to $\mathbb{G}_{\mathrm{a}}^2 \times E$). This indeed can be proved, although we omit details here.

6. A few words on the proofs and about further questions

We have illustrated some aspects of the proof of finiteness of the set denoted $\mathcal{E}$ above; and we have remarked (e.g., in (c) above) that they crucially rely on other finiteness proofs obtained with Masser, representing special cases of Pink's conjectures. Hence now we shall only comment on the proofs of these auxiliary ingredients. (See the book [34] for a more complete overview of the topic of Unlikely Intersections, and see the article [22] by Pila in this volume for further and more recent directions and advances in the subject.)

On the proofs of finiteness for torsion specializations. So, we have a pencil of abelian varieties $\mathcal{A} \to B$ over a curve B, and a section $\sigma : B \to \mathcal{A}$, all defined over $\overline{\mathbb{Q}}$.[23] Then, under suitable assumptions (for instance that the image $\sigma(B)$ is not contained in any proper algebraic group subscheme) we aim to prove that $\sigma(l)$ can be torsion only for finitely many $l \in B(\overline{\mathbb{Q}})$. (Below, we also keep the previous conventions, where we had denoted by λ - resp. l - a generic - resp. algebraic - point of B, and by A_λ, A_l the respective fibers.)

A main principle is to view the abelian fibers A_l (also for $l \in \mathbb{C}$) as complex tori (varying analytically) and then the torsion points, read in terms of real coordinates in the lattice bases for the tori, become rational points.

Now, a torsion point $\sigma(l) \in A_l$ yields other ones by conjugation over a number field of definition (on other - conjugate - fibers $A_{l'}$). Here one can get a lower bound for the number of such conjugates through deep results by Masser, David, Masser-Wüstholz; note that by conjugation one jumps around the various fibers, so some uniformity is needed. On the other

[23] We have already remarked that the case when the field of definition is $\mathbb{C}$ requires additional arguments, which in part are still the object of work in progress with Corvaja and Masser.

hand, one can estimate efficiently their number from above, since the corresponding rational points lie on a certain *transcendental* real surface, which is obtained as the inverse image of $\sigma(B)$ by the abelian maps. These last estimates stem from work of Bombieri-Pila for curves, then of Pila for surfaces, and finally of Pila-Wilkie for transcendental varieties of arbitrary dimension.[24] Comparison of estimates yields a contradiction (on the appropriate assumptions) if the torsion order is large enough, concluding the argument.

The question of looking at rational points on transcendental objects (whereas the original motivations mainly concerned algebraic varieties) was raised especially by Sarnak; one should also mention that Sarnak indeed foresaw some principles of this method in the case of tori long ago, in an unpublished paper [30].

Pila and the writer obtained a new proof of the Raynaud's theorem (former Manin-Mumford conjecture) by this method. Masser and the writer first used the method on a 'test' problem of Masser, asking for a proof of finiteness of the set of complex numbers l such that two points with abscissa 2 or 3 on the Legendre curve $E_l : y^2 = x(x-1)(x-l)$ are torsion; later this problem was realized to be a case of the Pink's conjectures. The proof of Masser's expectation was achieved in [14], [15], and the already mentioned further papers extended this systematically. In another direction, Pila applied this kind of method to prove new and considerably general cases of the Andrè-Oort conjecture; moreover he found that the counting of rational points was indeed 'doubly useful' in the whole context. Pila, Tsimerman, Ullmo and others extended this last principle to further issues. (See [34] for more details on this brief history and for some references, and see [22].)

Further (delicate) results needed in this kind of proof are:

- A bound by Silverman (1983) on the height of algebraic points l such that $\sigma(l)$ becomes torsion. (This bound has been already mentioned above; in particular, it is useful to deal with issue (b) in the previous section, but also elsewhere in the proofs. It requires appropriate assumptions on which we do not pause here.)
- An inequality by David (1991) relating the order of a torsion point x of a simple abelian variety $A/\overline{\mathbb{Q}}$ with the degree over $\mathbb{Q}$ of a common field of definition for A, x, and with the Faltings height of A. This is proved by transcendence techniques, and in particular offers explicit dependencies compared to previous bounds of Masser. (See Masser's Appendix D in [34] for a sketch of such a proof in a special case.) It is also to be remarked that our application with Masser of this result of David needs, in the case of 'unexpected' splitting of the abelian variety, other results of Masser-Wüstholz, in order to use this theorem for the simple factors.
- A result by André (1992) asserting algebraic independence, as locally analytic functions on B, of abelian logarithms of the given section and periods for the tori corresponding to the abelian fibers. This is crucial to show that the real surface containing the relevant rational points (to which one has to apply the Pila-Wilkie estimates) is 'highly' transcendental, in the sense that actually it does not contain any arc of a real algebraic curve.

Here we omit references for these auxiliary ingredients, and instead refer to [18], [22] or [34] for that.

[24] Other applications of these results may be found in the already mentioned paper [22] by Pila in the present volume.

Effectivity within this method is expected, but not yet proved. (The mentioned height bounds and lower bounds for degrees are already effective, but the situation is not yet clear for the upper bounds in the Bombieri-Pila-Wilkie work.) This reflects towards an ineffectivity for the finiteness theorems in the quoted papers, and hence also concerning the present context: for instance, at the moment there is no available procedure to exhibit the finite set in Example 2.4(ii).

Analogues and a conjecture of Grothendieck. Indefinite integration of a given differential $h(z)\mathrm{d}z$ corresponds to a linear differential equation $y'(z) := \mathrm{d}y/\mathrm{d}z = h(z)$ for a function $y = y(z)$. (This may be also reduced to the homogeneous form $hy'' = h'y'$.) Needless to say, one can consider more general equations, and especially relevant generalizations are obtained with linear ones of any order, with rational (or algebraic) function coefficients. The study of the fields generated by the solutions originated *differential Galois theory*, and information on the relevant Galois groups often enables one to answer questions like whether the solutions can be expressed in terms of a certain prescribed class of functions. Previously in this paper we have considered the class of elementary functions, but one may change this, and for instance either restrict to algebraic functions, or, conversely, allow more freedom, for instance including in the class all the integrals of algebraic functions, or all solutions of special types of differential equations.[25]

So, we see that there are somewhat different types of questions that may be asked, and it turns out that their study may require different tools. For instance, in the special case of elementary integrals considered above in this paper, the mere differential Galois groups does not provide any useful information. Still, sometimes the issues may be strictly linked; for example, the analysis of §2 led to the equation $c\mathrm{d}y = \omega y$ and in turn to torsion on a Jacobian and the Pell's equation, and this is the same that one finds on asking for algebraic solutions of the differential equation (see also [3], in connection with Remark 2.2 above).

Now, similarly to the problems discussed above, one can consider parametric families of such differential equations, and it makes sense to ask how often the structure of the field generated by the solutions of the specialized equations reflects the generic structure. Here again we may ask several types of questions:

> *For which values of the parameter does the Galois group equal the generic one?*

or

> *For which values of the parameter can the solutions be expressed within some prescribed class, assuming this can't be done for the generic solution?*

And so on. Again, the analysis and the answers may be quite different in the various cases.

For instance, concerning a pencil of differentials ω_λ on X_λ (notation being as above in this section) it would be easy to prove that ω_λ has an *algebraic* (rather than an *elementary*) integral identically in λ if and only if ω_l has an algebraic integral for infinitely many $l \in B(\overline{\mathbb{Q}})$. (A proof follows similarly to the first cases of Example 4.1(i), (ii), in §4 above.) However, even for a differential equation of the first order, we may have algebraic solutions (i.e. finite Galois group) precisely for *rational* values of the parameter, whereas the generic Galois group is $\mathbb{G}_{\mathrm{m}}$: this is what happens for $zy' = \lambda y$, with solutions $c \cdot z^\lambda$.

[25] For examples of this, see the books quoted in §1, and [3]. A relevant category is the class of *liouvillian extensions*, see [24].

In particular, if we formulate our issue in terms of the Galois group, a finiteness assertion for the exceptional specializations does not hold generally even restricting to algebraic function coefficients for our equations.[26] Concerning other classes of functions, here is a (vague) problem in this direction.

Problem. Let us be given a linear differential equation $\sum_{i=0}^{n} a_{i\lambda}(z)y^{(i)} = 0$ with coefficients $a_{i\lambda} \in \overline{\mathbb{Q}}(\lambda)[z]$, and let us assume that it has no nonconstant solution which is an elementary function (in the above sense) over the constant field $\overline{\mathbb{Q}(\lambda)}$. Under what conditions can we conclude that there are only finitely many $l \in \overline{\mathbb{Q}}$ for which the specialized equation $\sum_{i=0}^{n} a_{il}(z)y^{(i)} = 0$ has a nonconstant elementary function solution?

Perhaps the assumptions here could be changed by replacing throughout 'a nonconstant solution' with 'a full system of linearly independent solutions'; and perhaps one should require that all singularities of the operator are regular.[27] Observe that in the above formulation we do not have finiteness in general, as shown by the equation $zy'' - (z+\lambda)y' = 0$, satisfied by $\int z^{\lambda}e^{z}\mathrm{d}z$, which is elementary precisely for $\lambda \in \mathbb{N}$.[28]

In any case, at the moment we have no definite general conjecture in this direction, but we believe it should be interesting to explore the questions, the classes of functions and the conditions under which one can expect finiteness.

Another analogy concerns `reduction modulo a prime` p instead of specialization of a parameter. Namely, we suppose to be given a differential ω on an algebraic curve X defined over $\mathbb{Q}$ (or a number field K), so that we can reduce modulo almost all primes p (or places v of K), to obtain a differential ω_p on the reduced curve X_p, defined over the residue field $\mathbb{F}_p$. This is of course a kind of specialization, and we may ask as before for which primes p is ω_p integrable in finite terms, assuming that ω is not likewise integrable.

Naturally, the fact that the residue field has positive characteristic changes much, if not for the fact that the function field $\mathbb{F}_p(X_p)$ has finite degree over the constant field for a derivation. Indeed, there are several features which distinguish this analysis from the former one. Let us see two simple examples in this direction.

Example 6.1.
(i) Let E be an elliptic curve over $\mathbb{Q}$, with Weierstrass equation $w^2 = f(z)$ ($f \in \mathbb{Q}[z]$ a cubic monic polynomial with simple roots) and let $\omega = \mathrm{d}z/w$ be a regular differential (unique up to constants).

We have seen in §2 that in characteristic zero a regular differential is never integrable in finite terms. On the other hand, concerning the (good) reduction(s) E_p of E, we have:

- *If p is a prime of supersingular reduction for E* [29]*, i.e. if E_p is supersingular, then ω_p is exact, i.e. $\omega_p = \mathrm{d}u_p$ for some $u_p \in \overline{\mathbb{F}_p}(X_p)$.*
- *If E_p is ordinary, then $\omega_p = c_p \cdot \mathrm{d}u_p/u_p$ for some constant c_p and some nonzero $u_p \in \overline{\mathbb{F}_p}(X_p)$.*

See [12], Appendix 2.4, for a proof using the Cartier operator. So, we see that now

[26] In the paper [2], see especially §7, André has studied the context of a conjecture of Grothendieck on reductions modulo p of differential equations (to be mentioned also below) in the case of families in characteristic zero.

[27] This assumption is often relevant in the context, for instance to relate the differential Galois group to monodromy.

[28] Note that this equation has an irregular singularity at infinity.

[29] At least for curves over $\mathbb{Q}$, there are infinitely many such primes after a result of Elkies.

the reduction of ω is *always* integrable in finite terms, and is even exact for infinitely many primes.

This is in marked contrast with our previous conclusions (regarding specializations) in characteristic zero. (On the other hand, an integral of ω_p is algebraic only in the case of supersingular reduction.)

(ii) Let now $r \in \mathbb{Z}$ and, similarly to Example 4.1(ii), set $f(z) = z^4 + z + r$, and consider the curve E defined as a projective smooth model of $w^2 = f(z)$; the function z has two poles denoted $\infty_\pm$ and E becomes an elliptic curve on choosing e.g. ∞_- as an origin.

Consider $\omega := z\mathrm{d}z/w$; as in §2, ω has two simple poles at $\infty_\pm$ and no other poles. As recalled in Example 2.4(i), the Pell's equation (2.3) may be solvable for the present $f(z)$ only for finitely many $r \in \mathbb{Q}$; hence, Proposition 2.3 shows that for almost all $r \in \mathbb{Z}$, as in (i), ω is not integrable in finite terms. Let us then fix one such r, and as above let us p vary.

We haven't mentioned any analogue of Theorem 1.1 in positive characteristic, but we shall only need the sufficiency (for integrability in finite terms) of the condition stated therein. And actually it shall be sufficient to study whether $\omega_p = \mathrm{d}v_p + c_p \cdot \mathrm{d}u_p/u_p$ for rational functions u_p, v_p on E_p and a constant c_p.

Observe, by the way, that after reduction the Pell's equation is always solvable (as in the classical case of $\mathbb{Z}$), because any point on E_p defined over a finite field has finite order; however the analysis parallels only in part the one for Proposition 2.3.

Note that (after a possible finite extension of the constant field) there exists a function u_p whose divisor is of the shape $\infty_+ - \infty_- - pD_p$, where D_p is a divisor of degree 0 on E_p. Indeed, since $J_p := Pic^o(E_p)$ is a divisible group we can find $\gamma \in J_p$ so that $\delta = p\gamma$, where δ is the class of $\infty_+ - \infty_-$. And then, if D_p is a divisor of degree 0 with class γ, we find what is required.

Now, $\mathrm{d}u_p/u_p$ has only simple poles, exactly at $\infty_\pm$, with respective residues ± 1, and adjusting the constant c_p we can ensure that $\omega_p - c_p \cdot \mathrm{d}u_p/u_p$ has no poles, i.e. is a regular differential on E_p (possibly 0): $\omega_p = c_p \cdot \mathrm{d}u_p/u_p + \eta_p$, where η_p is regular on E_p.

But then, by what has been recalled in part (i) of this example, η_p is always either exact or logarithmic up to a constant. We conclude that again ω_p is always integrable in finite terms.

These examples show in particular that in this context things behave rather differently compared to what we have previously seen, since it happens that the reduction is always integrable in finite terms but the differential is not. On the contrary, if we look at an *algebraic* integral, things are different. Let us pause a moment on this interesting issue.

An attractive conjecture attributed to Pólya was as follows:

> *Let $f(z) = \sum_{n=0}^{\infty} a_n z^n$ be a power series with coefficients $a_n \in \mathbb{Z}$, representing an algebraic function. Suppose that an indefinite integral of $f(z)$ has also integral coefficients (which amounts to $n+1 | a_n$ for all $n \in \mathbb{N}$). Then the integral (that is, the power series $\sum_{n=0}^{\infty} a_n z^{n+1}/(n+1)$) also represents an algebraic function.*

This statement might look perhaps innocuous, however turned out to be deep; a proof for *rational functions* $f(z)$ is not too difficult, and similarly if $(z, f(z))$ describes a rational curve, but the case of positive genus is at a quite different level. A general proof was given by André, partly relying on a method of Chudnovski; see [2], Prop. 6.2.1.

Actually, André worked under weaker assumptions; he looked at the differential equation $y'(z) = f(z)$ and assumed the solvability of the reduction of this equation modulo p, in a power series in $\mathbb{F}_p[[z]]$, for all primes p in a set of density 1 (or even density $> 1/2$), to obtain the same conclusion that the equation has algebraic function solutions. André proved a similar theorem for the equation $y' = f(z)y$.

These theorems of André represent cases of a well-known conjecture of Grothendieck, which (roughly speaking) predicts *a complete system of algebraic function solutions for a linear differential equation over $\mathbb{Q}(z)$ whose reduction modulo p has a complete system of power series solutions over a finite field, for almost all primes p.* Other important cases of this deep conjecture, still open in general, were proved by Katz [9].

Naturally, one may replace $\mathbb{Q}$ by a number field.

We note that for the conclusion it does not suffice that the hypothesis holds for *infinitely many primes p*: indeed, as remarked in Example 6.1(i), a nonzero regular differential on an elliptic curve over $\mathbb{Q}$ becomes exact for the infinitely many primes of supersingular reduction (and if the curve is CM this set of primes has even density $1/2$).

We refer to [2], to §8 of [3] and to Katz's paper [9] for extensive discussions and results towards the Grothendieck conjecture and related topics. (As mentioned above, in [2] an analogue of the conjecture is studied in generality for fields of characteristic zero, including for instance pencils of differential equations over a curve.)

To conclude, we remark it would be interesting to formulate a general statement embracing the examples we have met so far.

Acknowledgements. The author is grateful to the ERC for providing support during the writing of this paper. We thank David Masser, with whom the whole research at the basis of this article has been carried out; he also provided many helpful illustrations and comments. We further thank Yves André and Jonathan Pila for other comments and references.

Small gaps between primes and primes in arithmetic progressions to large moduli

Yitang Zhang

Abstract. Let p_n denote the n-th prime. We describe the proof of the recent result

$$\liminf_{n\to\infty}(p_{n+1}-p_n)<\infty,$$

which is closely related to the distribution of primes in arithmetic progressions to large moduli. A major ingredient of the argument is a stronger version of the Bombieri-Vinogradov theorem which is applicable when the moduli are free from large prime factors.

Mathematics Subject Classification (2010). 11N05, 11N13.

Keywords. Gaps between primes, primes in arithmetic progressions, Bombieri-Vinogradov theorem, Kloostermann sums.

1. Introduction

Let p_n denote the n-th prime and write $d_n=p_{n+1}-p_n$. The prime number theorem implies that the average value of d_n is $\sim \log p_n$. The study of the upper and lower bounds for d_n is one of the central subjects in analytic number theory.

Currently, the best result on the upper bound for d_n is due to Baker, Harman and Pintz [1] that gives

$$d_n \ll p_n^{21/40}.$$

The lower bound for d_n has attracted great interest. For eighty years, the work on this problem had concentrated on estimating the quantity

$$\Delta=\liminf_{n\to\infty}\frac{d_n}{\log p_n}.$$

The inequality $\Delta\le 1$ is a trivial consequence of the prime number theorem. In 1926 Hardy and Littlewood [13] obtained $\Delta\le 2/3$ on assuming GRH. In 1940 Erdös [8] obtained $\Delta<1-c$ unconditionally with a small unspecified computable constant $c>0$. In 1965 Bombieri and Davenport [2] obtained $\Delta\le 0.4665....$ In 1988 Maier [16] obtained $\Delta\le 0.2484....$ In 2005 Goldston, Pintz and Yildirim [11] eventually proved

$$\Delta=0.$$

In 2013 Zhang [18] proved the following

Proceedings of the International Congress of Mathematicians, Seoul, 2014

Theorem 1.1.

$$\liminf_{n\to\infty} d_n < \infty. \tag{1.1}$$

This result may be regarded as a weak form of the twin prime conjecture

$$\liminf_{n\to\infty} d_n = 2. \tag{1.2}$$

In fact, Zhang proves (1.1) with the right side replaced by 7×10^7. This specific number has been considerably reduced.

A major ingredient of the proof is a stronger version of the Bombieri-Vinogradov theorem which is not implied by the Generalized Riemann Hypothesis directly, but it relies on some deep results in algebraic geometry.

Recently Maynard [15] obtained some stronger results via different methods. In particular, he proved

$$\liminf_{n\to\infty}(p_{n+k} - p_n) < \infty$$

for any fixed $k > 0$.

2. Admissible sets

Let

$$\mathcal{H} = \{h_1, h_2, ..., h_k\}$$

be a set composed of distinct non-negative integers. We say that $\mathcal{H}$ is admissible if $\nu_p(\mathcal{H}) < p$ for every prime p, where $\nu_p(\mathcal{H})$ denotes the number of distinct residue classes modulo p occupied by the h_j.

The reason for introducing admissible sets may be described as follows. Assume that $\mathcal{H}$ is not admissible. Then there is a prime p such that, for any positive integer n, the tuple

$$(n + h_1, n + h_2, ..., n + h_k) \tag{2.1}$$

contains at least one multiple of p. Thus we conclude

Suppose that there are infinitely many positive integers n such that each element in the tuple (2.1) is a prime. Then $\mathcal{H}$ must be admissible.

A conjecture of Hardy and Littlewood asserts the converse. Here we state a weak form of their conjecture only.

Conjecture 2.1. *Suppose that $\mathcal{H}$ is admissible. There are infinitely many positive integers n such that each element in the tuple* (2.1) *is a prime.*

Note that the twin prime conjecture is a special case of this conjecture with $\mathcal{H} = \{0, 2\}$.

It is easy to see that Theorem 1.1 can be deduced from the following

Theorem 2.2. *Suppose that $\mathcal{H}$ is admissible with k sufficiently large. There are infinitely many positive integers n such that the tuple* (2.1) *contains at least two primes.*

Theorem 2.2 actually gives

$$\liminf_{n\to\infty} d_n \le \max_{i\neq j} |h_i - h_j|. \tag{2.2}$$

The initial step in the proof of Theorem 2.2 consists in transferring the problem to evaluate and compare certain arithmetic sums. Write

$$\theta(n) = \begin{cases} \log n & \text{if } n \text{ is prime,} \\ 0 & \text{otherwise.} \end{cases}$$

Let x denote a large number, and let f be defined on $(x, 2x) \cap \mathbf{Z}$ such that

$$f(n) \geq 0. \tag{2.3}$$

We introduce

$$S_1(x, f) = \sum_{x<n<2x} f(n) \tag{2.4}$$

and

$$S_2(x, f; \mathcal{H}) = \sum_{x<n<2x} \left(\sum_{j=1}^{k} \theta(n + h_j) \right) f(n). \tag{2.5}$$

The key point is to prove that, for any sufficiently large x, there is a function f satisfying (2.3), such that

$$\frac{S_2(x, f; \mathcal{H})}{S_1(x, f)} > \log 3x. \tag{2.6}$$

This implies that there is an integer $n \in (x, 2x)$ such that the tuple (2.1) contains at least two primes.

3. The choice of f by Goldsdon-Pintz-Yildirim

From now on, the set $\mathcal{H}$ is assumed to be admissible and fixed.

To choose f and show that (2.6) holds, the following conditions are necessary.

(i) f should be non-negative.

(ii) One should be able to evaluate the sums $S_1(x, f)$ and $S_2(x, f; \mathcal{H})$ efficiently.

(iii) The sum $S_2(x, f; \mathcal{H})$ should be "large" in comparison with $S_1(x, f)$.

Let $\Lambda(n)$ denote the von Mangoldt function. To satisfy the condition (iii), one may choose

$$f(n) = \sum_{j=1}^{k} \Lambda(n + h_j)$$

(the difference $\theta - \Lambda$ is negligible). However, this is not valid in practice since one is unable to evaluate $S_2(x, f; \mathcal{H})$.

It is known that

$$\Lambda(n) = \sum_{d|n} \mu(d) \log \frac{n}{d}, \tag{3.1}$$

where $\mu(d)$ denotes the Möbius function. This relation may not be applicable directly in

many sieve problems, since one is unable to handle the contribution from the terms on the right side with d large. In practice, $\Lambda(n)$ is often approximated (replaced) by

$$\Lambda_D(n) = \sum_{\substack{d|n \\ d<D}} \mu(d) \log \frac{D}{d} \tag{3.2}$$

for $n < 2x$, where D is a parameter $< x$. Usually, D is of the form

$$D = x^b, \qquad 0 < b < \frac{1}{2}. \tag{3.3}$$

If one chooses

$$f(n) = \sum_{j=1}^{k} \Lambda_D(n + h_j),$$

then, with D given by (3.3), $S_1(x, f)$ and $S_2(x, f; \mathcal{H})$ can be evaluated. However, the condition (i) may not hold.

In order to satisfy the condition (i), a simple idea which comes from Selberg's sieve is that f takes the form

$$f(n) = \lambda(n)^2, \qquad \lambda(n) \in \mathbf{R}. \tag{3.4}$$

From now on, we assume that f is of the form (3.4) and write $D = x^b$. The problem is reduced to choosing λ.

It was Goldston, Pintz and Yildirim who found a form of $\lambda(n)$ which proves very efficient. Let

$$P_{\mathcal{H}}(n) = \prod_{j=1}^{k} (n + h_j), \tag{3.5}$$

and let l be a fixed positive integer. They choose

$$\lambda(n) = \frac{1}{(k+l)!} \sum_{\substack{d|P_{\mathcal{H}}(n) \\ d<D}} \mu(d) \bigg(\log \frac{D}{d} \bigg)^{k+l}. \tag{3.6}$$

One may also consider the general form

$$\lambda(n) = \sum_{\substack{d|P_{\mathcal{H}}(n) \\ d<D}} \mu(d) h\bigg(\frac{\log(D/d)}{\log D} \bigg), \tag{3.7}$$

where h is a real polynomial satisfying

$$h^{(i)}(0) = 0, \qquad 0 \le i \le k.$$

The form (3.7) and its variants also find application to other problems in analytic number theory, which is usually called the GPY sieve.

From now on, we assume that $b < 1/2$ and write ν_p, $P(n)$, S_1 and S_2 for $\nu_p(\mathcal{H})$, $P_{\mathcal{H}}(n)$, $S_1(x, f)$ and $S_2(x, f; \mathcal{H})$ respectively; similar abbreviations will apply in the sequel. Let $\lambda(n)$ be as in (3.6). Write

$$g(d) = \frac{1}{(k+l)!} \bigg(\log \frac{D}{d} \bigg)^{k+l} \quad \text{if} \quad d < D \tag{3.8}$$

and

$$g(d) = 0 \quad \text{if} \quad d \geq D, \tag{3.9}$$

so that

$$\lambda(n) = \sum_{d|P(n)} \mu(d)g(d). \tag{3.10}$$

The evaluation of S_1 is not difficult. Squaring out $\lambda(n)^2$ and changing the order of summation we obtain

$$S_1 = \sum_{d_1} \sum_{d_2} \mu(d_1)\mu(d_2)g(d_1)g(d_2) \sum_{\substack{x<n<2x \\ P(n)\equiv 0([d_1,d_2])}} 1, \tag{3.11}$$

where $[d_1, d_2]$ denotes the l.c.m. of d_1 and d_2. Note that $[d_1, d_2]$ is square-free and

$$[d_1, d_2] < D^2 = x^{2b}$$

if $\mu(d_1)\mu(d_2)g(d_1)g(d_2) \neq 0$. Let

$$\varrho_1(d) = |\mu(d)| \prod_{p|d} \nu_p. \tag{3.12}$$

For any square-free d, $d|P(n)$ if and only if n lies in exactly $\varrho_1(d)$ distinct residue classes $(\mathrm{mod}\ d)$. It follows that the innermost sum in (3.11) is equal to

$$\frac{\varrho_1([d_1, d_2])}{[d_1, d_2]} x + O(\varrho_1([d_1, d_2])).$$

This yields

$$S_1 = xT_1 + O(x^{2b+\varepsilon}), \tag{3.13}$$

where

$$T_1 = \sum_{d_1} \sum_{d_2} \frac{\mu(d_1)\mu(d_2)g(d_1)g(d_2)\varrho_1([d_1, d_2])}{[d_1, d_2]}. \tag{3.14}$$

The error term in (3.13) is acceptable since $b < 1/2$.

We now turn to S_2. In a way similar to the proof of (3.11), we deduce that

$$S_2 = \sum_{d_1} \sum_{d_2} \mu(d_1)\mu(d_2)g(d_1)g(d_2) \sum_{j=1}^{k} \sum_{\substack{x<n<2x \\ P(n)\equiv 0([d_1,d_2])}} \theta(n + h_j). \tag{3.15}$$

If d is square-free, $d < D^2$, $n \in (x, 2x)$ and $n + h_j$ is a prime, then $d|P(n)$ if and only if

$$d \equiv c(\mathrm{mod}\ d) \quad \text{for some} \quad c \in \mathcal{C}_j(d),$$

where

$$\mathcal{C}_j(d) = \{c : 1 \leq c \leq d,\ (c, d) = 1,\ P(c - h_j) \equiv 0(\mathrm{mod}\ d)\}. \tag{3.16}$$

Thus the innermost sum in (3.15) is equal to

$$\sum_{c\in\mathcal{C}_j([d_1,d_2])} \sum_{\substack{x<n<2x \\ n\equiv c([d_1,d_2])}} \theta(n + h_j). \tag{3.17}$$

Let

$$\varrho_2(d) = |\mu(d)| \prod_{p|d} (\nu_p - 1). \tag{3.18}$$

For square-free d it can be shown that

$$|\mathcal{C}_j(d)| = \varrho_2(d).$$

It follows from (3.17) and the prime number theorem that the innermost sum in (3.15) is equal to

$$\frac{\varrho_2(d)}{\varphi(d)} x + O\Big(\sum_{c \in \mathcal{C}_j(d)} \mathcal{R}(x; c, d) \Big) + O(x^{\varepsilon}), \tag{3.19}$$

where $\varphi(d)$ denotes the Euler function, and where

$$\mathcal{R}(x; d, c) = \Big| \sum_{\substack{x<n<2x \\ n \equiv c(d)}} \theta(n) - \frac{x}{\varphi(d)} \Big|. \tag{3.20}$$

Inserting (3.19) into (3.15) we obtain

$$S_2 = xT_2 + O((\log x)^{2k+2l} E) + O(x^{2b+\varepsilon}), \tag{3.21}$$

where

$$T_2 = k \sum_{d_1} \sum_{d_2} \frac{\mu(d_1)\mu(d_2) g(d_1) g(d_2) \varrho_2([d_1, d_2])}{\varphi([d_1, d_2])} \tag{3.22}$$

and

$$E = \sum_{d < D^2} |\mu(d)| \tau_3(d) \varrho_2(d) \sum_{j=1}^{k} \sum_{c \in \mathcal{C}_j(d)} \mathcal{R}(x; c, d).$$

Here $\tau_3(d)$ denotes the 3-fold divisor function.

The problem is now reduced to evaluation T_1 and T_2 and estimating E.

4. The main term

By (3.13) and (3.21), we need only prove the following which lead to (2.6).

(a) With k sufficiently large and with l appropriately chosen,

$$\frac{T_2}{T_1} > (1 + c) \log x \tag{4.1}$$

for some positive constant c.

(b) The sum E can be efficiently bounded, namely,

$$E \ll x(\log x)^{-A} \tag{4.2}$$

for any large constant A.

Note that ϱ_1 is supported on square-free integers. Substituting $d_0 = (d_1, d_2)$ and rewriting d_1 and d_2 for d_1/d_0 and d_2/d_0 respectively, we deduce that

$$T_1 = \sum_{d_0} \sum_{d_1} \sum_{d_2} \frac{\mu(d_1 d_2)\varrho_1(d_0 d_1 d_2)}{d_0 d_1 d_2} g(d_0 d_1) g(d_0 d_2). \tag{4.3}$$

Similarly,

$$T_2 = k \sum_{d_0} \sum_{d_1} \sum_{d_2} \frac{\mu(d_1 d_2)\varrho_2(d_0 d_1 d_2)}{\varphi(d_0 d_1 d_2)} g(d_0 d_1) g(d_0 d_2). \tag{4.4}$$

The right sides of (4.3) and (4.4) can be evaluated by standard methods. It is shown that

$$T_1 \sim \frac{1}{(k+2l)!} \binom{2l}{l} \mathfrak{S} (\log D)^{k+2l}$$

and

$$T_2 \sim \frac{k}{(k+2l+1)!} \binom{2l+2}{l+1} \mathfrak{S} (\log D)^{k+2l+1},$$

where

$$\mathfrak{S} = \prod_p \left(1 - \frac{\nu_p}{p}\right) \left(1 - \frac{1}{p}\right)^{-k}.$$

(Note that $\mathfrak{S} = 0$ if $\mathcal{H}$ is not admissible.) It follows that

$$\frac{T_2}{T_1} \sim \frac{bk}{k+2l+1} \frac{(2l+2)(2l+1)}{(l+1)^2} \log x. \tag{4.5}$$

If $b > 1/4$, then, with k is sufficiently large in terms of b and with l appropriately chosen, we have

$$\frac{bk}{k+2l+1} \frac{(2l+2)(2l+1)}{(l+1)^2} > 1. \tag{4.6}$$

This leads to (4.1). On the other hand, the relation (4.6) is not valid for $b \le 1/4$.

Thus we conclude

Theorem 2.2 will be valid if (4.2) *holds for some* $b > 1/4$.

5. The error term

We say that the primes have level of distribution ϑ if, for any large constant A and for any small positive constant ε,

$$\sum_{d<Q} \max_{y \le x} \max_{(c,d)=1} \left| \sum_{\substack{n \le y \\ n \equiv c(d)}} \Lambda(n) - \frac{y}{\varphi(d)} \right| \ll x (\log x)^{-A} \tag{5.1}$$

with $Q = x^{\vartheta - \varepsilon}$. Since the estimate

$$\sum_{\substack{n \le y \\ n \equiv c(d)}} \Lambda(n) - \frac{y}{\varphi(d)} \ll y^{1/2+\varepsilon}$$

is implied by the GRH, the primes have level of distribution $1/2$ if GRH is true. This result was unconditionally proved by Bombieri and Vinogradov in 1965.

Theorem 5.1. *The primes have level of distribution* $1/2$.

Elliott and Halberstam [7] conjectured that the primes have level of distribution 1. By Cauchy's inequality, we see that (4.2) will be valid if the primes have level of distribution $\vartheta = 2b + \varepsilon$. Thus, by the discussion in Section 4, we conclude

> *Theorem 2.2 will be valid if the primes have level of distribution* ϑ *for some* $\vartheta > 1/2$.

6. Refinement of the GPY method

One is unable to prove that the primes have level of distribution ϑ for some $\vartheta > 1/2$, even if the GRH is assumed. We introduce a refinement of the GPY method which applies to the main and error terms equally.

Let $\varpi > 0$ be a small constant, and let $b = 1/4 + \varpi$. Our first observation is that, on the right sides of (4.3) and (4.4), the terms with $d_0d_1d_2$ having a large prime factor p, say $p \geq x^{\varpi}$, make minor contribution. Thus, if we modify the sum in (3.6) by imposing the constraint that $p|d$ implies $p < x^{\varpi}$, the resulting main terms in S_1 and S_2 will have minor changes only. This was independently observed by Motohashi and Pintz. Our second observation, which is the most novel part of the proof, is that with such a constraint imposed in (3.6), the resulting error in S_2 can be efficiently bounded.

From now on, let S_1, S_2 and $f(n)$ be as in (2.4), (2.5) and (3.4) respectively, but let $\lambda(n)$ be redefined by

$$\lambda(n) = \sum_{d|(P(n),\mathcal{P})} \mu(d)g(d)$$

with $g(d)$ given by (3.8) and (3.9), where

$$\mathcal{P} = \prod_{p<x^{\varpi}} p.$$

Repeating the arguments in Section 4 we obtain

$$S_1 = xT_1^* + O(x^{2b+\varepsilon})$$

and

$$S_2 = xT_2^* + O((\log x)^{2k+2l}E^*) + O(x^{2b+\varepsilon}),$$

where

$$T_1^* = \sum_{d_1|\mathcal{P}} \sum_{d_2|\mathcal{P}} \frac{\mu(d_1)\mu(d_2)g(d_1)g(d_2)\varrho_1([d_1,d_2])}{[d_1,d_2]},$$

$$T_2^* = k \sum_{d_1|\mathcal{P}} \sum_{d_2|\mathcal{P}} \frac{\mu(d_1)\mu(d_2)g(d_1)g(d_2)\varrho_2([d_1,d_2])}{\varphi([d_1,d_2])}$$

and

$$E^* = \sum_{\substack{d<D^2\\ d|\mathcal{P}}} |\mu(d)|\tau_3(d)\varrho_2(d)\sum_{j=1}^{k}\sum_{c\in\mathcal{C}_j(d)}\mathcal{R}(x;c,d).$$

By routine estimations of the differences $T_1 - T_1^*$ and $T_2 - T_2^*$ and (4.5), it can be shown that

$$\frac{T_1^*}{T_2^*} > (1+c)\log x$$

for some constant $c > 0$, if k is sufficiently large and if l is appropriately chosen. The proof of Theorem 2.2 is therefore reduced to proving

Theorem 6.1. *If ϖ is sufficiently small, then*

$$E^* \ll x(\log x)^{-A}$$

for any large constant A.

7. Sketch of the proof of Theorem 6.1

Note that $D^2 = x^{1/2+2\varpi}$. By Theorem 5.1 and Cauchy's inequality, the proof of Theorem 6.1 is reduced to showing that

$$\sum_{\substack{x^{1/2-\varepsilon}<d<D^2\\ d|\mathcal{P}}}\sum_{c\in\mathcal{C}_j(d)}\mathcal{R}(x;c,d) \ll x(\log x)^{-2A} \qquad 1\le j\le k. \tag{7.1}$$

The constraint $d|\mathcal{P}$ is crucial in the proof of (7.1). This is originally due to the simple fact that if $1 < R < d$, $d > x^{1/2-\varepsilon}$ and $d|\mathcal{P}$, then d can be factored as

$$d = rq \qquad \text{with} \qquad R < r < x^{\varpi}R. \tag{7.2}$$

We can replace θ by Λ in the expression for $\mathcal{R}(x;c,d)$. The proof of (7.1) is described as follows. For any function γ supported on $(x, 2x)\cap\mathbf{Z}$ we define

$$\Delta(\gamma;c,d) = \Big|\sum_{n\equiv c(d)}\gamma(n) - \frac{1}{\varphi(d)}\sum_{(n,d)=1}\gamma(n)\Big|, \qquad (c,d)=1.$$

Using a combinatorial identity for Λ due to Heath-Brown [14], the proof of (7.1) is reduced to estimating the sum of $\Delta(\gamma;c,d)$ for certain Dirichlet convolutions γ. There are three types of the convolutions involved in the proof. Write

$$\eta = 1 + (\log x)^{-2A}, \qquad x_1 = x^{3/8+8\varpi}, \qquad x_2 = x^{1/2-4\varpi}.$$

In the first two types the function γ is of the form $\gamma = \alpha * \beta$ such that

(i) $\alpha = (\alpha(m))$ is supported on $[M,\ \eta^{19}M)$,

(ii) $\beta = (\beta(n))$ is supported on $[N,\ \eta^{19}N)$,

(iii) $MN \in (x, 2x)$.

(There are some other conditions on $\alpha(m)$ and $\beta(n)$.) We say that γ is of Type I if $x_1 < N \le x_2$; we say that γ is of Type II if $x_2 < N < 2x^{1/2}$; we say that γ is of Type III if it is of the form $\gamma = \alpha * \varkappa_{N_1} * \varkappa_{N_2} * \varkappa_{N_3}$ where α is as in (i) and $\varkappa_N$ is the characteristic function of $[N,\, \eta N) \cap \mathbf{Z}$, such that

(iv) $N_3 \le N_2 \le N_1, \qquad MN_1 \le x_1$,

(v) $MN_1N_2N_3 \in (x, 2x)$.

It should be stressed that, without the constraint $d|\mathcal{P}$, we are unable to efficiently bound the sum

$$\sum_{x^{1/2-\varepsilon}<d<D^2} \sum_{c\in\mathcal{C}_j(d)} \Delta(\gamma; c, d)$$

if γ is of Type I or II. However, by (7.2), the Type I and II estimates are reduced to bounding sums of the type

$$\sum_{R<r<2R} \sum_{Q<q<2Q} \sum_{c\in\mathcal{C}_j(rq)} \Delta(\gamma; c, rq) \tag{7.3}$$

with R appropriately chosen such that it is close to N in the logarithmic scale. Thus, using the dispersion method due to Bombieri, Fouvry, Friedlander and Iwaniec [3–5, 9], and Weil's bound for Kloosterman sums, we can prove that the sum (7.3) is

$$\ll x(\log x)^{-43A}. \tag{7.4}$$

The Type III estimate essentially relies on the Birch-Bombieri result in the appendix to Friedlander and Iwaniec [10]. This result in turn relies on Deligne's proof of the Riemann Hypothesis for varieties over finite fields (the Weil Conjecture)[6]. Assuming γ is of Type III, we estimate each $\Delta(\gamma; c, d)$ directly. However, without the constraint $d|\mathcal{P}$, efficient bounds for $\Delta(\gamma; c, d)$ can not be obtained unless we relax the condition $MN_1 \le x_1$. Our argument is carried out by combining the method in [10] and the factorization (7.2) (here r is chosen to be relatively small), the latter will allow us to save a factor $r^{1/2}$. Thus we obtain

$$\Delta(\gamma; c, d) \ll \frac{x^{1-\varepsilon}}{d} \tag{7.5}$$

for $x^{1/2-\varepsilon} < d < D^2$, $d|\mathcal{P}$ and $(c, d) = 1$.

The estimate (7.1) follows from (7.4) and (7.5).

Linear equations in primes and dynamics of nilmanifolds

Tamar Ziegler

Abstract. In this paper we survey some of the ideas behind the recent developments in additive number theory, combinatorics and ergodic theory leading to the proof of Hardy-Littlewood type estimates for the number of prime solutions to systems of linear equations of finite complexity.

Mathematics Subject Classification (2010). Primary 11B30, 37A30 ; Secondary 11B25, 37A45.

Keywords. Multiple recurrence, arithmetic progressions, Szemerédi's Theorem, Gowers norms, Hardy-Littlewood conjectures.

1. Introduction

A famous conjecture of Hardy and Littlewood [29] predicts that given a k-tuple of integers $\mathcal{H} = \{h_1, \dots, h_k\}$, there are infinitely many k-tuples

$$x + h_1, \dots, x + h_k,$$

such that all elements are simultaneously prime unless there is an obvious divisibility obstruction. Denote by $\nu_{\mathcal{H}}(p)$ the number of congruence classes modulo p that $\mathcal{H}$ occupies, and call a k-tuple of integers admissible if $\nu_{\mathcal{H}}(p) < p$ for all primes p. Then the Hardy-Littlewood conjecture amounts to the statement that $x + h_1, \dots, x + h_k$ are simultaneously prime infinitely often if and only if $\mathcal{H}$ is admissible. Moreover, they conjectured a precise formula for the asymptotic number of k-tuples for an admissible $\mathcal{H}$: Let $\mathbb{P}$ denote the set of primes, then

$$|\{x \in [1, N], \{x + h_1, \dots, x + h_k\} \subset \mathbb{P}\}| \sim \mathfrak{S}(\mathcal{H}) \frac{N}{(\log N)^k}.$$

The constant $\mathfrak{S}(\mathcal{H})$ is an Euler product and is called the singular series.[1] While there have recently been extraordinary developments towards our understanding of gaps between primes and prime tuples [17, 36, 37, 51], some of them presented at the current ICM, we are still far from proving this conjecture.

One can relax the conjecture by looking for prime points in higher rank affine sublattices of $\mathbb{Z}^k$. In a series of papers by Green-Tao [21, 22], Green-Tao-Z [24] we prove:

Proceedings of the International Congress of Mathematicians, Seoul, 2014

Theorem 1.1 (Green-Tao-Z (2012)). *Let $\{\psi_i(\vec{x})\}_{i=1}^k$ be a collection of k affine linear forms in m variables with integer coefficients, $\psi_i(\vec{x}) = \sum_{j=1}^m a_{ij}x_j + b_i$. Suppose no two forms are affinely dependent*[2]*. Then*

$$|\{\vec{x} \in [0,N]^m, \{\psi_1(\vec{x}), \dots, \psi_k(\vec{x})\} \subset \mathbb{P}\}| \sim \mathfrak{S}(\vec{\psi})\frac{N^m}{(\log N)^k}$$

where $\mathfrak{S}(\vec{\psi})$ is an explicit Euler product (analogous to $\mathfrak{S}(H)$).

As a special case of this theorem we obtain the asymptotic number of k-term arithmetic progressions of primes. The reader will observe that the condition that no two forms are affinely dependent rules out the important case of twin primes, or more generally any k-tuple with bounded gaps as described above, however its non-homogeneous nature allows one to use it in various applications that were previously conditional on the Hardy-Littlewood conjectures (see for example [8, 30]). Theorem 1.1 may be viewed as a vast generalization of Vinogradov's 3-prime theorem [49]: any large enough odd number is a sum of three primes. We remark that very recently Vinogradov's result has been extended to include all odd numbers greater that 5 [31], thus verifying the weak Goldbach conjecture.

In this paper we give an outline of intertwining developments in ergodic theory, combinatorics and additive number theory leading to Theorem 1.1.

2. Arithmetic progressions in sets of positive density

Our starting point on the combinatorial front is the following result of K. Roth [39]. Let $E \subset \mathbb{N}$. The *upper density* of E is defined to be

$$\bar{d}(E) = \limsup_{N\to\infty} \frac{|E \cap [1,N]|}{N}.$$

Theorem 2.1 (Roth 1953). *Let $E \subset \mathbb{N}$ be a set of positive upper density, then E contains a non trivial 3-term arithmetic progression.*

Roth's proof plays an important role in later developments - we outline the idea below. Let $\delta > 0$, and suppose E has density δ in an arithmetic progression P of size N, namely $E \subset P$ and $|E| = \delta N$. We first observe that if each element in P were to be chosen independently at random to be in E with probability δ then E would typically contain many 3-term progressions - approximately $\delta^3 N^2$. In view of this, Roth's argument is based on the following:

- either E has at least $\frac{\delta^3 N^2}{2}$ 3-term progressions, or

[1]The singular series $\mathfrak{S}(\mathcal{H})$ is given by the Euler product

$$\mathfrak{S}(\mathcal{H}) = \prod_p \left(1 - \frac{\nu_{\mathcal{H}}(p)}{p}\right)\left(1 - \frac{1}{p}\right)^{-k}.$$

We refer the reader to [42] for an excellent exposition of the heuristics leading to the conjecture above. We write $a(N) \sim b(N)$ if $a(N) = b(N)(1 + o(1))$.

[2]Affine linear forms are affinely dependent is their linear parts are linearly dependent; e.g. the forms x and $x+2$ are affinely dependent. A collection of k affine linear forms no two forms are affinely dependent is said to be of *finite complexity* [21].

- E has density at least $\delta + c(\delta)$ on a sub-progression $Q \subset P$ of size $N^{\frac{1}{3}}$, where c is a decreasing positive function.

Our starting point is a subset $E \subset P = [1, N]$, of density δ. After running the above argument at most $s = 1/c(\delta)$ times we obtain a subset $E' \subset E$ which is of density (exactly) 1 in a subprogression $P' \subset [1, N]$ of size at least $N^{\frac{1}{3^s}}$. Namely, either at some point we have many 3-term arithmetic progressions, or after finitely many steps we find an arithmetic progression of size $N^{\frac{1}{3^s}}$ in E; if N is sufficiently large then $N^{\frac{1}{3^s}} \geq 3$.

We remark that a more careful analysis allows one to have the density δ depend on N in the form $\delta = 1/(\log\log N)^t$ [3].

The main issue is, of course, the second step in this argument - namely, obtaining increased density on a large subprogression. This can be achieved via discrete Fourier analysis - one considers E as a subset of $\mathbb{Z}_N = \mathbb{Z}/N\mathbb{Z}$. Denoting 1_E the characteristic function of E, one shows that if E does not contain roughly the expected number of 3-term progressions, then the function $1_E - \delta$ has a large non trivial Fourier coefficient, namely, there exist an integer r such that

$$\left| \frac{1}{N} \sum_{x \in \mathbb{Z}_N} (1_E - \delta)(x) e^{2\pi i x \frac{r}{N}} \right| \geq c(\delta).$$

Using equidistribution properties of the sequence $\{x\frac{r}{N}\}$ mod 1, one finds a large subprogression Q - of size $N^{\frac{1}{3}}$ - on which $x\frac{r}{N}$ is roughly constant. This in turn can be translated into an increased density of at least $\delta + c(\delta)$ on (many) translates of Q. This type of argument is referred to nowadays as a *density increment argument*.

Generalizing Roth's theorem to k-term progressions for $k > 3$ turned out to be very difficult, and was shown by Szemerédi in his famous theorem [44]:

Theorem 2.2 (Szemerédi 1975). *Let E be a set of positive upper density, then E contains a non trivial k-term arithmetic progression.*

By now there are many proofs of Szemerédi's theorem. In this paper we will focus on two of them: Furstenberg's ergodic theoretic proof, which marked the beginning of the ergodic theoretic side of our story, and Gowers's proof, which pioneered the application of tools from additive combinatorics to the study of arithmetic progressions.

3. Furstenberg's proof of Szemerédi's theorem

Shortly after Szemerédi proved the theorem on arithmetic progressions in sets of positive upper density in the integers, Furstenberg gave an ergodic theoretic proof of Szemerédi's theorem [15]. The ideas behind this proof initiated a new field in ergodic theory, referred to as *ergodic Ramsey theory*, and are the foundation of all subsequent ergodic theoretic developments on which the story in our paper is based.

Furstenberg first observed that one can translate questions about patterns in subsets of positive density in the integers to return time questions for sets of positive measure in a measure preserving system. More precisely:

[3] The state of the art in the question of 3-term progressions is the recent result of T. Sanders stating that one can have the density as small as $\delta = 1/\log N^{1-o(1)}$ [41].

Theorem 3.1 (Furstenberg correspondence principle). *Let $\delta > 0$, and let $E \subset \mathbb{N}$ be a set with positive upper density*[4]*. There exists a probability measure preserving system*[5] *$(X, \mathcal{B}, \mu, T)$, and a measurable set A with $\mu(A) > 0$, such that the following holds: if for some integers $n_1, \ldots, n_k$*

$$\mu(A \cap T^{-n_1} A \cap \ldots \cap T^{-n_k} A) > 0,$$

then

$$\bar{d}(E \cap (E - n_1) \cap \ldots \cap (E - n_k)) > 0.$$

In particular, there exists an integer x such that $x, x + n_1, \ldots, x + n_k \in E$.

It follows that if we seek a $k+1$ term arithmetic progression in E, it suffices to show that for any probability measure preserving system $(X, \mathcal{B}, \mu, T)$, and any A with $\mu(A) > 0$, there is a positive integer n with $\mu(A \cap T^{-n} A \cap \ldots \cap T^{-kn} A) > 0$. Observe that the case $k = 1$ is the famous Poincaré recurrence theorem. Indeed, Furstenberg proves the following theorem:

Theorem 3.2 (Furstenberg multiple recurrence theorem). *Let $(X, \mathcal{B}, \mu, T)$ be a measure preserving system, and let A be with $\mu(A) > 0$. Then for any $k > 0$*

$$\liminf_{N \to \infty} \frac{1}{N} \sum_{n \leq N} \mu(A \cap T^{-n} A \cap \ldots \cap T^{-kn} A) > 0. \tag{3.1}$$

On first impression, it might seem that in replacing the arbitrary set E of positive density with an arbitrary set A of positive measure, our situation is not much improved. However, in the ergodic theoretic context one might hope to prove and apply useful structure theorems. In the case at hand - the averages (3.1) are studied via morphism to more structured measure preserving systems, as we will try to demonstrate below.

We will henceforth assume that the system $\mathbf{X}$ is *ergodic*, namely any T-invariant set is of measure either 0 or 1. Any system can be decomposed to its ergodic components, thus we lose no generality in Theorem 3.2 by making this assumption.

We first briefly discuss Furstenberg's ergodic theoretic proof of Roth's theorem on 3-term progressions. We wish to evaluate the average

$$\frac{1}{N} \sum_{n \leq N} \mu(A \cap T^{-n} A \cap T^{-2n} A) = \frac{1}{N} \sum_{n \leq N} \int 1_A(x) 1_A(T^n x) 1_A(T^{2n} x) d\mu$$

where $1_A(x)$ is the characteristic function of A. Furstenberg proves that there exists a measure preserving system $\mathbf{Z} = (Z, \mathcal{B}_Z, \mu_Z, T_Z)$ that is a *Kronecker system*[6], and a morphism[7]

[4]Furstenberg's correspondence principle as well as his multiple recurrence theorem hold in the more general context when one considers the *upper Banach density* of the set E,

$$d^*(E) = \limsup_{N - M \to \infty} \frac{|E \cap [M, N-1]|}{N - M}.$$

We will keep to the upper density for simplicity.

[5]A probability *measure preserving system* $\mathbf{X} = (X, \mathcal{B}, \mu, T)$ consists of a probability space $(X, \mathcal{B}, \mu)$ and an invertible measurable map $T : X \to X$ with $T_* \mu = \mu$.

[6]A Kronecker system $\mathbf{Z} = (Z, \mathcal{B}_Z, \mu_Z, T_Z)$ is a system where Z is a compact Abelian group, $\mathcal{B}_Z$ the Borel σ-algebra, μ_Z the Haar measure, and T_Z is a rotation $T_Z(x) = x + \alpha$ for some $\alpha \in Z$

[7]A morphism between measure preserving systems $\mathbf{X}, \mathbf{Y}$ is a measure preserving map between the corresponding measure spaces that intertwines the actions of T_X, T_Y. In this case $\mathbf{Y}$ is called a *factor* of $\mathbf{X}$.

$\pi : \mathbf{X} \to \mathbf{Z}$ such that for any $f_0, f_1, f_2 \in L^\infty(X)$,

$$\frac{1}{N}\sum_{n\leq N}\int f_0(x)f_1(T^n x)f_2(T^{2n}x)d\mu$$

is asymptotically the same as

$$\frac{1}{N}\sum_{n\leq N}\int \pi_* f_0(z)\pi_* f_1(T_Z^n z)\pi_* f_2(T_Z^{2n}z)d\mu_Z.$$

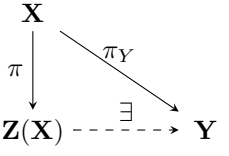
That is, rather than trying to evaluate the average in an arbitrary (ergodic) system, we need to evaluate it in a very special system - a compact abelian group rotation system: we are left with evaluating

$$\lim \frac{1}{N}\sum_{n\leq N}\int \pi_* 1_A(z)\pi_* 1_A(z+n\alpha)\pi_* 1_A(z+2n\alpha)d\mu_Z.$$

Via Fourier analysis the above limit is easily seen to equal

$$\int \pi_* 1_A(z)\pi_* 1_A(z+b)\pi_* 1_A(z+2b)d\mu_Z(z)d\mu_Z(b).$$

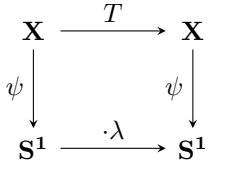
Now the projection π_* is a positive operator, namely if $f \geq 0$ then $\pi_* f \geq 0$. It follows that $\pi_* 1_A \geq 0$, and since $\int \pi_* 1_A d\mu_Z = \int 1_A d\mu = \mu(A) > 0$, the above average is clearly positive. The system $\mathbf{Z} = \mathbf{Z}(\mathbf{X})$ is called the *Kronecker factor* of $\mathbf{X}$ and satisfies the following universal property. If $\mathbf{Y}$ is a Kronecker system that is a factor of X and $\pi_Y : \mathbf{X} \to \mathbf{Y}$ the factor map, then π_Y factors through $\mathbf{Z}(\mathbf{X})$ as demonstrated in the diagram below:



The factor $\mathbf{Z}(\mathbf{X})$ is constructed via the eigenfunctions of $\mathbf{X}$. Let us demonstrate why a non trivial eigenfunction implies the existence of a non-trivial circle rotation factor. Let ψ be an eigenfunction of $\mathbf{X}$,

$$\psi(Tx) = \lambda\psi(x).$$

The function $|\psi|$ is a T-invariant function, and by ergodicity $|\psi|$ is constant a.e. Thus we can normalize ψ to take values in the unit circle. Any normalized eigenfunction gives rise to a morphism to a circle rotation system $\psi : \mathbf{X} \to (S^1, \mathrm{Borel}, \mathrm{Haar}, \cdot\lambda)$:



The factor $\mathbf{Z}(\mathbf{X})$ would then be the image of the map $(\psi_i) : X \to (S^1)^{\mathbb{N}}$ given by $x \to (\psi_i(x))$, where $\{\psi_i\}$ is the collection of normalized eigenfunctions[8] of $\mathbf{X}$.

If $\mathbf{X}$ has no non-trivial eigenfunctions, then $\mathbf{Z}(\mathbf{X})$ is trivial (a point system), and thus $\pi_* f = \int f \, d\mu$. In this case $\mathbf{X}$ is called *weakly mixing*. We then have

$$\frac{1}{N}\sum_{n=1}^{N}\int f(x)f(T^n x)f(T^{2n}x)\,d\mu \to \left(\int f\,d\mu\right)^3,$$

and we can thus think of the points $x, T^n x, T^{2n}x$ as asymptotically independent on average. The content of Furstenberg's argument is then that if $x, T^n x, T^{2n}x$ are *not* asymptotically independent on average, then the obstruction lies in an Abelian group rotation factor. We remark that it is clear that an Abelian group rotation factor is an obstruction as in Abelian groups $z + 2n\alpha$ is determined by $z, z + n\alpha$.

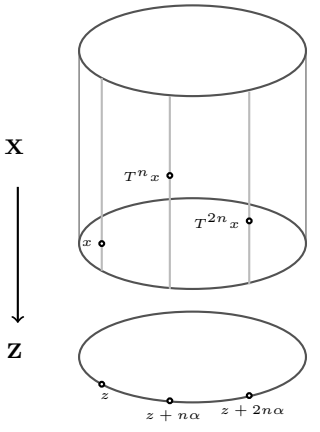


Figure 3.1. The points $x, T^n x, T^{2n}x$ are independent (asymptotically on average) in the fibers over the maximal Abelian group rotation factor.

To summarize, Furstenberg's proof of Roth's Theorem is based on the following dichotomy:

- either $\mathbf{X}$ is weakly mixing, or
- there is a morphism from $\mathbf{X}$ to a non trivial group rotation system.

The above argument motivates the following definition ([16]):

Definition 3.3 (k-characteristic factor). Let $\mathbf{Y}$ be a factor of $\mathbf{X}$, and let $\pi : \mathbf{X} \to \mathbf{Y}$ be the factor map. We say that $\mathbf{Y}$ is *k-characteristic* if

$$\frac{1}{N}\sum_{n=1}^{N}\int f_0(x)f_1(T_{\mathbf{X}}^n x)\dots f_k(T_{\mathbf{X}}^{kn}x)d\mu_{\mathbf{X}}$$

[8]We implicitly assume that the system $\mathbf{X}$ is separable and thus has at most countably many normalized eigenfunctions.

is asymptotically the same as

$$\frac{1}{N}\sum_{n=1}^{N}\int \pi_* f_0(y)\pi_* f_1(T_{\mathbf{Y}}^n y)\dots\pi_* f_k(T_{\mathbf{Y}}^{kn} y)d\mu_{\mathbf{Y}}.$$

We make the following observations:

- The system $\mathbf{X}$ itself is k-characteristic for all k.
- The trivial system is 1-characteristic. In this case $\pi_* f(x) = \int f(x)d\mu_{\mathbf{X}}$, and by the *mean ergodic theorem*

$$\frac{1}{N}\sum_{n=1}^{N}\int f(x)f(T_{\mathbf{X}}^n x)d\mu_{\mathbf{X}} \sim \left(\int f d\mu_{\mathbf{X}}\right)^2.$$

- The Kronecker factor $\mathbf{Z}(\mathbf{X})$ is 2-characteristic (Furstenberg [15]).

The Furstenberg-Zimmer structure theorem [15, 55] relativizes the dichotomy between weak mixing and an abelian rotation factor. One can show, using spectral theory, that $\mathbf{X}$ being weakly mixing is equivalent to the product system with the diagonal action $\mathbf{X}\times\mathbf{X}$ being ergodic. One can relativize this notion as follows. Let $\mathbf{X}\times_{\mathbf{Y}}\mathbf{X}$ be the fiber product over $\mathbf{Y}$. Say that $\pi:\mathbf{X}\to\mathbf{Y}$ is a *relatively weak mixing extension* if the map $\pi\times_{\mathbf{Y}}\pi:\mathbf{X}\times_{\mathbf{Y}}\mathbf{X}\to\mathbf{Y}$ is relatively ergodic, namely any $T\times T$ invariant subset in $\mathbf{X}\times_{\mathbf{Y}}\mathbf{X}$ is lifted from $\mathbf{Y}$ via the map $\pi\times_{\mathbf{Y}}\pi$. The role of the compact abelian group rotation is replaced by the notion of an isometric extension. Say that $\pi:\mathbf{X}\to\mathbf{Y}$ is an *isometric extension* if $\mathbf{X}=\mathbf{Y}\times_\sigma\mathbf{M}$ where $\mathbf{M}=(M,\mathcal{B}_{\mathbf{M}},\mu_{\mathbf{M}})$ with M a compact metric space, $\mathcal{B}_{\mathbf{M}}$ the Borel σ-algebra and μ_M the probability measure invariant under the the action of the isometry group of M, $T_{\mathbf{X}}(y,m)=(T_{\mathbf{Y}}y,\sigma(y)m)$, where σ is a (measurable) map from Y to the isometry group of M, and $\mu_{\mathbf{X}}=\mu_{\mathbf{Y}}\times\mu_M$.

Theorem 3.4 (Furstenberg-Zimmer structure theorem [15, 55]). *There exists a sequence of factors*

$$\mathbf{X}\to\ldots\to\mathbf{Z}_k(\mathbf{X})\to\mathbf{Z}_{k-1}(\mathbf{X})\to\ldots\to\mathbf{Z}_1(\mathbf{X})\to\star$$

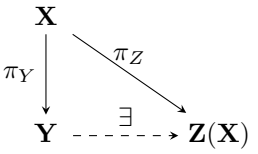
such that for each k, either $\mathbf{X}\to\mathbf{Z}_k(\mathbf{X})$ is relatively weakly mixing, or there is a morphism from $\mathbf{X}$ to a non trivial isometric extension of $\mathbf{Z}_k(\mathbf{X})$.

Theorem 3.5 (Furstenberg [15]). *The factors $\mathbf{Z}_k(\mathbf{X})$ are $(k+1)$-characteristic.*

Observe that the factor $\mathbf{Z}_0(\mathbf{X})$ is the trivial factor and the factor $\mathbf{Z}_1(\mathbf{X})$ is the Kronecker factor. With the above structure theorem at hand it then suffices to prove the multiple recurrence theorem for systems which are towers of isometric extensions. Furstenberg utilizes this structure to show multiple recurrence - the idea being that if the multiple recurrence property holds for any k for a system $\mathbf{Y}$, and $\mathbf{X}$ is an isometric extension of $\mathbf{Y}$, then multiple recurrence holds for $\mathbf{X}$ as well.

4. Obstructions to 4-term progressions

The Kronecker factor $\mathbf{Z}_1(\mathbf{X})=\mathbf{Z}(\mathbf{X})$ is also a *universal 2-characteristic factor* : it satisfies the property that if $\mathbf{Y}$ is any 2-characteristic factor and $\pi_Y:\mathbf{X}\to\mathbf{Y}$ the factor map, then the factor map $\pi_Z:\mathbf{X}\to\mathbf{Z}(\mathbf{X})$ factors through $\mathbf{Y}$ as demonstrated in the diagram below:



The factors $\mathbf{Z}_k(\mathbf{X})$ that were constructed by Furstenberg are *not* universal $(k+1)$-characteristic for $k > 1$. This raises the following natural problem: classify the universal $(k+1)$-characteristic factors $Z_k(X)$. In other words, we try to understand the exact obstructions on the points $x, T^n x, \ldots, T^{(k+1)n} x$ preventing them from moving about freely in X.

For the case $k = 1$, the upshot of the discussion regarding Furstenberg's proof of Roth's theorem on 3-term progressions in the previous section was that the only obstructions to the independence (asymptotically on average) of $x, T^n x, T^{2n} x$ come from a compact abelian group rotation factor, associated to the non trivial eigenfunctions of $\mathbf{X}$. Already in the case $k = 2$ (corresponding to 4-term progressions) we have new obstructions. Consider for example the system

$$\mathbf{Y} = (\mathbb{T} \times \mathbb{T}, \text{Borel}, \text{Haar}, T_{\mathbf{Y}})$$

where

$$T_{\mathbf{Y}} y = T_{\mathbf{Y}}(z, w) = (z + \alpha, w + 2z + \alpha),$$

where α is irrational. Iterating S we obtain

$$T^n_{\mathbf{Y}} y = T^n_{\mathbf{Y}}(z, w) = (z + n\alpha, w + 2nz + n^2\alpha).$$

We now observe that

$$y = 3T^n_{\mathbf{Y}} y - 3T^{2n}_{\mathbf{Y}} y + T^{3n}_{\mathbf{Y}} y$$

Namely, the point y is determined by the three points $T^n_{\mathbf{Y}} y, T^{2n}_{\mathbf{Y}} y, T^{3n}_{\mathbf{Y}} y$.

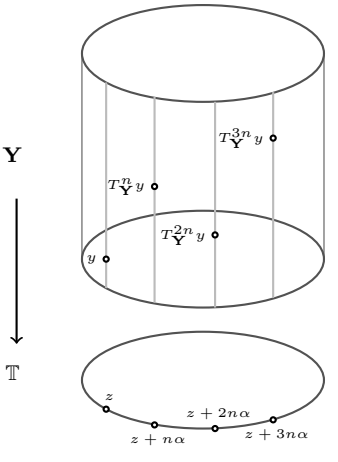


Figure 4.1. The points $y, T^n_{\mathbf{Y}} y, T^{2n}_{\mathbf{Y}} y, T^{3n}_{\mathbf{Y}} y$ are not independent in the fibers over $\mathbb{T}$.

If there is a morphism $\mathbf{X} \to \mathbf{Y}$, these new obstructions to the (asymptotic on average) independence of the points $x, T_{\mathbf{X}}^n x, T_{\mathbf{X}}^{2n} x, T_{\mathbf{X}}^{3n} x$ will surface. Another way to see the obstructions coming from the system $\mathbf{Y}$ is by observing that the system $\mathbf{Y}$ exhibits *second order eigenfunctions*, namely functions ϕ satisfying $\phi(T_{\mathbf{Y}} y) = \psi(y)\phi(y)$ where ψ is an ordinary (first order) eigenfunction; for example the function $\phi(y) = \phi(z, w) = e^{2\pi i w}$ is a second order eigenfunction. Any second order eigenfunction satisfies

$$\phi(y) = \phi^3(T_{\mathbf{Y}}^n y)\phi^{-3}(T_{\mathbf{Y}}^{2n} y)\phi(T_{\mathbf{Y}}^{3n} y)$$

Thus choosing $f_0 = \phi^{-1}$, $f_1 = \phi^3$, $f_2 = \phi^{-3}$, and $f_3 = \phi$ we see that

$$\begin{aligned} 1 &= \int f_0(x) f_1(T_{\mathbf{Y}}^n y) f_2(T_{\mathbf{Y}}^{2n} y) f_3(T_{\mathbf{Y}}^{3n} x) dm \\ &= \frac{1}{N} \sum_{n \le N} \int f_0(x) f_1(T_{\mathbf{Y}}^n y) f_2(T_{\mathbf{Y}}^{2n} y) f_3(T_{\mathbf{Y}}^{3n} x) dm. \end{aligned}$$

On the other hand one can verify that a (non trivial) 2nd order eigenfunction ϕ (and its powers) is orthogonal to ordinary eigenfunctions, thus for any $i = 0, 1, 2, 3$ the projection of the function f_i on the Kronecker factor is 0.

It turns out, however, that second order eigenfunctions are not the only obstructions. Consider the Heisenberg nilsystem: the phase space Y is the Heisenberg nilmanifold

$$Y = N/\Gamma = \begin{pmatrix} 1 & \mathbb{R} & \mathbb{R} \\ 0 & 1 & \mathbb{R} \\ 0 & 0 & 1 \end{pmatrix} \Big/ \begin{pmatrix} 1 & \mathbb{Z} & \mathbb{Z} \\ 0 & 1 & \mathbb{Z} \\ 0 & 0 & 1 \end{pmatrix}$$

equipped with the Borel σ-algebra and the Haar measure, and the transformation $T_{\mathbf{Y}}$ given by $T_{\mathbf{Y}} g\Gamma = ag\Gamma$, where

$$a = \begin{pmatrix} 1 & \alpha & 0 \\ 0 & 1 & \beta \\ 0 & 0 & 1 \end{pmatrix}.$$

Topologically Y is a circle bundle over a two dimensional torus. This system shares with the system in the above example the property that the point $g\Gamma$ is determined by $a^n g\Gamma, a^{2n} g\Gamma$, $a^{3n} g\Gamma$. However this dependence can not be described by a simple equation as in the previous example. Moreover, $\mathbf{Y}$ has *no* non-trivial second order eigenfunctions[9].

The Heisenberg nilsystem is a special case of the following system:

$$\mathbf{Y} = (N/\Gamma, \text{Borel}, \text{Haar}, T_{\mathbf{Y}}),$$

where N/Γ a 2-step nilmanifold, and

$$T_{\mathbf{Y}} : g\Gamma \to ag\Gamma \qquad a \in N.$$

The system $\mathbf{Y}$ is called a 2-step nilsystem. It turns out that we need not look for further obstructions in the case $k = 2$ - all obstructions to 4-term progressions come from 2-step pro-nilsystems - inverse limits of 2-step nilsystems [10–12, 16]:

Theorem 4.1 (Conze-Lesigne, Furstenberg-Weiss). *Let* $\mathbf{X}$ *be an ergodic measure preserving system. There exists a* 2*-step pro-nilsystem* $\mathbf{Y}$ *and a morphism* $\pi : \mathbf{X} \to \mathbf{Y}$ *such that* $\mathbf{Y}$ *is*

[9]The easiest way to see this is via equidistribution properties of polynomial orbits on nilmanifolds [34].

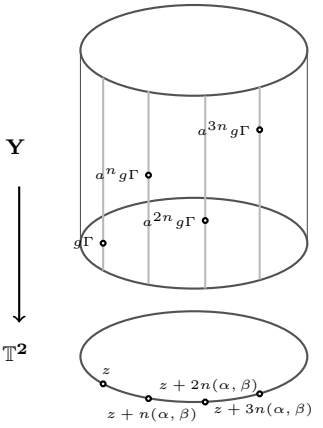

Figure 4.2. The points $g\Gamma, a^n g\Gamma, a^{2n} g\Gamma, a^{3n} g\Gamma$ are not independent in the fibers over the two dimensional torus.

the universal 3*-characteristic factor of* $\mathbf{X}$*, namely*

$$\frac{1}{N}\sum_{n=1}^{N}\int f(x)f(T_{\mathbf{X}}^{n}x)f(T_{\mathbf{X}}^{2n}x)f(T_{\mathbf{X}}^{3n}x)d\mu_{\mathbf{X}}$$

is asymptotically the same as

$$\frac{1}{N}\sum_{n=1}^{N}\int \pi_* f(y)\pi_* f(T_{\mathbf{Y}}^{n}y)\pi_* f(T_{\mathbf{Y}}^{2n}y)\pi_* f(T_{\mathbf{Y}}^{3n}y)d\mu_{\mathbf{Y}}.$$

We can now prove Szemerédi's theorem for 4-term progressions by verifying that in a 2-step nilsystem the above limit is positive (when $f = 1_A$).

Let us say a few words about the proof. By Furstenberg's structure theorem it is sufficient to study systems $\mathbf{X}$ of the form $\mathbf{Z} \times_\sigma \mathbf{M}$ where $\mathbf{Z} = \mathbf{Z}_1(\mathbf{X})$ is the Kronecker factor, $T_{\mathbf{Z}}(z) = z + \alpha$, and M is a compact metric space and $\sigma : Z \to \mathrm{ISO}(M)$. It is then shown that one can further reduce to the case where M is a compact abelian group and $\sigma : Z \to M$ satisfies a functional equation now called the Conze-Lesigne equation: for all b, a.e z

$$\sigma(z+b) - \sigma(z) = c(b) + F_b(z+\alpha) - F_b(z). \tag{4.1}$$

Describing how one can solve the above equation is beyond the scope of this paper, but let us hint how this equation is related to nilpotency. Consider the group

$$G = \{(b, f) : b \in Z, f : Z \to M \text{ measurable}\}$$

with the action

$$(b, f) * (c, g) = (b + c, f^c \cdot g)$$

where $f^c(z) = f(z+c)$. Then condition (4.1) can be interpreted as the fact that $[(\alpha, \sigma), (b, F_b)]$ is in the center of G, which hints at 2-step nilpotent behavior.

We mention another observation regarding equation (4.1). Upon examination one sees that

$$c(b_1 + b_2) - c(b_1) - c(b_2)$$

is an eigenvalue of $T_{\mathbf{Z}}$, and using the fact that there are only countably many of those, one can modify $c(b), F_b(z)$ so that $c(b)$ is linear in b in a neighborhood of zero in Z. A similar feature will surface in the combinatorial analysis described in section 8 below, devoted to the Inverse Theorem for the Gowers norms, which is why we mention it here.

5. Gowers proof of Szemerédi's Theorem

The next advancement (chronologically) was in the combinatorial front. Gowers gave a new proof for Szemerédi's theorem [27]. His proof is a generalization of Roth's argument to arbitrarily long arithmetic progressions using an ingenious combination of discrete Fourier analysis and additive combinatorics; in particular Gowers obtains a Roth type bound for the density of the form $1/(\log\log N)^{c(k)}$ for some constant depending on k - the length of the progression.

We first fix some notation. We denote by $[N]$ the interval $[1, N]$. For a finite set E we denote by $\mathbb{E}_{x\in E} f(x)$ the average $\frac{1}{|E|}\sum_{x\in E} f(x)$. For two functions $f, g : [N] \to \mathbb{C}$ we write $f(x) \ll g(x)$ if $|f(x)| \leq Cg(x)$ for some constant C independent of N, and we write $f(x) \ll_A g(x)$ if $|f(x)| \leq C(A)g(x)$ for some constant $C(A)$ independent of N.

In the course of the proof Gowers defines the following norms which play a very important role in further developments.

Definition 5.1 (Gowers norms). Let $f : \mathbb{Z}/N\mathbb{Z} \to \mathbb{C}$. For $h \in \mathbb{Z}/N\mathbb{Z}$ define the discrete derivative in direction h

$$\Delta_h f(x) = f(x + h)\overline{f(x)}$$

We define the k-th Gowers uniformity norms U_k on $\mathbb{C}^N$ by

$$\|f\|^{2^k}_{U^k[N]} = \mathbb{E}_{x,h_1,\dots h_k\in[N]}\Delta_{h_1}\dots\Delta_{h_k} f(x)$$

Remark 5.2. One can define the Gowers norms on any abelian group; of special interest is the group $\mathbb{F}_2^n$ where the Gowers norms are intimately related to polynomial testing.

We make a few initial observations. For 1-bounded functions f ($\|f\|_\infty \leq 1$)

- $\|f\|_{U^k[N]} = 1$ if an only if $f(x) = e^{2\pi i q(x)}$ where q is a polynomial of degree $< k$.
- By repeated application of the Cauchy-Schwarz inequality, if f correlates with $e^{2\pi i q(x)}$ where q is a polynomial of degree $< k$ then f has large Gowers norms; namely

$$|\mathbb{E}_{x\in[N]} f(x)e^{-2\pi i q(x)}| > \delta \implies \|f\|_{U^k[N]} \gg_\delta 1.$$

- If f is a random function taking the values ± 1 with probability $1/2$ for any $x \in [N]$, then by the law of large numbers, $\|f\|_{U^k[N]} = o(1)$.

The Gowers uniformity norms play an important role in the study of arithmetic progressions. If f and g are close in the U_k norm, i.e $\|f-g\|_{U^k[N]}$ is small, then they have approximately the same number of $k+1$ term progressions. Denote by $AP_k(f)$ the number of $(k+1)$-term progressions in f: denote

$$AP_k(f) = \mathbb{E}_{x,d\in[N]} f(x)f(x+d)\dots f(x+kd).$$

Then

$$|AP_k(f) - AP_k(g)| \ll_k \|f-g\|_{U^k[N]}. \tag{5.1}$$

In fact a more general statement regarding linear forms is true:

Proposition 5.3. *Let $f_1,\dots,f_k$ be 1-bounded functions. Let $L_1(\vec{x}),\dots,L_m(\vec{x})$ be k affine linear forms in d variables with integer coefficients: $L_i(\vec{x}) = \sum_{j=1}^{d} l_{ij}x_j + b_i$, no two of which are affinely dependent. Then there exists $k>0$ such that*

$$|\mathbb{E}_{\vec{x}\in[N]^d} f_1(L_1(\vec{x}))\cdots f_k(L_m(\vec{x}))| \ll \min_j \|f_j\|_{U^k[N]}.$$

The proposition is proved via repeated applications of the Cauchy-Schwarz inequality, and this is where the Gowers norms enter the picture in the proof of Theorem 1.1; it is the source of the condition that no two forms are affinely dependent.

The strategy of Gowers is similar in spirit to that of Roth. The idea is as follows. Let $E\subset[N]$ be with $|E|=\eta N$. Then

- either the number of $(k+1)$-term progressions is more than half of that expected in random set, namely $\geq \eta^{k+1}N^2/2$, or
- $\|1_E-\eta\|_{U^k[N]} \gg_\eta 1$.

In order to proceed one needs to understand the condition $\|1_E-\eta\|_{U^k[N]} \gg_\eta 1$. For $k=2$ we observe that

$$\|f\|_{U^2[N]}^4 = \|\hat{f}\|_4^4 \leq \|\hat{f}\|_2^2\|\hat{f}\|_\infty^2.$$

Thus if $\|f\|_2\leq 1$ then we find that $\|f\|_{U^2[N]}\geq\eta$ implies $\|\hat{f}\|_\infty\geq\eta^2$. This implies that f has a large Fourier coefficient, namely

$$|\mathbb{E}_{x\in[N]} f(x)e(x\alpha)| \geq \eta^2.$$

For larger k the situation is much more complicated. Gowers proves the following local inverse theorem for higher Gowers norms.

Theorem 5.4 (Local inverse theorem for Gowers norms). *Let $f:\mathbb{Z}/N\mathbb{Z}\to\mathbb{C}$ be with $|f|\leq 1$. Then*

$$\|f\|_{U^k[N]}\geq\delta \implies |\mathbb{E}_{x\in P} f(x)e^{2\pi i q(x)}| \gg_\delta 1,$$

where P is a progression of length at least N^t, $q(x)$ is a polynomial of degree $k-1$, and t depends[10] on k,δ.

[10] In fact Gowers shows that one can find many such progressions: one can partition $\mathbb{Z}/N\mathbb{Z}$ into progressions $P_1,\dots,P_M$ of average length greater than N^t, such that $\sum_{i=1}^{M}|\sum_{x\in P_i} f(x)e^{2\pi i q(x)}| \gg_\delta N$.

The word 'local' in this context refers to the fact that the correlation in the above theorem is obtained not on the full interval $[N]$ but rather on a short progression of length at least N^t with $t < 1$ (for $k > 2$). This theorem provides sufficient structure to obtain increased density on a subprogression of length at least N^s: we apply Theorem 5.4 to the function $1_E - \eta$, and use the equidistribution properties of the sequence $\{q(x)\}$ mod 1 to find an arithmetic progression of length at least N^s ($s < t$) on which $\{q(x)\}$mod 1 is roughly constant.

6. Classification of universal k-characteristic factors

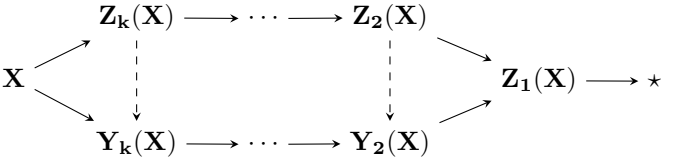
We return now to the question of classifying k-characteristic factors. Recall that we are interested in the averages

$$\frac{1}{N}\sum_{n\leq N}\int f(x)f(T^n x)f(T^{2n}x)\dots f(T^{kn}x)d\mu. \tag{6.1}$$

The universal 4-characteristic factors were classified by Host and Kra [33], and independently in the author's PhD thesis [52], and were shown to be 3-step pro-nilsystems. Both methods were extended to work for general k - by Host and Kra in [32], and by the author in [54].

Theorem 6.1 (Host-Kra (05), Z (07)). *Let* $\mathbf{X}$ *be an ergodic measure preserving system. The universal* k*-characteristic factor* $\mathbf{Y_k}(\mathbf{X})$ *is a* $(k-1)$*-step pro-nilsystem.*

We have the following diagram displaying the relation between the factors $\mathbf{Z_k}(\mathbf{X})$ defined by Furstenberg in his proof of Szemerédi's theorem and the pro-nilfactors $\mathbf{Y_k}(\mathbf{X})$ which are the universal characteristic factors:



As a corollary of this structure theorem one can calculate the asymptotic formula for the averages in (6.1) via a limit formula for the corresponding averages on nilsystems [53].

Theorem 6.2 (Z (05)). *Let* $\mathbf{X}$ *be a* $(k-1)$*-step nilsystem. Then*

$$\lim \frac{1}{N}\sum_{n\leq N}\int f_0(x)f_1(T^n x)\dots f_k(T^{kn}x)d\mu = \int f_0(x_0)f_1(x_1)\dots f_k(x_k)dm_H$$

where m_H *is the Haar measure on the subnilmanifold* $H\Gamma^{k+1}/\Gamma^{k+1} \subset X^{k+1} = (G/\Gamma)^{k+1}$*, where* H *is the subgroup*

$$\left\{\left(g_0, g_0g_1, g_0g_1^2g_2, g_0g_1^3g_2^3g_3, \dots, g_0g_1^k g_2^{\binom{k}{2}}\dots g_{k-2}^{\binom{k}{k-2}}\right) : g_i \in G_i\right\}$$

where $\{1\}=G_{k-1}\subset G_{k-2}\subset\dots\subset G_1=G_0=G$ *is the derived series, i.e.* $G_{i+1} = [G_i, G]$.

One can now prove Szemerédi's theorem by showing that the above limit is positive if $f_i = 1_A$ for $i = 0, \dots, k$. This approach to proving Szemerédi's theorem (and various generalizations) was taken in [6].

The proof in [54] generalizes the methods in [10–12]. Inductively, one is led to the problem of solving a functional equation similar in nature to equation (4.1), only the extension cocycles are now defined on a (pro)-nilmanifolds (rather than a compact abelian group). Such cocycles are in general much more difficult to handle, but one can still use the fact that orbits on products of nilmanifolds are well understood and have a nice algebraic nature (as one can see in Theorem 6.2 above).

The proof in [32] introduces seminorms, which are similar, at least semantically, to the Gowers uniformity norms[11]

Definition 6.3 (Host-Kra-Gowers semi-norms).

$$\|f\|_{U^k(\mathbf{X})}^{2^k} := \lim_{N\to\infty} \mathbb{E}_{h_1,\dots,h_k\in[N]} \int \Delta_{h_1} \dots \Delta_{h_k} f(x) d\mu(x).$$

It is then proved that characteristic factors for averages associated with the ergodic U_k semi-norms defined above are also pro-nilsystems. Or, in a different formulation:

$$\|f\|_{U^{k+1}(\mathbf{X})} > 0 \implies \pi : \mathbf{X} \to k\text{-step nilsystem}, \quad \pi_* f \neq 0.$$

This suggests a far reaching generalization of the Gowers local inverse theorem, which we will discuss in section 8 below.

7. The Green-Tao theorem from a characteristic factor point of view

In their famous paper, Green and Tao prove a Szemerédi's type theorem in the prime numbers [19]:

Theorem 7.1 (Green-Tao (05)). *Let $E \subset \mathbb{P}$ of positive relative density, then E contains long arithmetic progressions.*

We present the idea of the proof from a characteristic factor point of view. Our starting point will be the following version of Szemerédi's theorem: Let $f : [N] \to [0,1]$ be a function with $|\mathbb{E}_{n\in[N]} f(x)| > \delta$. Then for any integer $k > 0$

$$AP_k(f) = \mathbb{E}_{x,d\in[N]} f(x) f(x+d) \dots f(x+kd) \geq c(\delta) + o(1) \tag{7.1}$$

where $c(\delta) > 0$, and is independent of N.

If we naively try to apply this theorem for a subset E of the prime numbers of relative density δ, we run into an obvious problem that $\mathbb{E}_{x\in[N]} 1_E(x) = o(1)$. We can try to fix this problem by putting a weight on each prime - we consider the von-Mangoldt function $\Lambda(x)$ which takes the value $\log p$ if x is a positive power of p and 0 otherwise. In this case we will have

$$\mathbb{E}_{x\in[N]} \Lambda(x) 1_E(x) = \delta + o(1),$$

[11] Such averages as the one below were studied in the case $k = 2$ already by Bergelson in [4].

for some constant $\delta > 0$ (independent of N). But now we face the problem that the function $\tilde{1}_E(x) = \Lambda(x)1_E(x)$ does not take values in $[0,1]$; in fact the function $\tilde{1}_E(x)$ is unbounded. Green and Tao show that for a certain class of unbounded functions (functions bounded by a k-psuedorandom function) one can find a "k-characteristic factor" for the average (7.1) generated by *bounded* functions ! We can summarize the procedure as follows:

- Introduce combinatorial notions of (approximate) *factor* and *projection* onto a factor.
- Find a convenient combinatorial "k-characteristic factor" for averages associated with the U_k norms, in this case a factor of functions bounded by a constant $C(k)$ (depending only on k).
- Let $\pi_*(\tilde{1}_E)$ be the (approximate) projection on the factor. Then $0 \leq \pi_*(\tilde{1}_E) \leq C(k)$, the average of the function $\pi_*\tilde{1}_E$ is approximately the same as that of $\tilde{1}_E$, namely approximately δ, and $\|\tilde{1}_E - \pi_*(\tilde{1}_E)\|_{U^k[N]}$[12] is small. A version of the Gowers-Cauchy-Schwarz inequality (for functions bounded by k-pseudoradnom functions) gives then, as in (5.1), that

$$|AP_k(\tilde{1}_E) - AP_k(\pi_*\tilde{1}_E)| \ll \|\tilde{1}_E - \pi_*\tilde{1}_E\|_{U^k[N]} \tag{7.2}$$

- Apply Szemerédi's Theorem to the $C(k)$-bounded function $\pi_*\tilde{1}_E$, to obtain $AP_k(\pi_*\tilde{1}_E) \gg_\delta 1$, and thus $AP_k(\tilde{1}_E) \gg_\delta 1$

A different way to say this is that given $\epsilon > 0$ we can decompose

$$\tilde{1}_E = g + h \tag{7.3}$$

where g is a $C(k)$-bounded function, and h is a function with $\|h\|_{U^k[N]} < \epsilon$. This type of theorem is now referred to as a *decomposition* theorem. There is a very nice modern and more abstract treatment of general decomposition theorems in [28], and [38] using the Hahn-Banach theorem. We remark that Theorem 7.1 has since been extended to include polynomial configurations [46], and multidimensional configurations [13, 14, 48].

8. The Inverse Theorem for the Gowers Norms

The argument in the Green-Tao theorem is based on Szemerédi's theorem which is valid for *any* subset of positive density in the integers. This has two major caveats. The first is that it can not lead to an asymptotic formula for the number of arithmetic progressions, only a lower bound. The second is that it can not be used to study non homogeneous linear configurations, since there are counter examples within periodic sets of positive density. How then can we hope to get an asymptotic formula as in Theorem 1.1 ?

[12]We defined the Gowers norms for functions f on the group $\mathbb{Z}/N\mathbb{Z}$. We can define Gowers norms for functions $f : [N] \to \mathbb{C}$, setting $G := \mathbb{Z}/\tilde{N}\mathbb{Z}$ for some integer $\tilde{N} \geq 2^d N$, and defining a function $\tilde{f} : G \to \mathbb{C}$ by $\tilde{f}(x) = f(x)$ for $x = 1, \ldots, N$ and $\tilde{f}(x) = 0$ otherwise. We then set

$$\|f\|_{U^d[N]} := \|\tilde{f}\|_{U^d(G)} / \|1_{[N]}\|_{U^d(G)},$$

where $1_{[N]}$ is the indicator function of $[N]$. It is easy to see that this definition is independent of the choice of $\tilde{N}$.

We recall now that - in the ergodic theoretic context - to get a limit formula we needed to identify the universal characteristic factors. Motivated by theorem 6.1, Green and Tao conjectured in 2006 that the combinatorial "universal characteristic factors" for the U_k norm come from *nilsequences* - sequences arising in a natural way from nilsystems.

Conjecture 8.1 (Inverse conjecture for the Gowers norms ($\mathrm{GI}(s)$)). *Let $s \geq 0$ be an integer, and let $0 < \delta \leq 1$. Then there exists a finite collection $\mathcal{M}_{s,\delta}$ of s-step nilmanifolds G/Γ, each equipped with some smooth Riemannian metric $d_{G/\Gamma}$ as well as constants $C(s,\delta), c(s,\delta) > 0$ with the following property. Whenever $N \geq 1$ and $f : [N] \to \mathbb{C}$ is a 1-bounded function such that $\|f\|_{U^{s+1}[N]} \geq \delta$, there exists a nilmanifold $G/\Gamma \in \mathcal{M}_{s,\delta}$, some $g \in G$ and a function $F : G/\Gamma \to \mathbb{C}$ bounded in magnitude by 1 and with Lipschitz constant at most $C(s,\delta)$ with respect to the metric $d_{G/\Gamma}$, such that*

$$|\mathbb{E}_{n\in[N]} f(n)\overline{F(g^n x)}| \geq c(s,\delta). \tag{8.1}$$

That is, the global obstruction (scale N) to Gowers uniformity come from sequences arising from nilsystems. Recall that the local theorem for the Gowers norms shows that local obstructions (at scale N^t) to Gowers U^{s+1} uniformity norms come from phase polynomials of degree s. We remark that the converse to Conjecture 8.1 is true and relatively easy to prove via repeated applications of the Cauchy-Schwarz inequality. Namely, if (8.1) holds then $\|f\|_{U^{s+1}[N]} \gg_\delta 1$. We also mention that if δ is sufficiently close to 1 then the conjecture is true; moreover, f is close (in L^1) to a genuine (unique) phase polynomial [1], and thus correlates with a (unique) phase polynomial[13]; uniqueness allows one to try an intelligent guess. In the realm when $\delta > 0$, we cannot expect uniqueness, and as it turns out, we also can't expect correlation with a genuine phase polynomial.

One can ask a similar question in the context of finite field geometry. Given a function $f : \mathbb{F}_p^n \to \mathcal{D}$ with large Gowers norm (fixing p and letting n approach ∞), what can be said about f? It was conjectured that such functions would correlate with polynomial phase functions. More precisely:

Conjecture 8.2 (Inverse conjecture for the Gowers norms in finite fields). *Let p be a prime and let $f : \mathbb{F}_p^n \to \mathbb{C}$ be 1-bounded, with $\|f\|_{U^{s+1}[\mathbb{F}_p^n]} \geq \delta$. Then there exists a polynomial $P : \mathbb{F}_p^n \to \mathbb{F}_p$ of degree $\leq k$ such that*

$$|\mathbb{E}_{x\in\mathbb{F}_p^n} f(x) e^{2\pi i P(x)/p}| \geq c(s,\delta).$$

The case $s = 1$ of both conjectures follows from a short Fourier-analytic computation. The case $s = 2$ of Conjecture 8.1 was proved in [20]. The case $s = 2$ of Conjecture 8.2 was proved in [20] for odd p and for $p = 2$ in [40]. Surprisingly, Conjecture 8.2 turned out to be *false*; a counter example for the $U^4[\mathbb{F}_2^n]$ was constructed independently in [18, 35]. However, it turned out that with a small modification ofConjecture 8.2 is actually true [7, 45, 47]. Call $P : \mathbb{F}_p^n \to \mathbb{C}$ a non-standard polynomial of degree $< k$ if for all $h_1, \ldots, h_s \in \mathbb{F}_p^n$ we have

$$\Delta_{h_1} \ldots \Delta_{h_s} P \equiv 1$$

If char $\mathbb{F} \geq s$, then a non-standard polynomial is a standard phase polynomial, i.e $e^{2\pi i P(x)/p}$ where $P : \mathbb{F}_p^n \to \mathbb{F}_p$ a polynomial of degree $< s$, but otherwise the class of non-standard polynomials is larger.

[13] One can exhibit a polynomial phase function $e^{p(x)}$ as a nilsequence see e.g. [24]

Theorem 8.3 (Bergelson-Tao-Z (10), Tao-Z (10,12)). *Let p be a prime and let $f : \mathbb{F}_p^n \to \mathbb{C}$ be 1-bounded, with $\|f\|_{U^{s+1}[\mathbb{F}_p^n]} \geq \delta$. Then there exists a non-standard polynomial P of degree $\leq s$, and a constant $c(s,\delta) > 0$ such that*

$$|\mathbb{E}_{x \leq \mathbb{F}_p^n} f(x) e^{P(x)}| \gg c(s,\delta).$$

The proof of theorem 8.3 is via an ergodic theoretic structure theorem, similar in nature to Theorem 6.1, and a correspondence theorem - translating the finitary question to a question about limiting behavior of multiple averages for an $\oplus \mathbb{F}_p$ ergodic action.

Finally Conjecture 8.1 was proved [24]:

Theorem 8.4 (Green-Tao-Z (12)). *The inverse conjecture for the Gowers norms $GI(s)$ norms is true.*

The proof of Theorem 8.4 is long an complicated and is carried out in [24]. For a more gentle introduction to the proof we refer the reader to either [26], where the case $k = 3$ (the U^4 norm) is handled, or to the announcement in [25]. We now try to give the flavor of the proof. Suppose $\|f\|_{U^{s+1}[N]} \geq \delta$, then by definition

$$\mathbb{E}_{h \in N} \|\Delta_h f(n)\|_{U^s[N]}^{2^s} \gg_\delta 1.$$

It follows that for all h in a set H of size $\gg_\delta N$ we have $\|\Delta_h f(n)\|_{U^s[N]} \gg_\delta 1$. Now, inductively we know that, for $h \in H$, $\Delta_h f(n)$ correlates with an $s-1$-step nilsequence $F_h(g_h^n x_h \Gamma)$ (of complexity $\ll_\delta 1$), namely

$$|\mathbb{E}_{h \in N} \Delta_h f(n) F_h(g_h^n x_h \Gamma)| \gg_\delta 1$$

In the case $GI(2)$, this 1-step nilsequence can be taken to be $e^{2\pi i \lambda_h n}$, but in general we can't hope for anything as simple. The key difficulty now is to try to find some extra structure relating the nilsequences $F_h(g_h^n x_h \Gamma)$ for different values of h. This is already quite difficult in the $GI(2)$ case. In this case, an ingenious argument of Gowers involving tools from additive combinatorics, coupled with some geometry of numbers allows one to linearize λ_h on a nice set - a generalized arithmetic progression (GAP). This argument is then combined with a symmetry argument to construct a 2-step nilsequence $g(h)$ with $\Delta_h g(n) = e^{2\pi i \lambda_h n}$ for many values of h [20]). For general s, we follow the same strategy, however it turns out to be rather difficult to extract some algebraic structure relating the various nilsequences $F_h(g_h^n x_h \Gamma)$. An alternate approach to the inverse theorem was subsequently developed by Szegedy [9, 43]. We remark that both Theorems 8.3, 8.4 are qualitative; it is a major open question to find quantitative proofs for them.

How can one apply Theorem 8.4 to obtain Theorem 1.1? We give a very rough sketch. One needs to calculate the projection of the function $\tilde{1}_{\mathbb{P}}(n) = (\log n) 1_{\mathbb{P}}(n)$ onto the combinatorial nil-factor. It turns out that the projection essentially lies in the much smaller factor of periodic functions (with bounded period). More precisely, one first performs pre-sieving to eliminate the periodic contributions. Let $W = \prod_{p<w} p$ for w a slowly increasing function of N. For $(b,W) = 1$ consider $\tilde{1}_{W,b,\mathbb{P}}(n) = \tilde{1}_{\mathbb{P}}(Wn+b)$. The projection of this function on the combinatorial nil-factor should be constant, and since its average is 1 - this constant should be 1; namely one must show that

$$\|\tilde{1}_{W,b,\mathbb{P}}(n) - 1\|_{U^k[N]} = o(1).$$

Suppose $\|\tilde{1}_{W,b,\mathbb{P}}(n)-1\|_{U^k[N]}>\delta$. Fix $\varepsilon>0$, and decompose as in (7.3)

$$\tilde{1}_{W,b,\mathbb{P}}(x)-1=f+g$$

where f is bounded $f\ll_k 1$, and $\|g\|_{U^k[N]}<\varepsilon$. Then since U_k is a norm we get that $\|f\|_{U^k[N]}>\delta/2$. By Theorem 8.4 there is a nilsequence $F(g^nx\Gamma)$ of complexity $\ll_\delta 1$ (i.e. all parameters associated with the nilsequence such as the dimension of the nilmanifold are bounded in terms of δ), such that $|\mathbb{E}f(x)F(g^nx\Gamma)|\gg_\delta 1$. From the easy direction of Theorem 8.4 (which is valid for non bounded functions as well, via repeated applications of the Cauchy-Schwarz inequality) we have $|\mathbb{E}g(x)F(g^nx\Gamma)|<c(\varepsilon)$ (with c a decreasing function). In [22] it is shown that for any bounded complexity nilsequence we have $\mathbb{E}(\tilde{1}_{W,b,\mathbb{P}}(n)-1)F(g^nx\Gamma)=o(1)$. Choosing ε sufficiently small in the decomposition (7.3), we get a contradiction.

Acknowledgements. The author is supported by ISF grant 407/12. I thank H. Furstenberg for introducing me to ergodic theory and to the rich subject of multiple recurrence. I thank V. Bergelson and T. Tao for their valuable comments on an earlier version of this paper.

4. Algebraic and Complex Geometry

On the virtual fundamental class

Kai Behrend

Abstract. We make a few general remarks about derived schemes, and explain the formalism of the virtual fundamental class. We put particular emphasis on the case of symmetric obstruction theories, and explain why the associated intersection numbers and enumerative invariants (such as those of Donaldson-Thomas) exhibit motivic behaviour. Motivated by this, we raise the question of categorification, and explain why this leads into derived symplectic geometry.

Mathematics Subject Classification (2010). Primary 14N35; Secondary 14D20.

Keywords. Virtual fundamental class, symmetric obstruction theory, motivic invariants, derived geometry.

1. Introduction

One of the most remarkable success stories in algebraic geometry in the last 20 years has been the advances made in enumerative geometry by the introduction of new invariants such as those of Gromov-Witten [17], or Donaldson-Thomas [26], [20]. A key concept in these developments is the virtual fundamental class [4], [19]. It provides a substitute for smoothness in the case that moduli spaces are far from non-singular. Before it was even constructed, it was clear [16] that the virtual fundamental class should be some kind of 'classical shadow' of a 'derived moduli scheme'.

In differential geometry, such issues are usually dealt with by moving objects into general position (for example, replacing holomorphic curves by pseudo-holomorphic curves), but in algebraic geometry, this is often not possible, and a more intrinsic approach is required. Thus, one seeks to construct the virtual fundamental class from data intrinsic to the moduli problem in question: this is the derived geometry of the moduli problem. The virtual fundamental class provides a cycle against which one can integrate natural cohomology classes to obtain enumerative invariants.

There is a fundamental difference between the enumerative theories à la Gromov-Witten, and those à la Donaldson-Thomas. The latter belong to derived symplectic geometry, and therefore display motivic behaviour (which the former do not). That these invariants might satisfy some kind of motivic behaviour was realized right away, because it is apparent when the moduli spaces are non-singular. In the general case, the proof of this fact was then furnished in [2]. The key realization was, that the correct way to count the contribution of a point of the moduli space to the virtual count was a generalization of the Milnor number of a critical point. This opened the door to motivic generalizations of Donaldson-Thomas theory [18], and derived symplectic geometry [24].

Proceedings of the International Congress of Mathematicians, Seoul, 2014

This article is divided into two parts.

In the first, we give a brief idea of some properties of derived schemes in general, and delve into the theory of the virtual fundamental class in more detail. We will not define derived schemes, and will completely ignore many important issues, such as, for example, all higher categorical phenomena.

In the second part we consider Lagrangian intersections, and explain how this leads to the motivic nature of Donaldson-Thomas invariants and the discovery of derived symplectic geometry.

2. The virtual fundamental class

The virtual fundamental class is a *classical shadow* of a *derived space*. We start by explaining what this means.

We will generally put ourselves in the context of algebraic geometry over the field of complex numbers. By a *classical scheme* we mean a 'usual scheme' as discussed in [12], for example. Let us agree that all our schemes are of finite type over $\mathbb{C}$.

2.1. Derived schemes. We will not define what a derived scheme is, but rather list the most important of its 'classical shadows'. Suppose $\mathfrak{X}$ is a derived scheme.

2.1.1. Classical locus. There is a classical scheme $X \subset \mathfrak{X}$, contained as a closed subscheme inside $\mathfrak{X}$. Usually the classical scheme X is highly singular, even if $\mathfrak{X}$ is not. It may happen that $\mathfrak{X} = X$.

2.1.2. Amplitude. Derived schemes have an 'amplitude of smoothness'. This is an integer $n \geq 0$. If $n = 0$, then $\mathfrak{X} = X$ and X is non-singular. (In fact, every smooth scheme can be considered as a derived scheme of amplitude 0.)

If the amplitude satisfies $n \leq 1$, the derived scheme $\mathfrak{X}$ is often called *quasi-smooth*. If $\mathfrak{X}$ has amplitude 1, and $X = \mathfrak{X}$, then X is necessarily a local complete intersection scheme. (Conversely, every local complete intersection scheme is a quasi-smooth derived scheme.)

The smoothness amplitude may be ∞, although that case should be considered pathological. (Classical schemes which are not local complete intersections are always of infinite amplitude when considered as derived schemes.)

2.1.3. Virtual dimension. If the amplitude is finite, the derived scheme $\mathfrak{X}$ has a virtual dimension. This agrees with the usual notion of dimension in the case of amplitude zero (and also in the case of amplitude 1, if $\mathfrak{X} = X$).

2.1.4. Virtual fundamental class. This exists only in the case that the smoothness amplitude is at most 1, i.e., the quasi-smooth case.

If the amplitude is 0, the virtual fundamental class is the usual fundamental class $[X]$ of X, as an oriented real manifold. If X is compact, it is an element of $H_{2d}(X, \mathbb{Z})$, where d is the complex dimension of X, in the general case it is an element of Borel-Moore homology, i.e., homology with locally finite supports. In algebraic geometry, we usually prefer to use Chow homology, then the fundamental class is in $A_d(X)$, the group of cycles of dimension d modulo rational equivalence. We will use the Chow homology version.

2.1.5. Tangent complex. There is a derived category object $\mathbb{T}_{\mathfrak{X}} \in D^b_{\mathrm{coh}}(\mathscr{O}_X)$ in the derived category of the classical locus called the *tangent complex*. In the amplitude zero case, $\mathbb{T}_{\mathfrak{X}}$ is the tangent bundle of the classical scheme $X = \mathfrak{X}$. More generally, in the case $X = \mathfrak{X}$, the tangent complex $\mathbb{T}_{\mathfrak{X}}$ is the dual of the more fundamental cotangent complex of X.

The tangent complex determines the amplitude: if the tangent complex $\mathbb{T}_{\mathfrak{X}}$ is a complex of vector bundles $E^0 \to E^1 \to \ldots \to E^n$ over X, then the derived scheme $\mathfrak{X}$ has amplitude in $[0, n]$. More precisely, $\mathfrak{X}$ has amplitude in $[0, n]$, if and only if, *locally in* X, the tangent complex is quasi-isomorphic to a complex $E^0 \to \ldots \to E^n$ of vector bundles over X.

The tangent complex also determines the virtual dimension. In fact, the virtual dimension of $\mathfrak{X}$ is the rank of $\mathbb{T}_{\mathfrak{X}}$, which is equal to $\sum_{i=0}^{\text{amplitude}} (-1)^i \dim E^i$, for a (local) presentation $\mathbb{T}_{\mathfrak{X}} = E^\bullet$.

Let us denote the cohomology sheaves of $\mathbb{T}_{\mathfrak{X}}$ by $h^i(\mathbb{T}_{\mathfrak{X}})$. There are coherent sheaves on X. We always have that $h^0(\mathbb{T}_{\mathfrak{X}}) = T_X = \mathscr{D}er(\mathscr{O}_X, \mathscr{O}_X)$ is the Zariski tangent sheaf of X.

In the quasi-smooth case, we denote $h^1(\mathbb{T}_{\mathfrak{X}})$ by $ob_{\mathfrak{X}}$, and call it the *obstruction sheaf*. In this latter case, we may think of $\mathbb{T}_{\mathfrak{X}}$ as a 2-extension of $ob_{\mathfrak{X}}$ by T_X, i.e., an element of $\mathrm{Ext}^2_{\mathscr{O}_X}(ob_{\mathfrak{X}}, T_X)$:

$$0 \longrightarrow T_X \longrightarrow \mathbb{T}^0_{\mathfrak{X}} \longrightarrow \mathbb{T}^1_{\mathfrak{X}} \longrightarrow ob_{\mathfrak{X}} \longrightarrow 0$$

In case X is non-singular as a scheme, $ob_{\mathfrak{X}}$ is a vector bundle, and so the 2-extension $\mathbb{T}_{\mathfrak{X}}$ is a cohomology class in $H^2\big(X, ob^\vee_{\mathfrak{X}} \otimes T_X\big)$.

2.1.6. Canonical bundle. In the finite amplitude case, the determinant of $\mathbb{T}_{\mathfrak{X}}$ is a well-defined line bundle on X. Its dual is denoted by $K_{\mathfrak{X}}$ and called the *virtual canonical bundle* of $\mathfrak{X}$.

2.1.7. Higher structure sheaves. There is a graded sheaf of $\mathscr{O}_X$-algebras on the classical locus X, denoted $\pi_*(\mathscr{O}_{\mathfrak{X}})$. It satisfies $\pi_0(\mathscr{O}_{\mathfrak{X}}) = \mathscr{O}_X$ and $\pi_i(\mathscr{O}_{\mathfrak{X}}) = 0$, for all $i < 0$. Every $\pi_i(\mathscr{O}_{\mathfrak{X}})$ is a coherent sheaf of $\mathscr{O}_X$-modules. Moreover, $\pi_*(\mathscr{O}_{\mathfrak{X}})$ is a *graded commutative* sheaf of $\mathscr{O}_X$-algebras, so there are operations $\pi_i(\mathscr{O}_{\mathfrak{X}}) \otimes_{\mathscr{O}_X} \pi_j(\mathscr{O}_{\mathfrak{X}}) \to \pi_{i+j}(\mathscr{O}_{\mathfrak{X}})$. In the quasi-smooth case, $\pi_*(\mathscr{O}_{\mathfrak{X}})$ is bounded above. In general (even in the finite amplitude case) it will be unbounded.

2.2. Examples. Here are a few typical sources of derived schemes.

2.2.1. Affine variety cut out by a set of equations. Any collection of r polynomials $f_1, \ldots, f_r \in \mathbb{C}[x_1, \ldots, x_n]$ in n variables defines a derived scheme $\mathfrak{X}$ of amplitude contained in $[0, 1]$, i.e. a quasi-smooth derived scheme. Its virtual dimension is equal to $n - r$, the 'expected' dimension of the common zero locus of r equations in n variables. The underlying classical scheme is $X = \mathrm{Spec}\, \mathbb{C}[x_1, \ldots, x_n]/(f_1, \ldots, f_r)$. Every irreducible component of X has dimension $n - r$ or larger. If X is of pure dimension $n - r$, then it is a local complete intersection scheme, and $\mathfrak{X} = X$. All derived phenomena are due to excess dimension in the intersection of the r hypersurfaces $Z(f_1), \ldots, Z(f_r)$.

2.2.2. Toy model of quasi-smooth derived schemes. Slightly more generally, suppose that M is a non-singular $\mathbb{C}$-variety, and $E \to M$ an algebraic vector bundle over M, with a global section $s : M \to E$. In this case the scheme-theoretic zero locus $X \subset M$ of s is naturally

endowed with a derived scheme structure $X \subset \mathfrak{X} \subset M$. The smoothness amplitude of $\mathfrak{X}$ is contained in $[0,1]$, and the virtual dimension is $\dim M - \operatorname{rk} E$.

Differentiating the section $s : M \to E$ gives rise to a homomorphism of vector bundles $T_M|_X \to E|_X$ over X, this represents the tangent complex $\mathbb{T}_{\mathfrak{X}} \in D^b_{\mathrm{coh}}(\mathscr{O}_X)$, if we put $T_M|_X$ in degree 0 and $E|_X$ in degree 1. The kernel of $T_M|_X \to E|_X$, i.e., $h^0(\mathbb{T}_{\mathfrak{X}})$, is the Zariski tangent sheaf of X, denoted T_X. It is isomorphic to the sheaf of derivations $\mathscr{O}_X \to \mathscr{O}_X$, and does not depend on $\mathfrak{X}$, only on X. The obstruction sheaf $ob_{\mathfrak{X}} = h^1(\mathbb{T}_{\mathfrak{X}})$, is the cokernel of $T_M|_X \to E|_X$. It depends on $\mathfrak{X}$ in an essential way. There is an exact sequence of coherent sheaves on X

$$0 \longrightarrow T_X \longrightarrow T_M|_X \longrightarrow E|_X \longrightarrow ob_{\mathfrak{X}} \longrightarrow 0 \ .$$

(To get the signs right, let us remark that, strictly speaking, the complex $\mathbb{T}_{\mathfrak{X}}$ is given by the canonical homomorphism $T_M|_X \to E|_X$, *multiplied by* -1, as it is the dual of the cotangent complex of $\mathfrak{X}$, which is considered more fundamental.)

The name *obstruction sheaf* comes from deformation theory. The obstruction sheaf contains all obstructions to the smoothness of X, although it can be much bigger. (Moreover, the obstructions to smoothness of X are, of course, intrinsic to X, whereas $ob_{\mathfrak{X}}$ is not.)

The virtual fundamental class of $\mathfrak{X}$ is the *localized top Chern class* of E, which is an element of $H_{2\dim M - 2\operatorname{rk} E}(X, \mathbb{Z})$, or $A_{\dim M - \operatorname{rk} E}(X)$, respectively. Let us review its construction via *deformation to the normal cone*, [11].

The graph of s is a subvariety Γ_s of the total space of E, isomorphic to the base M via the projection $\pi : E \to M$. We multiply Γ_s by a scalar $\lambda \in \mathbb{C}^*$ using the vector bundle structure on E, and let $\lambda \to \infty$. The limit maps to $X \subset M$ via the projection π, and it is invariant under the $\mathbb{C}^*$-action on E. Therefore, it is is a cone C_X inside the restriction $E|_X$ of the bundle E to X. The cone C_X is known as the *normal cone* of X in M. As an abstract scheme, $C_X \to X$ depends only on the embedding $X \hookrightarrow M$, in fact, $C_X = \operatorname{Spec}_X \bigoplus_{i=0}^{\infty} I^i/I^{i+1}$, where I is the ideal sheaf of X in M. (The embedding $C_X \hookrightarrow E|_X$ comes from writing X as the zero locus of the section $s : M \to E$ of π.) The cone $C_{X/M}$ is of pure dimension $\dim M$.

We are not interested in this cone as a scheme, but only in its *fundamental cycle*. If $C_1, \ldots, C_s$ are the irreducible components of $C_{X/M}$ and $r_1, \ldots, r_s$ their multiplicities in the scheme $C_{X/M}$, then the fundamental cycle is $[C_{X/M}] = r_1[C_1] + \ldots + r_s[C_s] \in A_{\dim M}(E|_X)$. The images of the components C_i under π are subvarieties of X, the *distinguished subvarieties*. They will play a role in 3.2.5, below.

Pulling back cycles via the projection $\pi : E|_X \to X$ induces an isomorphism on Chow groups $A(X) \to A(E|_X)$, by homotopy invariance of Chow homology. The inverse of this isomorphism is the *Gysin map* $0^!_E : A(E|_X) \to A(X)$. It lowers degrees by $\operatorname{rk} E$, because pulling back increases degrees by $\operatorname{rk} E$. The localized top Chern class is $c_{\mathrm{top}}(E) = 0^!_E[C_{X/M}]$. As mentioned, this is the virtual fundamental class of the derived scheme $\mathfrak{X}$.

$$[\mathfrak{X}]^{\mathrm{vir}} = c_{\mathrm{top}}(E) = 0^!_E[C_{X/M}] \, .$$

The image of this class in $A(M)$ is the usual top Chern class of E as a bundle over M.

If all irreducible components of X have the expected dimension $\dim M - \operatorname{rk} E$, we are in the case where $X = \mathfrak{X}$ and X is a local complete intersection. Then $[\mathfrak{X}]^{\mathrm{vir}} = [X]$.

In the case where X is non-singular (as a scheme), the obstruction sheaf $ob_{\mathfrak{X}}$ is a vector bundle. Its rank is the excess dimension determined by the equation

$$\dim X = \dim M - \operatorname{rk} E + \operatorname{rk} ob_{\mathfrak{X}} \ .$$

Its top Chern class is the virtual fundamental class:

$$[\mathfrak{X}]^{\mathrm{vir}} = c_{\mathrm{top}}(ob_{\mathfrak{X}}) \cap [X] \,.$$

2.2.3. Intersection theory. Still more generally, consider two smooth subvarieties M, N inside a smooth ambient variety V. The classical intersection scheme is the fibered product $X = M \times_V N$. If X has the expected dimension, its scheme structure carries all relevant intersection theory phenomena, in particular the intersection multiplicities. In the case of excess intersection dimension, there is a refined fibered product $\mathfrak{X}$ in the category of derived schemes, whose underlying classical scheme is X. The virtual dimension of $\mathfrak{X}$ is $\dim V - \dim M - \dim N$.

Again, the amplitude of $\mathfrak{X}$ is contained in $[0, 1]$. It is equal to 0 if and only if the intersection of M and N inside V is *transverse*, which means that at every point P in the intersection X, we have $T_M|_P + T_N|_P = T_V|_P$.

Again, $X = \mathfrak{X}$ if and only if X has dimension $\dim V - \dim M - \dim N$ at every one of its points, i.e., if and only if the intersection is *proper*.

The tangent complex is $\mathbb{T}_{\mathfrak{X}} = [T_M|_X \oplus T_N|_X \to T_V|_X]$. The obstruction sheaf fits into the exact sequence

$$0 \longrightarrow T_X \longrightarrow T_M|_X \oplus T_N|_X \longrightarrow T_V|_X \longrightarrow ob_{\mathfrak{X}} \longrightarrow 0 \ .$$

So if X is non-singular, then $ob_{\mathfrak{X}}$ is equal to the *excess bundle* of the intersection.

The virtual fundamental class is the *refined intersection product* $[\mathfrak{X}]^{\mathrm{vir}} = [M] \cdot [N] \in A(X)$, which maps to the (global) intersection product in $A(V)$. (This is the top Chern class of the excess bundle in the case that X is non-singular.)

The higher structure sheaves are derived tor-sheaves:

$$\pi_i(\mathscr{O}_{\mathfrak{X}}) = \mathscr{T}or_i^{\mathscr{O}_V}(\mathscr{O}_M, \mathscr{O}_N) \,.$$

(This is the origin of the word *derived scheme*.)

If M and N have complementary dimension, then the virtual dimension of $\mathfrak{X}$ is 0, and hence $[\mathfrak{X}]^{\mathrm{vir}}$ is a 0-cycle on X. If, moreover, X is proper (the algebraic analogue of compact), then $[\mathfrak{X}]^{\mathrm{vir}}$ has a well-defined degree. This is the *intersection number* of M and N in V, which we think of as the virtual number of points of $\mathfrak{X}$:

$$\#^{\mathrm{vir}}(\mathfrak{X}) = \deg[\mathfrak{X}]^{\mathrm{vir}} = \int_{[\mathfrak{X}]^{\mathrm{vir}}} 1 \in \mathbb{Z} \,.$$

If the intersection is transverse, $\#^{\mathrm{vir}}(\mathfrak{X}) = \#(X)$. If it is proper, $\#^{\mathrm{vir}}(\mathfrak{X})$ is equal to the length of the 0-dimensional scheme X.

2.2.4. Gauge theory. Suppose that $L = L^{\geq 0}$ is a *differential graded Lie algebra*. As a standard example, let Y be a compact C^∞-manifold, and let

$$L^k = C^\infty(Y, \Omega_Y^k \otimes_{\mathbb{C}} M_{n\times n})$$

be the $\mathbb{C}$-vector space of matrix-valued C^∞-forms of degree k on Y. The differential is the de Rham differential, the Lie bracket is the anti-commutator of the natural associative product on L given by combining wedge product of forms with matrix multiplication in the natural way.

The *curvature map* is the quadratic map $F : L^1 \to L^2$, defined by

$$x \mapsto dx + \tfrac{1}{2}[x, x]\,.$$

The vanishing locus of the curvature in L^1 is the *Maurer-Cartan locus* of L. In our example, L^1 is the set of all connections on the trivial vector bundle of rank n on Y, and the Maurer-Cartan locus is the set of flat connections.

Let G be a *gauge group* for L. This is a complex Lie group whose Lie algebra is L^0, and which acts on L by automorphism of the differential graded Lie algebra structure, in such a way that the derivative of the action of G on L^k is the Lie algebra action of L^0 and L^k given by the graded Lie algebra structure of L. In our example, $G = C^\infty(Y, GL_n)$ is the group of invertible sections in $L^0 = C^\infty(Y, M_{n\times n})$.

Moreover, assume given a *gauge cocycle*, i.e., a map $\gamma : G \to L^1$, satisfying

1. $\gamma(gh) = {}^g\gamma(h) + \gamma(g)$,
2. $d\gamma(g) + \frac{1}{2}[\gamma(g), \gamma(g)] = 0$,
3. ${}^g\big(d({}^{g^{-1}}x)\big) = dx + [\gamma(g), x]$,

then we define the *gauge action* of G on L^1 by $g * x = {}^g x + \gamma(g)$. In our example, $\gamma(g) = -(dg)g^{-1}$.

The *moduli space* of (L, G, γ) is the quotient of the Maurer-Cartan locus by the gauge action. In our example, this is the set of flat connections on the trivial bundle modulo gauge equivalence, or, equivalently, the set of isomorphism classes of flat vector bundles of rank n, whose underlying C^∞-bundle is trivial. In other words, it is the moduli space of (topologically trivial) local systems on Y.

For the quotient by G to be well-behaved, we have to restrict to an open subset of L^1, where G has trivial, or almost trivial stabilizers. In our example, this leads to the moduli space of *simple* local systems. Unfortunately, it is not compact.

Strictly speaking (in our example), each L^k, as well as G, is infinite-dimensional, so the above constructions do not make sense within algebraic geometry, but the ideas are nevertheless very important. On the other hand, there are many examples where L and G are finite-dimensional, so we are within algebraic geometry, and the quotient by the gauge group can be treated with geometric invariant theory, and the well-behaved subspace of L^1 is the *stable* locus with respect to a linearization of the gauge group action.

For example, Kapranov[13] has shown how our example can be made finite-dimensional by triangulating the manifold Y, and considering simplicial matrix valued cochains.

Anyway, let us call the moduli space $X = MC(L)/G$. It is the classical locus of a derived scheme $\mathfrak{X}$. To construct the tangent complex $\mathbb{T}_{\mathfrak{X}}$, we start with the trivial graded vector bundle with fibre L over $MC(L)$, and endow it with the differential which is given by d^x in the fibre over the Maurer-Cartan element x. Here d^x is the differential d twisted by $\mathrm{ad}(x)$, i.e., $d^x(y) = dy + [x, y]$. The gauge groups acts on the complex of vector bundles (L, d^x) over X, on the fibres via the linear action, on the base via the gauge action. The complex (L, d^x) therefore descends to a complex of vector bundles on the quotient. This is the shift $\mathbb{T}_{\mathfrak{X}}[-1]$. Therefore, $H^i(\mathbb{T}_{\mathfrak{X}}|_x) = H^{i+1}(L, d^x)$. (If $H^0(L, d^x) \neq 0$, then the stabilizer of G at x, whose Lie algebra is $H^0(L, d^x)$, is positive-dimensional. This stabilizer would have been 'ignored' when taking the G-quotient, and hence in this case $\mathbb{T}_{\mathfrak{X}}[-1]$ is obtained as the truncation $\tau_{\geq 1}(L, d^x)$.)

In our example, (L, d^x) is the de Rham complex of Y with values in the endomorphism bundle of the flat bundle E defined by x. Therefore its cohomology groups are $H^i(L, d^x) = H^i\big(Y, \mathrm{End}(E)\big)$, and hence $H^i(\mathbb{T}_{\mathfrak{X}}|_x) = H^{i+1}\big(Y, \mathrm{End}(E)\big)$. The virtual dimension of this derived scheme is therefore

$$\sum_{i=0}^{\dim Y - 1} (-1)^i H^{i+1}\big(Y, \mathrm{End}(E)\big) = 1 - \chi\big(Y, \mathrm{End}(E)\big)\,,$$

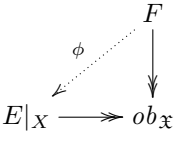
and its amplitude is contained in the interval $[0, \dim Y - 1]$.

For the Zariski tangent space of the point of X defined by the flat bundle E we get $T_X|_E = H^1\big(Y, \mathrm{End}(E)\big)$. This is the space of infinitesimal deformations of E, and this result would have been predicted by deformation theory. The next space $H^2\big(Y, \mathrm{End}(E)\big)$ contains the obstructions to the smoothness of X at the point represented by E. This is another fact proved in deformation theory.

If we pull back the higher structure sheaves form X to $MC(L)$, and take global sections, we get essentially the differential graded Lie algebra cohomology of L (a generalization of ordinary Lie algebra cohomology to the differential graded case), with values in the trivial module $\mathbb{C}$.

So if Y is a surface, then $\mathfrak{X}$ is quasi-smooth, and we should have a virtual fundamental class. But it turns out, at least when Y is orientable, that there is more symmetry (see 3.3.1, below), and therefore X is smooth. The spaces X we get are known as *character varieties*, there is a rich body of literature devoted to their study.

2.3. Construction of the virtual fundamental class. Suppose $\mathfrak{X}$ is a quasi-smooth derived scheme. For simplicity, let us assume that the underlying classical scheme X is quasi-projective. Then it is possible to write the obstruction sheaf $ob_{\mathfrak{X}} = h^1(\mathbb{T}_{\mathfrak{X}})$ as a quotient of a locally free sheaf $F \twoheadrightarrow ob_{\mathfrak{X}}$. There is then an associated scheme of closed subcones $C \hookrightarrow F$. It is characterized by the property that whenever $\mathfrak{X}$ is (locally!) written as the derived scheme associated to a toy model $M \xrightarrow{s} E$, then for any lift ϕ as in the diagram



we have $C = \phi^{-1}(C_{X/M})$.

It can be shown that C is the preimage under the epimorphism $F \twoheadrightarrow ob_{\mathfrak{X}}$ of the cone $cv_{\mathfrak{X}} \subset ob_{\mathfrak{X}}$ of *small curvi-linear obstructions*.

The virtual fundamental class of $\mathfrak{X}$ is then

$$[\mathfrak{X}]^{\mathrm{vir}} = 0^!_F[C] \in A(X)\,.$$

It does not depend on the choice of F nor on the choice of the epimorphism $F \twoheadrightarrow ob_{\mathfrak{X}}$.

As this construction shows, the virtual fundamental class of $\mathfrak{X}$ depends only on the tangent complex $\mathbb{T}_{\mathfrak{X}}$, and its properties. Abstracting these properties, leads to the notion of *perfect obstruction theory*. We explain this formalism next.

2.3.1. The truncated tangent complex of a scheme. Given a scheme X, which is embedded as a closed subscheme into a non-singular scheme M, there is a canonical homomor-

phism of coherent sheaves on X

$$T_M|_X \longrightarrow \mathscr{N}_{X/M} \ .$$

Here, $\mathscr{N}_{X/M}$ is the *normal sheaf* of X in M, it is the dual of the coherent $\mathscr{O}_X$-module I/I^2, where I is the ideal sheaf of X in M. A standard argument shows that the associated object of $D^b_{\mathrm{coh}}(\mathscr{O}_X)$, obtained by putting $T_M|_X$ in degree 0 and $\mathscr{N}_{X/M}$ in degree 1 (and multiplying the map by -1), does not depend on the embedding $X \hookrightarrow M$ chosen, and exists naturally even when no such embedding exists globally. This derived category object is the *truncated tangent complex* of X, notation $\mathbb{T}_X$. (It is the dual of $\tau_{\geq -1}L_X$, where L_X is the cotangent complex of the scheme X.)

As $\mathscr{N}_{X/M}$ is the dual of a coherent sheaf, it is, in fact, a scheme over X. The normal cone of the embedding $X \subset M$ is naturally a $\mathbb{C}^*$-invariant closed subscheme $C_{X/M} \hookrightarrow \mathscr{N}_{X/M}$.

2.3.2. Perfect obstruction theories. A *perfect obstruction theory* on the scheme X is an object of the derived category $F \in D^b_{\mathrm{coh}}(\mathscr{O}_X)$, together with a morphism $\phi : \mathbb{T}_X \to F$, such that

1. F is of perfect amplitude contained in $[0,1]$, in other words, X being quasi-projective, F is given by a two term complex of vector bundles $F^0 \to F^1$ over X,
2. whenever we represent ϕ (locally over X) by a homomorphism of complexes

$$\begin{array}{ccc} T_M|_X & \longrightarrow & \mathscr{N}_{X/M} \\ {\scriptstyle \phi^0}\downarrow & & \downarrow{\scriptstyle \phi^1} \\ F^0 & \longrightarrow & F^1 \end{array} \tag{2.1}$$

the square we obtain is a pullback diagram of schemes over X.

Given a perfect obstruction theory $\mathbb{T}_X \to F$ on X, we define the corresponding obstruction sheaf to be $ob_F = h^1(F)$. Any way of representing F as $F^0 \to F^1$ gives an epimorphism $F^1 \to ob_F$ from a vector bundle, and hence, as explained above, a cone $C \hookrightarrow F^1$, and the virtual fundamental class

$$[X,F]^{\mathrm{vir}} = 0^!_{F^1}[C] \in A(X) \, .$$

which depends only on the scheme X, and the perfect obstruction theory $\mathbb{T}_X \to F$. (For any diagram (2.1), the cone $C \hookrightarrow F^1$ pulls back to the normal cone $C_{X/M} \subset \mathscr{N}_{X/M}$ under ϕ^1.)

Whenever $\mathfrak{X}$ is a quasi-smooth derived scheme, there is a natural homomorphism $\mathbb{T}_X \to \mathbb{T}_{\mathfrak{X}}$ in $D^b_{\mathrm{coh}}(\mathscr{O}_X)$, which is, in fact, a perfect obstruction theory. The virtual fundamental class of $\mathfrak{X}$ is then equal to the virtual fundamental class of the underlying classical scheme X with respect to the obstruction theory $\mathbb{T}_{\mathfrak{X}}$.

In general, perfect obstruction theories are much easier to construct than derived schemes. Usually, they come directly from deformation theory, and the fact that they are perfect also follows from standard facts in deformation theory (if it is true).

2.3.3. K-theory fundamental class. The original suggestion of Kontsevich to construct the virtual fundamental class was via the higher structure sheaves. In fact, for any quasi-smooth derived scheme $\mathfrak{X}$, the following is true [7]:

$$[\mathfrak{X}]^{\mathrm{vir}} = \tau_X[\pi_*(\mathscr{O}_{\mathfrak{X}})] \cdot \mathrm{Td}^{-1}(\mathbb{T}_{\mathfrak{X}}) \, .$$

Here τ_X is the homological Chern character of Baum-Fulton-MacPherson, applied to the class of the alternating sum of the higher structure sheaves in K-theory of coherent sheaves on X.

2.4. Applications. When the scheme X is endowed with a virtual fundamental class $[X,F]^{\mathrm{vir}} \in A_d(X)$, defined by a perfect obstruction theory F (which may or may not come from a quasi-smooth derived scheme $\mathfrak{X}$ via $F = \mathbb{T}_{\mathfrak{X}}$), and X is *proper*, then the virtual fundamental class defines a homomorphism

$$A^d(X) \longrightarrow \mathbb{Z}\,, \qquad \psi \longmapsto \int_{[X]^{\mathrm{vir}}} \psi\,.$$

Here d is the virtual dimension of (X,F). The cohomology classes ψ of degree d which are integrated against the virtual fundamental class to obtain integers are often called *insertions*. Thus combining the virtual fundamental class with suitable insertions gives integers, which are often referred to as *invariants*, because being constructed by means of intersection theory, they are usually invariant under deformations of the underlying geometry.

2.4.1. Donaldson Invariants. As an example, consider the algebraic geometry analogue of our gauge theory example, above. Instead of flat bundles on a compact C^∞-manifold, we consider holomorphic bundles on a compact complex manifold, or algebraic vector bundles on a non-singular projective variety, denoted Y. For a vector bundle E over Y, its infinitesimal deformations are given by the vector space $H^1\big(Y,\mathrm{End}(E)\big)$, and obstructions are contained in the vector space $H^2\big(Y,\mathrm{End}(E)\big)$. This suggests, by analogy with the above gauge theory example, that the derived moduli scheme $\mathfrak{X}$ of bundles on Y should have a tangent complex $\mathbb{T}_{\mathfrak{X}}$ with the property that $H^i(\mathbb{T}_{\mathfrak{X}}|_E) = H^{i+1}\big(Y,\mathrm{End}(E)\big)$ at every point E of the classical moduli scheme X of bundles on Y. This leads us to expect that the derived category object $\big(\tau_{\geq 1} R\pi_*\,\mathscr{H}om(\mathscr{E},\mathscr{E})\big)[1]$ on X might serve as a perfect obstruction theory, and define a virtual fundamental class on X. (Here $\mathscr{E}$ is the universal bundle over $X\times Y$, and $\pi : X\times Y \to X$ is the projection.) As one of the requirements on a perfect obstruction theory is that it has to exist in the interval $[0,1]$, we will need to require that $H^i\big(Y,\mathrm{End}(E)\big) = 0$, for all $i > 2$. The best way to assure this in general, is to assume that Y is of dimension 2, i.e., an algebraic surface. We then do, indeed, get a perfect obstruction theory, and a virtual fundamental class for X. To compactify X, we pass to stable sheaves. In good cases, i.e., where there are no strictly semi-stable sheaves, the moduli space will be compact, and with suitable insertions, we get numerical invariants. These are, essentially, *Donaldson invariants* [10]. See [22] for a treatment using virtual fundamental classes.

2.4.2. Gromov-Witten invariants. An example for which the theory of perfect obstruction theories and virtual fundamental classes was very successful is that of Gromov-Witten invariants. The relevant moduli space is essentially a moduli space of morphisms $X = \mathrm{Mor}(C,V)$, where C is a fixed algebraic curve (with at most nodal singularities) and V a fixed non-singular projective variety. Deformation theory tells us that infinitesimal deformations of $f : C \to V$ are given by $H^0(C, f^*T_V)$, i.e., by vector fields tangent to V, supported by C. Moreover, obstructions are contained in $H^1(C, f^*T_V)$. So $R\pi_* f^*T_V$ is a perfect obstruction theory for X. (Here $f : X\times C \to V$ is the universal map, and $\pi : X\times C \to X$ the projection.) The key construction that makes this useful, is the compactification of $X = \mathrm{Mor}(C,V)$ using *stable maps* due to Kontsevich. In the compact-

ification the curve C exhibits 'bubbling phenomena', i.e. it sprouts off trees of projective lines (or Riemann spheres), connected to each other by nodal singularities. No matter how bad the bubbling, we always have $H^i(C, f^*T_V) = 0$, for $i > 1$, because C always stays one-dimensional.

For the theory of Gromov-Witten invariants one makes this construction relative to the moduli space of all stable curves. So one keeps V fixed, but varies C. The additional complication that arises, is that the automorphism groups of curves, although finite, may jump in families. This means that the moduli space will be a *stack of Deligne-Mumford type* rather than a scheme. The only difference this makes is that the integrals of the insertions against the virtual fundamental class, and hence the Gromov-Witten invariants, will take values in rational numbers, rather than integers.

3. The virtual fundamental class in symplectic geometry

We continue in the context of algebraic geometry over $\mathbb{C}$. Thus, a *symplectic manifold* is a non-singular scheme over $\mathbb{C}$, endowed with an everywhere non-degenerate closed algebraic (hence holomorphic) 2-form. A *Lagrangian submanifold* is an algebraic (in particular holomorphic) submanifold of half the dimension of the ambient symplectic manifold, whose tangent space is everywhere isotropic for the symplectic form.

3.1. Lagrangian intersections. In symplectic geometry it is natural to consider the intersection of two Lagrangian submanifolds inside a symplectic manifold. First of all, we notice that the expected dimension of such an intersection is always 0, because two Lagrangian submanifolds always have complementary dimensions. Thus, if the intersection is compact, intersection theory gives rise to intersection numbers, without the need for cohomological insertions.

3.1.1. Motivic nature of intersection. Now something quite unexpected happens: the intersection number is *motivic*, i.e., it behaves like an Euler characteristic. To explain what we mean by this, suppose that S is a symplectic manifold of dimension $2n$, and let L, M be Lagrangian submanifolds, with intersection $X = L \cap M$.

1. the intersection number $\#^{\mathrm{vir}}(X)$ makes sense whether or not the intersection X is compact,
2. the intersection number is additive over open covers: if $S = U \cup V$, for Zariski open subsets U, V of S, then

$$\#^{\mathrm{vir}}(X) + \#^{\mathrm{vir}}(X \cap U \cap V) = \#^{\mathrm{vir}}(X \cap U) + \#^{\mathrm{vir}}(X \cap V)\,.$$

One of our goals is to explain why this is so.

3.1.2. Punctual contributions to the intersection number. The two motivic properties imply that we can make sense of the contribution to the intersection number of every single point $P \in X$. Simply set

$$\nu_X(P) = \#^{\mathrm{vir}}(X) - \#^{\mathrm{vir}}(X \setminus P)\,.$$

It turns out that the function

$$\nu_X : X \longrightarrow \mathbb{Z}$$

is *constructible* (i.e. constant along the strata of a suitable stratification of X), and that

$$\#^{\mathrm{vir}}(X) = \sum_{n\in\mathbb{Z}} n\,\chi^{\mathrm{top}}\{x \in X \colon \nu_X = n\}$$

is the weighted Euler characteristic with respect to the constructible function ν_X.

Another surprising fact is that $\nu_X(P)$ depends only on the scheme structure of X near P, i.e., the singularity of X at P. Thus the constructible function ν_X is *intrinsic* to X.

3.1.3. Obstruction sheaf. Another unexpected fact is that also the obstruction sheaf is intrinsic to the classical intersection scheme X. To determine the obstruction sheaf, recall the tangent complex $\mathbb{T}_{\mathfrak{X}} = [T_L \oplus T_M \to T_S]|_X$. We take its dual, and shift it back into the interval $[0,1]$: $\mathbb{T}^\vee_{\mathfrak{X}}[-1] = [\Omega_S \to \Omega_L \oplus \Omega_M]|_X$. Now the symplectic form defines an isomorphism $\sigma : T_S \to \Omega_S$, such that $\sigma^\vee = -\sigma$. We use σ to construct the homomorphism $\theta = \frac{1}{2}(\sigma \oplus \sigma) : T_L|_X \oplus T_M|_X \to \Omega_S|_X$ giving rise to a commutative diagram

$$\begin{array}{ccc} \mathbb{T}_{\mathfrak{X}} & & T_L|_X \oplus T_M|_X \xrightarrow{1\oplus -1} T_S|_X \\ {\scriptstyle(\theta,-\theta^\vee)}\downarrow & & {\scriptstyle\theta}\downarrow \qquad\qquad \downarrow{\scriptstyle -\theta^\vee} \\ \mathbb{T}^\vee_{\mathfrak{X}}[-1] & & \Omega_S|_X \xrightarrow{-1\oplus 1} \Omega_L|_X \oplus \Omega_M|_X \end{array}$$

Since the kernel of $\Omega_S|_X \to \Omega_L|_X$ is equal to $T_L|_X$, by the Lagrangian nature of L, and a similar fact holds for M, we see that the kernel of $[\Omega_S \to \Omega_L \oplus \Omega_M]|_X$ is equal to T_X, and that θ induces the identity on T_X. Similar reasoning proves that the cokernel of $[T_L \oplus T_M \to T_S]|_X$ is equal to Ω_X, and that $-\theta^\vee = \theta$ induces the identity on Ω_X. We deduce that $(\theta, -\theta^\vee) : \mathbb{T}_{\mathfrak{X}} \to \mathbb{T}^\vee_{\mathfrak{X}}[-1]$ is a canonical quasi-isomorphism, hence an isomorphism in the derived category. We conclude that

$$ob_{\mathfrak{X}} = h^1(\mathbb{T}_{\mathfrak{X}}) = h^1(\mathbb{T}^\vee_{\mathfrak{X}}[-1]) = \Omega_X\,.$$

From this it also follows that

$$T_X = h^0(\mathbb{T}_{\mathfrak{X}}) = ob^\vee_{\mathfrak{X}}\,,$$

in other words, *deformations are dual to obstructions*, and *the obstruction sheaf is the sheaf of differentials*.

3.1.4. Smooth intersection. Let us explain the origin of the motivic nature of Lagrangian intersection numbers in the case where the intersection X is smooth (as a scheme). (Sometimes, this condition is referred to as *clean* intersection.) It means that the dimension of the intersection $T_L|_x \cap T_M|_x$ inside $T_S|_x$ is a locally constant function of $x \in X$. The obstruction sheaf is locally free, and called the excess bundle. We see that the excess bundle of the intersection is always the cotangent bundle of the intersection variety. Its top Chern class is therefore equal to $c_{\mathrm{top}}(\Omega_X) = (-1)^{\dim X} c_{\mathrm{top}}(T_X)$, i.e., up to sign, equal to the Euler class of X. By the Gauß-Bonnet formula we conclude, if X is proper:

$$\#^{\mathrm{vir}}(X) = \int_{[X]} c_{\mathrm{top}}(ob_{\mathfrak{X}}) = (-1)^{\dim X} \int_{[X]} c_{\mathrm{top}}(T_X) = (-1)^{\dim X} \chi^{\mathrm{top}}(X)\,, \qquad (3.1)$$

where χ^{top} denotes the topological Euler characteristic. (Apologies for using 'top' in two different senses.) Unlike the intersection number, the topological Euler characteristic is well-defined also for non-proper X. Moreover, it is additive over open covers.

We see that for the case of smooth intersection, the weight function is constant (and intrinsic to X):

$$\nu_X \equiv (-1)^{\dim X}\,.$$

Every point $P \in X$ contributes $(-1)^{\dim X}$ to the intersection number.

3.1.5. Toy model: Critical locus of a regular function. The toy model for a Lagrangian intersection is the critical locus of a regular function. Suppose that M is a manifold and $f : M \to \mathbb{C}$ a regular function. The graph of the exact differential form df is a Lagrangian submanifold inside the cotangent bundle Ω_M of M with its tautological symplectic structure. The zero section of the cotangent bundle is another Lagrangian, and the intersection of these two Lagrangians is the critical locus of f in M.

$$X = \mathrm{Crit}(f)\,.$$

For simplicity of exposition, assume that X is contained (at least set-theoretically) in the fibre of f over 0. As f is necessarily constant on every component of its critical set, this is not a serious restriction. Then X is a natural scheme structure on the set of singularities of the fibre $f^{-1}(0) \subset M$.

Let $P \in X$ be a point. The *Milnor fibre* of f at P is the intersection of a nearby fibre of $f : M \to \mathbb{C}$ with a small ball around $P \in M$:

$$F_f(P) = \{x \in M\colon ||x|| \leq \epsilon \text{ and } f(x) = \eta\} \tag{3.2}$$

for sufficiently small $\epsilon \gg \eta > 0$. The Milnor fibre $F_f(P)$ is a manifold with boundary (the boundary is the *link* of the singularity of f at P), which is independent of the choice of metric on M used to define the ball of radius ϵ, and of ϵ and η, as long as ϵ is sufficiently small, and η sufficiently small with respect to ϵ. It is called the Milnor fibre, because it is diffeomorphic to the fibre of the fibration

$$B_\epsilon(P) \setminus f^{-1}(0) \longrightarrow S^1\,, \qquad x \longmapsto \frac{f(x)}{||f(x)||}\,.$$

studied by Milnor [21].

In his well-known textbook [ibid.], Milnor studied mainly the case were P is an isolated singularity of $f^{-1}(0)$, i.e., an isolated point of X. In this case he proved that $F_f(P)$ has the homotopy type of a bouquet of spheres of real dimension $\dim_{\mathbb{C}} M - 1$. The number of spheres, which can be expressed as

$$\mu_f(P) = (-1)^{\dim M}\big(1 - \chi^{\mathrm{top}} F_f(P)\big)\,, \tag{3.3}$$

is called the *Milnor number*, and Milnor proved that it is equal to the dimension of $\mathscr{O}_{X,P}$, i.e., the multiplicity of P as a point on the scheme X. In local coordinates $x_1, \ldots, x_n$ on M near P, this is the dimension of

$$\mathbb{C}[[x_1, \ldots, x_n]]/(\partial_1 f, \ldots, \partial_n f)\,,$$

which is finite, as f has an isolated critical point at $x = 0$.

When X has positive dimension, so that P is not an isolated critical point of f, the expression (3.3) is still a well-defined integer. Just as in the case of an isolated singularity, the number $\mu_f(P)$ depends only on the scheme structure of X near P (not on the function f whose critical scheme X is), and it varies in a constructible fashion over X. It is a consequence of the *microlocal index theorem* of Kashiwara and MacPherson (and the fact that the characteristic variety of the perverse sheaf of vanishing cycles is equal to the normal cone of the critical set) that, if $\mathrm{Crit}\, f$ is proper,

$$\#^{\mathrm{vir}}(\mathrm{Crit}\, f) = \chi^{\mathrm{top}}(\mathrm{Crit}\, f, \mu_f)\,.$$

This is an analogue of formula (3.1), and proves the motivic nature of $\#^{\mathrm{vir}}(\mathrm{Crit}\, f)$, in the case $X = \mathrm{Crit}\, f$.

We see that in this case $\nu_X(P) = \mu_f(P)$, so the contribution of the point P to the virtual count is, up to sign, the reduced Euler characteristic of the Milnor fibre.

3.1.6. Homogeneous case. We explain one case where the generalized Milnor number $\nu_X(P) = \mu_f(P)$ of (3.3) is easy to determine. Consider a set of non-zero integers $r_1, \ldots, r_n \in \mathbb{Z}$, called *weights*, and assume we have a polynomial $f \in \mathbb{C}[x_1, \ldots, x_n]$ which is weighted homogeneous of degree 0, if we assign to x_i the weight r_i. Let $X \subset \mathbb{A}^n$ be the critical scheme of f, i.e., the affine scheme with affine coordinate ring $\mathbb{C}[x_1, \ldots, x_n]/(\partial_1 f, \ldots, \partial_n f)$. Let us further assume that $f \in (x_1, \ldots, x_n)^3$. This is not a serious restriction, if we are interested in the critical locus of f. It ensures that at the origin $P \in \mathbb{A}^n$, we have $T_X|_P = T_{\mathbb{A}^n}|_P$, and hence that $\dim T_X|_P = n$.

In this case the generalized Milnor number (3.3) is

$$\mu_X(P) = (-1)^n\,.$$

This is easy to see: consider the circle group $S^1 \subset \mathbb{C}^*$ and its action on $\mathbb{A}^n = \mathbb{C}^n$ given by $\theta \cdot (x_1, \ldots, x_n) = (\theta^{r_1} x_1, \ldots, \theta^{r_n} x_n)$. The Milnor fibre (3.2) is invariant under this S^1-action. Also, this S^1-action on the Milnor fibre is fixed point free. Therefore, the Euler characteristic of the Milnor fibre vanishes.

This calculation has non-trivial applications, for example, it implies that for the Hilbert scheme of n points on a smooth scheme of dimension 3 (proper or not), the weighted Euler characteristic is, up to sign, equal to the topological Euler characteristic:

$$\chi^{\mathrm{top}}(\mathrm{Hilb}^n Y, \nu_{\mathrm{Hilb}^n Y}) = (-1)^n \chi^{\mathrm{top}}(\mathrm{Hilb}^n Y)\,. \tag{3.4}$$

3.2. Symmetric obstruction theories.

3.2.1. Lagrangian intersection case. In the Lagrangian intersection case, the tangent complex is endowed with extra structure, namely an *odd pairing*. Above, we constructed the quasi-isomorphism $\Theta = (\theta, -\theta^\vee) : \mathbb{T}_{\mathfrak{X}} \to \mathbb{T}_{\mathfrak{X}}^\vee[-1]$. It has the property that $\Theta^\vee[-1] = -\Theta$. This means that it can be equivalently thought of as an alternating pairing of degree -1

$$\mathbb{T}_{\mathfrak{X}} \otimes \mathbb{T}_{\mathfrak{X}} \longrightarrow \mathscr{O}_X[-1]\,,$$

or a global section of $(\Lambda^2 \mathbb{T}_{\mathfrak{X}}^\vee)[-1]$. (This latter class is the classical shadow a (-1)-shifted symplectic structure on the derived scheme $\mathfrak{X}$ underlying this Lagrangian intersection. The closedness is not seen at the classical level.) The second exterior power of Θ is an isomorphism

$$\Lambda^2\Theta : \Lambda^2 \mathbb{T}_{\mathfrak{X}} \longrightarrow \Lambda^2(\mathbb{T}_{\mathfrak{X}}^\vee[-1]) = \mathrm{Sym}^2\, \mathbb{T}_{\mathfrak{X}}^\vee[-2]\,,$$

via which we can turn the pairing $\Lambda^2\mathbb{T}_{\mathfrak{X}} \to \mathscr{O}_X[-1]$ defined by Θ into a pairing $\mathrm{Sym}^2\,\mathbb{T}_{\mathfrak{X}}^\vee \to \mathscr{O}_X[1]$. This symmetric pairing is called the *symmetric obstruction theory* defined by the Lagrangian intersection $X = L \cap M$. (In the literature, it is usually $\mathbb{T}_{\mathfrak{X}}^\vee$ which is called the obstruction theory, not $\mathbb{T}_{\mathfrak{X}}$.)

3.2.2. General case. This leads us to the following definition. A perfect obstruction theory $\mathbb{T}_X \to F$ is *symmetric*, if F is endowed with a non-degenerate alternating pairing of degree -1. (Equivalently, $F^\vee$ is endowed with a non-degenerate symmetric pairing of degree $+1$, and this is where the name comes from.) This means that we are given an isomorphism $\Theta : F \to F^\vee[-1]$, such that $\Theta^\vee[-1] = -\Theta$.

In the toy model case $X = \mathrm{Crit}\, f$, the perfect obstruction theory is given by the *Hessian* of f, this is a self dual map $H(f) : T_M|_X \to \Omega_M|X$. In fact, the obstruction theory is

$$F = [T_M|_X \xrightarrow{-H(f)} \Omega_M|_X] \ .$$

Its shifted dual is

$$F^\vee[-1] = [T_M|_X \xrightarrow{H(f)} \Omega_M|_X] \ ,$$

and so $\Theta = (\mathrm{id}, -\mathrm{id}) : F \to F^\vee[-1]$ defines the required pairing.

In the general case, just like in the Lagrangian intersection case, the obstruction sheaf is always canonically isomorphic to the sheaf of differentials: $h^1(F) = \Omega_X$.

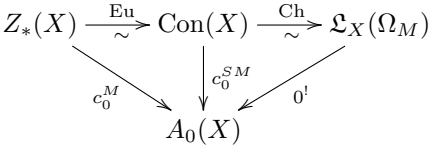
We will now explain what the presence of this additional structure says about the virtual fundamental class.

3.2.3. Almost closed 1-forms. In the non-symplectic case, there is no difference between the toy model for an intersection, and the toy model for a perfect obstruction theory. Every intersection of smooth varieties (étale or analytically) locally looks like the zero set of a section of a vector bundle on a smooth variety, and every perfect obstruction theory is locally isomorphic to the perfect obstruction theory given by a such a toy model.

In the present case this is no longer true. Every Lagrangian intersection looks locally like the critical scheme of a holomorphic function (by the holomorphic Darboux theorem), but this is not true for symmetric obstruction theories.

The local model for a scheme with symmetric obstruction theory is a non-singular variety with an *almost closed* 1-form on it. A 1-form on a non-singular scheme M is *almost closed*, if $d\omega$ vanishes in $\Omega^2_M|_X$, where X is the zero locus of ω. In other words, the equations $\partial_i f_j = \partial_j f_i$, saying that the 1-form $\omega = \sum f_i dx_i$ is closed, have to be satisfied only modulo the ideal (f_i). Almost closed 1-forms give rise to symmetric obstruction theories on their vanishing loci, and every scheme with symmetric obstruction theory locally comes from an almost closed 1-form. There are examples of almost closed 1-forms, whose associated symmetric obstruction theory does not admit a description as the symmetric obstruction theory of a critical set [23].

3.2.4. Microlocal geometry. Suppose X is a scheme embedded as a closed subscheme in the smooth scheme M. Microlocal geometry provides us with a commutative diagram



Here $Z_*(X)$ is the group of cycles on X, it is the free abelian group generated by the irreducible closed subvarieties (prime cycles) of X. The group $\mathrm{Con}(X)$ is the abelian group of all $\mathbb{Z}$-valued constructible functions on X. On the right, $\mathfrak{L}_X(\Omega_M)$ is the group of conic Lagrangian cycles on the cotangent bundle of M, which lie over X. The homomorphism Eu is MacPherson's local Euler obstruction, and Ch is the characteristic cycle map. The downward maps are the degree 0 Chern-Mather class, the degree 0 Schwartz-MacPherson Chern class, and the intersection with the zero section (Gysin map), respectively. The left hand triangle does not depend on the embedding into M.

The easiest of the horizontal maps to describe explicitly is the composition $L = \mathrm{Ch} \circ \mathrm{Eu}$. It maps a prime cycle V in X to the closure of the conormal bundle inside Ω_M of any non-singular open subset of V, multiplied by $(-1)^{\dim V}$.

The next easiest is the inverse of Ch. Let P be a point in X. Choose a Euclidean distance function from P in the complex manifold M, denote its square by ρ, and let Δ be the graph of $d\rho$ inside Ω_M. Then the value of the constructible function $\mathrm{Ch}^{-1}([C])$ at P is

$$\mathrm{Ch}^{-1}([C])(P) = I_{\{P\}}([C], [\Delta])\,,$$

the topological intersection number of the conic Lagrangian cycle $[C]$ with $[\Delta]$ at P. This is well-defined, because P is an isolated point of the intersection $C \cap \Delta$.

Thus, by composition, we have also described $\mathrm{Eu} = \mathrm{Ch}^{-1} \circ L$.

3.2.5. The distinguished cycle and its Euler obstruction. Let $C_{X/M}$ be the normal cone of X in M, and $\{C_i\}$ its irreducible components with their multiplicities r_i. Let $\mathfrak{c}_i$ be the prime cycle in X obtained as the image of C_i under the projection $C_{X/M} \to X$. Form the cycle

$$\mathfrak{c}_X = \sum (-1)^{\dim \mathfrak{c}_i} r_i \mathfrak{c}_i$$

on X. It is called the *distinguished* cycle of X. It is a standard fact that $\mathfrak{c}_X$ is intrinsic to X: it does not depend on the chosen embedding $X \hookrightarrow M$.

Define[1] $\nu_X = \mathrm{Eu}(\mathfrak{c}_X)$. This is a constructible function on X, which is intrinsic to X. The value $\nu_X(P)$ of ν_X at the point $P \in X$ only depends on an analytic neighbourhood of P in X, it is an invariant of the singularity of X at the point P. When not mentioned otherwise, the *weighted Euler characteristic* of a scheme is the weighted Euler characteristic with respect to the weight function ν_X.

If X is smooth near P, then $\nu_X(P) = (-1)^{\dim X}$. If X is the scheme-theoretic critical locus of an analytic function f on M near P, then $\nu_X(P) = \mu_f(P)$.

(Even in the presence of a symmetric obstruction theory, it is not true that $\nu_X(P)$ is always a generalized Milnor number for a function f, such that $X = \mathrm{Crit}(f)$ near P, by the above mentioned [23]. For such cases $\mu_f(P)$ is not defined, so in [2], we prove a

[1]This function ν_X is sometimes referred to as the *Behrend function* in the literature on Donaldson-Thomas theory.

formula expressing $\nu_X(P)$ as a linking number, which is similar in spirit to the Milnor fibre definition, and always applies.)

3.2.6. The main theorem. [2] Now suppose that X is endowed with a symmetric obstruction theory. The embedding $X \hookrightarrow M$ provides us with an epimorphism $\Omega_M|_X \twoheadrightarrow \Omega_X$ from a vector bundle to the obstruction sheaf. The obstruction theory then gives us, as explained in 2.3, an obstruction cone $C \subset \Omega_M|_X \subset \Omega_M$, and the virtual fundamental class is $[X]^{\mathrm{vir}} = 0^![C]$.

The obstruction cone is locally (as a cone scheme over X) isomorphic to the normal cone $C_{X/M}$. The local isomorphisms are given by locally existing almost closed 1-forms cutting out X in M.

The key fact is that the conic cycle $[C]$ in Ω_M is Lagrangian. This is a local calculation, so we can reduce to the case where X is the zero locus of an almost closed 1-form ω on M, and the symmetric obstruction theory is given by ω, too. The graph of ω is not Lagrangian in Ω_M, as ω is not closed, but multiplying the graph by a scalar, end letting the scalar go to infinity, we obtain C, which does turn out to be Lagrangian, as a conic cycle.

Therefore $[C]$ is obtained via $\mathrm{Ch} \circ \mathrm{Eu}$ from unique cycle in X. Because C is locally isomorphic to $C_{X/M}$, this cycle in X can only be the distinguished cycle $\mathfrak{c}_X$. We conclude that $[C] = \mathrm{Ch}(\nu_X)$, and

$$[X]^{\mathrm{vir}} = 0^![C] = c_0^{SM}(\nu_X) = c_0^M(\mathfrak{c}_X)\,.$$

So, just as the obstruction sheaf, the virtual fundamental class is intrinsic to X.

Now MacPherson's theorem, which generalizes the Gauß-Bonnet theorem to singular schemes (and is also equivalent to Kashiwara's microlocal index theorem), says that, if X is proper

$$\chi^{\mathrm{top}}(X, \nu) = \deg(c_0^{SM}\nu)\,,$$

for any constructible function ν on X. Applying this to our distinguished function ν_X, we get, if X is proper

$$\#^{\mathrm{vir}}(X) = \deg[X]^{\mathrm{vir}} = \deg(c_0^{SM}\nu_X) = \chi^{\mathrm{top}}(X, \nu_X)\,.$$

We conclude that the virtual count is equal to the weighted Euler characteristic, and hence satisfies the two motivic properties.

3.3. Discussion. Let us start by discussing a prototypical source of symmetric obstruction theories, which is not *a priori* an algebraic Lagrangian intersection.

3.3.1. Gauge theory. Let us continue with our above discussion of gauge theory. The additional ingredient we need, to move it into derived symplectic geometry is a symmetric bilinear pairing $\kappa : L \otimes L \to \mathbb{C}[-\ell]$ of degree $-\ell$, on our differential graded Lie algebra L. (The most important case is $\ell = 3$.) This pairing needs to be *cyclic*, which means, besides being symmetric, that

1. $\kappa(dx, y) + (-1)^{\deg x}\kappa(x, dy) = 0$,
2. $\kappa([x, y], z) = \kappa(x, [y, z])$.

Finally, κ needs to be non-degenerate. For the purposes of this superficial exposition, let us agree that this means that κ sets up a perfect pairing between L^i and $L^{\ell-i}$, for all i. It has

as immediate consequence that L exists entirely within the interval $[0, \ell]$. (In practice, this condition is too strong, it is almost never satisfied. Instead, one has to deal with κ which only induce perfect pairings on cohomology. This is, in fact, the source of many subtleties of derived symplectic geometry.)

In our standard example, where $L = C^\infty(Y, \Omega_Y^\bullet \otimes M_{n\times n})$, we need to assume that Y is oriented, so that it has a fundamental class $[Y]$. The pairing κ is then given by

$$\kappa(x, y) = \int_{[Y]} \mathrm{tr}(x \circ y)\,.$$

(The circle denotes the associative product on L.) We will ignore issues of topology on the infinite-dimensional L, and instead pretend that L is finite-dimensional.

The isomorphism of complexes $\kappa : (L, d^x) \to (L, d^x)^\vee[-\ell]$ over $MC(L)$ is invariant under the gauge action, and so descends to the moduli space X, and provides us with an isomorphism $\mathbb{T}_{\mathfrak{X}}[-1] \xrightarrow{\sim} \mathbb{T}_{\mathfrak{X}}[-1]^\vee[-\ell]$, hence $\mathbb{T}_{\mathfrak{X}} \xrightarrow{\sim} \mathbb{T}^\vee_{\mathfrak{X}}[2-\ell]$. As before, we need to truncate (L, d^x) into the interval $[1, \ell-1]$, if G acts with positive-dimensional stabilizer. If $\ell = 3$, we obtain $\mathbb{T}_{\mathfrak{X}}$ in the interval $[0, 1]$, together with an isomorphism $\mathbb{T}_{\mathfrak{X}} \xrightarrow{\sim} \mathbb{T}^\vee_{\mathfrak{X}}[-1]$, i.e., a symmetric obstruction theory.

In our example, the case $\ell = 3$ is the case where Y is a 3-manifold. A rigorous treatment would identify the corresponding virtual counts as *Casson invariants*. (Although, because of the technical difficulties of the gauge theoretic approach, the Casson invariant is usually treated differently.)

Let us continue discussing the case $\ell = 3$. The curvature map $F : L^1 \to L^2$ is now a map $F : L^1 \to (L^1)^\vee$, and can therefore be thought of as an algebraic differential form on the linear space L^1. The cyclicity of κ implies that this form is closed. It is therefore exact, and an antiderivative is easily written down:

$$f(x) = \tfrac{1}{2}\kappa(x, dx) + \tfrac{1}{6}\kappa(x, [x, x])\,.$$

This cubic function $f : L^1 \to \mathbb{C}$ is known as the *Chern-Simons* function. It satisfies $df = F$, and so the Maurer-Cartan locus $MC(L) = Z(F) = \mathrm{Crit}(f)$ is the critical locus of the Chern-Simons function.

It is almost true that $f : L^1 \to \mathbb{C}$ is invariant under the gauge action and induces a function $\tilde{f} : L^1/G \to \mathbb{C}$ of which the moduli space $X = MC(L)/G$ is the critical set. In fact, $\tilde{f}$ has values in $\mathbb{C}/\mathbb{Z}$, but this is sufficient to make sense of its critical locus.

Unfortunately, it is not straightforward to follow these arguments through in Kapranov's finite-dimensional model for moduli of local systems, because the cup product (unlike the wedge product) is not commutative on the level of cochains.

3.3.2. Donaldson-Thomas theory. Considering the algebraic geometry analogue of this gauge theory example leads to a holomorphic analogue of the Casson invariant, which is known as the *Donaldson-Thomas* invariant. If we are only interested in virtual counts, we can avoid all gauge theoretic complications, and directly construct a symmetric obstruction theory on the relevant moduli space of stable coherent sheaves on a fixed Calabi-Yau threefold Y. In fact, the perfect obstruction theory is essentially the same we mentioned above in 2.4.1, namely $\big(\tau_{[1,2]} R\pi_* \mathscr{H}om(\mathscr{E}, \mathscr{E})\big)[1]$. The symmetric structure is given by Serre duality, which implies that deformations, given by $\mathrm{Ext}^1(E, E)$ are dual to obstructions, which are given by $\mathrm{Ext}^2(E, E)$. Because Y is Calabi-Yau, its canonical sheaf, which would usually feature in Serre duality, is trivial.

As the virtual fundamental class comes from a symmetric obstruction theory, the associated virtual counts, i.e., the Donaldson-Thomas invariants, are of a motivic nature. This sets them apart from many other counting invariants for Calabi-Yau threefolds, and is the reason why they have been so intensely studied in recent years.

The simplest non-trivial example of a Donaldson-Thomas moduli space is the Hilbert scheme $\mathrm{Hilb}^n Y$. Using the above mentioned result (3.4), one can prove that for every projective Calabi-Yau 3-fold Y, the virtual count is, up to sign, equal to the Euler characteristic:

$$\#^{\mathrm{vir}}(\mathrm{Hilb}^n Y) = (-1)^n \chi^{\mathrm{top}}(\mathrm{Hilb}^n Y)\,.$$

This formula was first conjectured in [20].

3.3.3. Motivic invariants. Let $K(\mathrm{Var})$ be the Grothendieck group of varieties. It is generated as an abelian group by symbols $[X]$, for all finite type $\mathbb{C}$-schemes X, subject to the *scissor relations*, namely that, whenever $Z \hookrightarrow X$ is a closed immersion of schemes, we have $[X] = [Z] + [X/Z]$. The group $K(\mathrm{Var})$ is called the group of *motivic weights*, or sometimes simply the group of *motives*.

Mapping a scheme or variety X to $[X]$ defines the universal Euler characteristic. Every map from the category of schemes to an abelian group satisfying the scissor relations factors uniquely through $K(\mathrm{Var})$. So, since the virtual counts in Donaldson-Thomas theory behave somewhat like an Euler characteristic, it is tempting to try to construct, for every moduli space of sheaves X (compact or not) on a Calabi-Yau threefold Y, an element $DT(X)$ in $K(\mathrm{Var})$, such that $\chi^{\mathrm{top}}(DT(X)) = \chi^{\mathrm{top}}(X, \nu_X)$.

The main challenge is to replace the integer weights, given by the constructible function ν_X, by motivic weights. For this purpose, it turns out the symmetric obstruction theory is not sufficient. One has to construct locally Chern-Simons type functions and find motivic versions of μ_f, rather than ν_X. It is then natural to use motivic vanishing cycles [9] as motivic weights. This programme has been carried out by Kontsevich-Soibelman [18], in an even more ambitious context where sheaves on a Calabi-Yau threefold are replaced by objects of more general Calabi-Yau-three categories.

The simplest case is the Hilbert scheme. In [3] we write down the generating series

$$Z_Y(t) = \sum_{n=0}^{\infty} [\mathrm{Hilb}^n Y]_{\mathrm{mot}}\, t^n\,,$$

where Y is a Calabi-Yau threefold (compact or not), and $[\mathrm{Hilb}^n Y]_{\mathrm{mot}}$ denotes the motivic virtual count associated to the Hilbert scheme of n points on Y. For the case $Y = \mathbb{A}^3$, we have

$$Z_{\mathbb{A}^3}(t) = \prod_{m=1}^{\infty} \prod_{k=0}^{m-1} (1 - \mathbb{L}^{k+2-\frac{m}{2}} t^m)^{-1} = \mathrm{Exp}\Big(\frac{-\mathbb{L}^{\frac{3}{2}} t}{(1+\mathbb{L}^{\frac{1}{2}} t)(1+\mathbb{L}^{-\frac{1}{2}} t)}\Big)\,.$$

And for general Y

$$Z_Y(t) = \mathrm{Exp}\Big([Y] \frac{-\mathbb{L}^{-\frac{3}{2}} t}{(1+\mathbb{L}^{\frac{1}{2}} t)(1+\mathbb{L}^{-\frac{1}{2}} t)}\Big)\,.$$

(Here Exp is the motivic exponential.)

3.3.4. Categorification. The Euler characteristic of an algebraic variety X over $\mathbb{C}$ is given by

$$\chi^{\mathrm{top}}(X) = \sum_i (-1)^i \dim H^i(X^{\mathrm{top}}, \mathbb{C}) ,$$

the alternating sum of the dimensions of the cohomology groups of the topological space X^{top} (analytic topology) associated to X. We say that the cohomology spaces *categorify* the Euler characteristic. The terminology is justified by the fact that the cohomology lies in the *category* of vector spaces, rather the *set* of numbers. This is an important step, because it allows the full machinery of homological algebra to be applied to the calculation of Euler characteristics, and it gives much deeper information then the Euler characteristic alone.

The question arises, if one can write weighted Euler characteristics in a similar fashion. In the toy model case where $X = \mathrm{Crit}\, f$, for a function $f : M \to \mathbb{C}$ on a smooth scheme X, we have the perverse sheaf of vanishing cycles Φ_f on X, and

$$\chi^{\mathrm{top}}(X, \nu_X) = \chi^{\mathrm{top}}(X, \mu_f) = \sum_i (-1)^i \dim H^i(X^{\mathrm{top}}, \Phi_f) .$$

So we say that the perverse sheaf of vanishing cycles categorifies the virtual number of critical points of f.

Recently [6, 15], global versions of Φ_f on moduli spaces of sheaves have been constructed, thus categorifying Donaldson-Thomas theory in this sense. Gluing the locally defined sheaves of vanishing cycles requires an *orientation* on the moduli space.

3.3.5. Orientation. Even for the case of Lagrangian intersections, the question of orientation is non-trivial. For the derived scheme $\mathfrak{X}$, defined by the Lagrangian intersection $L \cap M$ inside S we have

$$\det \mathbb{T}_{\mathfrak{X}} = \det T_L|_X \otimes \det T_M|_X \otimes (\det T_S|_X)^{-1} = \det T_L|_X \otimes \det T_M|_X ,$$

because $\det \Omega_S = \Lambda^{2n}\Omega_S$ is trivial (the n-th power of the symplectic form trivializes it). So for the canonical line bundle, we have

$$K_{\mathfrak{X}} = K_L|_X \otimes K_M|_X .$$

A line bundle Υ on X, such that $\Upsilon^{\otimes 2} = K_{\mathfrak{X}}$ is called an *orientation* of the Lagrangian intersection. For example, if $K_L|_X = K_M|_X$, then the intersection is canonically oriented.

The systematic study of motivic invariants and categorification requires a thorough understanding of orientations.

3.4. Derived symplectic geometry. We will say a few words about the classical shadows of a derived symplectic scheme. Then we will discuss the toy model in more depth.

3.4.1. Tangent complex. On the level of tangent complexes, a symplectic structure on a derived scheme $\mathfrak{X}$ will induce an isomorphism

$$\theta : \mathbb{T}_{\mathfrak{X}} \longrightarrow \mathbb{T}^{\vee}_{\mathfrak{X}}[-n] \tag{3.5}$$

of some degree, which we have denoted by $-n$. As $\mathbb{T}_{\mathfrak{X}}$ is in degrees ≥ 0 and $\mathbb{T}^{\vee}_{\mathfrak{X}}$ in degrees ≤ 0, it follows that n is equal to the amplitude of $\mathfrak{X}$.

Moreover, θ is antisymmetric, i.e., satisfies $\theta = -\theta^\vee[-n]$.

For example, if the degree of θ is 0, then the complex $\mathbb{T}_\mathfrak{X}$ in the interval $[0, \ell]$ is quasi-isomorphic to the complex $\mathbb{T}_\mathfrak{X}^\vee$ in the interval $[-\ell, 0]$, which means that $\mathbb{T}_\mathfrak{X}$ is in fact concentrated in degree 0, and is simply a vector bundle. So if the symplectic structure θ is of degree $n = 0$, the derived scheme $\mathfrak{X}$ is a classical scheme X endowed with a classical symplectic structure.

If the degree of θ is -1, then the complex $\mathbb{T}_\mathfrak{X}$ in the interval $[0, \ell]$ is quasi-isomorphic to the complex $\mathbb{T}_\mathfrak{X}^\vee[-1]$ in the interval $[1-\ell, 1]$, which forces $\ell \leq 1$, so that $\mathfrak{X}$ is quasi-smooth, and θ is nothing but a symmetric obstruction theory on the underlying classical scheme X, as discussed above.

3.4.2. Higher structure sheaves. On the level of higher structure sheaves, a symplectic structure on $\mathfrak{X}$ will induce an analogue of the Poisson bracket. This will be a bracket $\{\,,\} : \pi_k(\mathscr{O}_\mathfrak{X}) \otimes_\mathbb{C} \pi_\ell(\mathscr{O}_\mathfrak{X}) \to \pi_{k+\ell-n}(\mathscr{O}_\mathfrak{X})$, which is a derivation with respect to the commutative product in each argument, and satisfies the graded Jacobi identity.

In the case of Lagrangian intersections, this bracket was constructed in [5]. It was then discovered [1], that this bracket comes naturally out of considering *deformation quantization up to first order*.

3.4.3. Quantization. To explain the approach to categorification via quantization, we cannot get by with our classical shadows any longer. So let us finish by discussing a toy model for a derived symplectic scheme. We restrict to the *odd* case.

We take the point of view that a derived scheme is a graded manifold with a homological vector field on it (in other words, a differential graded manifold). Thus, let $V = V^0 \oplus \ldots \oplus V^n$ be a finite-dimensional graded vector space which we think of as a linear graded manifold (so that the graded tangent space at every point is equal to V). The algebra of functions on V is $\operatorname{Sym} V^\vee$, the graded symmetric algebra generated by the dual $V^\vee$ of V. On $\operatorname{Sym} V^\vee$ we have a derivation $Q : \operatorname{Sym} V^\vee \to \operatorname{Sym} V^\vee$, of degree $+1$, which satisfies $[Q, Q] = 0$, or equivalently $Q \circ Q = 0$. The derived scheme is $\mathfrak{X} = (V, Q)$.

For example, if we consider the gauge theory context, and discard L^0 (and the gauge group), as well as L^ℓ (where ℓ is the top degree), we may take $V = L^{[1,\ell-1]}[1]$. The derivation Q corresponds to the vector field given by the algebraic map $x \mapsto dx + \frac{1}{2}[x, x]$, from V to V. (In general, Q may have higher order terms: this makes L an L_∞-algebra, instead of a differential graded Lie algebra.)

The classical shadows of $\mathfrak{X}$ are as following: the underlying classical scheme is $\operatorname{Spec} h^0(\operatorname{Sym} V^\vee, Q)$. The amplitude is n. The virtual dimension is $\sum_i (-1)^i \dim V^i$. The tangent complex is the trivial graded vector bundle with fibre V, endowed with the differential which is given by the derivative of Q, thought of as an algebraic map $Q : V \to V$. The higher structure sheaves are $\pi_i(\mathscr{O}_\mathfrak{X}) = h^{-i}(\operatorname{Sym} V^\vee, Q)$.

Given a non-degenerate alternating pairing $\kappa \in \Lambda^2 V^\vee\,[-n]$ of degree $-n$, we have an induced isomorphism $\kappa : V \xrightarrow{\sim} V^\vee\,[-n]$, such that $\kappa^\vee[-n] = -\kappa$. Let us assume that it commutes with Q. Then we have a symplectic structure on (V, Q). (The 2-form of degree $-n$ given by κ is closed, because it is constant.) In the gauge theory context, compatibility with Q is equivalent to cyclicity as defined in 3.3.1, above.

Let us now assume that n is odd. The second symmetric power of κ induces an isomor-

phism

$$(\mathrm{Sym}^2\,\kappa)[n] : \mathrm{Sym}^2\,V\,[n] \xrightarrow{\sim} \mathrm{Sym}^2(V^\vee[-n])\,[n] = \Lambda^2 V^\vee\,[-n]\ .$$

Taking the preimage of κ itself under this isomorphism, we obtain $\Delta \in \mathrm{Sym}^2\,V\,[n]$. We may interpret this as a map $\mathrm{Sym}^2\,V^\vee \to \mathbb{C}\,[n]$, which extends uniquely to a second order differential operator $\Delta : \mathrm{Sym}\,V^\vee \to \mathrm{Sym}\,V^\vee\,[n]$ of degree n, vanishing on $V^\vee$, called the *Batalin-Vilkovisky* operator.

We can also consider $\Delta : \mathrm{Sym}^2\,V^\vee \to \mathbb{C}[n]$ as a symmetric pairing, which extends uniquely to a symmetric biderivation $\{\,,\,\} : \mathrm{Sym}\,V^\vee \otimes \mathrm{Sym}\,V^\vee \to \mathbb{C}[n]$. This is the *Poisson bracket* of the symplectic structure κ. (It also exists in the case that n is even, although it is anti-symmetric in this case.) The BV operator Δ generates the Poisson bracket in the sense that

$$\Delta(xy) - (-1)^x x\,\Delta(y) - \Delta(x)\,y = \{x, y\}\,.$$

Let us now restrict to the case $n = 1$, so that $V = V^0 \oplus V^1$, and κ identifies V^1 with $(V^0)^\vee$. Then $\mathrm{Sym}\,V^\vee$ is identified with the algebra of polyvector fields on V^0, the Poisson bracket with the Schouten bracket, and Δ with the divergence operator associated to the linear structure on V. (Via the identification of polyvector fields with differentials given by a volume form compatible with the linear structure, Δ corresponds to the de Rham differential.)

As in the above gauge theory example, there exists a Chern-Simons map $f \in \mathrm{Sym}\,V^\vee$ of degree 0, such that $Q = \{f, \cdot\}$. The only difference is that f may have higher order terms. We may think of f as a polynomial function $f : V^0 \to \mathbb{C}$.

As Δ satisfies $\Delta^2 = 0$, it defines a differential on $\mathrm{Sym}\,V^\vee$, which commutes with Q. To obtain a double complex from the two commuting differential Q and Δ, we we introduce a formal variable $\hbar$, and pass to $\mathrm{Sym}\,V^\vee(\!(\hbar)\!)$, with differential $\Delta + \hbar Q$. Then it follows from a theorem recently proved by Sabbah [25], that for the generalized Milnor number of f at the origin $0 \in V^0$, we have

$$\mu_f(0) = \sum (-1)^k \dim_{\mathbb{C}(\!(\hbar)\!)} H^k\big(\mathrm{Sym}\,V^\vee(\!(\hbar)\!), Q + \hbar\Delta\big)$$

Thus the $\mathbb{C}(\!(\hbar)\!)$-vector spaces $H^k\big(\mathrm{Sym}\,V^\vee(\!(\hbar)\!), Q + \hbar\Delta\big)$ categorify the Donaldson-Thomas type virtual count.

Currently there is ongoing research to generalize this toy model to actual moduli spaces. As mentioned, the main difficulty is that many properties of κ, such as the non-degeneracy, or the compatibility with Q, are only satisfied up to homotopy (unless one is willing to work in infinite dimensions, which has its own problems). See [24].

3.4.4. Lagrangian intersections. For the case of Lagrangian intersections, the categorification via quantization was achieved by Kashiwara-Schapira [14], see also [8].

Quasimap theory

Ionuţ Ciocan-Fontanine and Bumsig Kim

Abstract. We provide a short introduction to the theory of ε-stable quasimaps and its applications via wall-crossing to Gromov-Witten theory of GIT targets.

Mathematics Subject Classification (2010). Primary 14D20, 14D23, 14N35.

Keywords. GIT quotients, Quasimaps, Gromov-Witten Theory, Mirror Symmetry, Cohomological Field Theory, Gauged Linear σ-models.

1. Introduction

This note is intended as a brief survey of the theory of quasimaps from curves to a certain (large) class of GIT quotients, and of its applications to Gromov-Witten theory, as developed in the papers [6, 10–14]. The theory may be viewed as an algebro-geometric realization of Witten's Gauged Linear σ-model (GLSM) [52] in the geometric phases. The study of GLSM and of its relation to Mirror Symmetry has been a very active area in String Theory, see [1, 22, 31, 32, 34, 42] for a (very incomplete) sampling of developments.

When such a geometric phase (a target with a GIT presentation) is fixed, there is a family of quasimap theories indexed by a stability parameter $\varepsilon \in \mathbb{Q}_{>0}$. When $\varepsilon > 1$ one recovers the "nonlinear σ-model", i.e., the Gromov-Witten theory of the target. There is a wall-and-chamber structure on $\mathbb{Q}_{>0}$, with walls at $1, \frac{1}{2}, \frac{1}{3}, \ldots, \frac{1}{d}, \ldots$, such that the theory stays unchanged in the chamber $(\frac{1}{d+1}, \frac{1}{d}]$. Wall-crossing formulas relating the invariants in different chambers of nonsingular targets are conjectured (and are established in many cases) in [11] for genus zero, and in [12] for all genera; the genus zero case is extend to orbifolds in [6]. These results are described in §4-5 of the paper. As explained there, the wall-crossing formulas may be viewed as generalizations in many directions of Givental's Mirror Theorems [26] for (complete intersections in) toric manifolds with semi-positive anti-canonical class. In addition, the *mirror map* is given a geometric interpretation as the generating series of primary quasimap invariants with a fundamental class insertion.

There is also an extension of the theory in a different direction, allowing the domain curves of quasimaps to carry weighted markings. When (some) markings are given infinitesimally small weights, this produces for many targets a *closed form* expression of a "big I-function" defined on the entire parameter space $H^*(X, \mathbb{Q})$ associated to the GIT target X. By a result in [13] the big J-function of the Gromov-Witten theory of X is obtained from this new big I-function via the "Birkhoff factorization" procedure of [18]. As a result, one obtains an explicit determination of all the genus zero Gromov-Witten invariants of X.

Proceedings of the International Congress of Mathematicians, Seoul, 2014

2. Maps from curves to quotient targets

2.1. A class of GIT quotients. Let $W = \mathrm{Spec}A$ be an affine algebraic variety over $\mathbb{C}$ and let $\mathbf{G}$ be a reductive algebraic group over $\mathbb{C}$, acting upon W from the right. Choose a character of $\mathbf{G}$, $\theta \in \mathrm{Hom}(\mathbf{G}, \mathbb{C}^*)$. Denote by $\mathbb{C}_\theta$ the associated 1-dimensional $\mathbf{G}$-representation space. This determines a $\mathbf{G}$-equivariant line bundle $L_\theta := W \times \mathbb{C}_\theta$ on W.

There are four quotients as follows.

(i) The *affine quotient* $W/\!\!/_{\mathrm{aff}}\mathbf{G} := \mathrm{Spec}(A^{\mathbf{G}})$, which is of finite type over $\mathbb{C}$ by Hilbert's Theorem.

(ii) The *stack quotient* $[W/\mathbf{G}]$ (see [20, 40]). One departure when working with algebraic stacks versus working with schemes is that algebraic stacks are groupoid-valued functors from the category of schemes, while schemes are set-valued functors. By the Yoneda lemma, the category $(\mathrm{Sch}/\mathbb{C})$ of $\mathbb{C}$-schemes is embedded into the category of functors of points. For schemes $X, Y \in (\mathrm{Sch}/\mathbb{C})$, the set of Y-points of X is $\mathrm{Hom}_{(\mathrm{Sch}/\mathbb{C})}(Y, X)$, i.e., the set of all morphisms from Y to X over $\mathbb{C}$. The stack $[W/\mathbf{G}]$ can be considered as a functor from $(\mathrm{Sch}/\mathbb{C})$ to the category of groupoids, defined as follows. A morphism from Y to $[W/\mathbf{G}]$ is by definition a triple $(Y, P, \tilde{f})$, where P is a principal $\mathbf{G}$-bundle on Y (which is trivializable in the étale topology of Y) and $\tilde{f} : P \to W$ is a $\mathbf{G}$-equivariant morphism. Equivalently, it is a triple (Y, P, f), with f a section of the induced fiber bundle $P \times_{\mathbf{G}} W \to Y$ with fiber W. An isomorphism from (Y, P, f) to (Y, P', f') is a $\mathbf{G}$-bundle homomorphism $\varphi : P \to P'$ such that $f' \circ \varphi = f$. Suppose that $Y = \mathrm{Spec}\mathbb{C}$; then the $\mathbb{C}$-points of $[W/\mathbf{G}]$ form a groupoid, the collection of orbits with the isomorphisms described above. A $\mathbb{C}$-point has non-trivial automorphisms if and only if the corresponding $\mathbf{G}$-orbit in Y has non-trivial stabilizer group.

Consider the trivial $\mathbf{G}$-bundle $W \times \mathbf{G}$ on W. It comes with the $\mathbf{G}$-equivariant map $W \times \mathbf{G} \to W$ given by the action. This gives a canonical morphism from W to $[W/\mathbf{G}]$, fitting in the cartesian diagram

$$\begin{array}{ccc} P & \xrightarrow{f} & W \\ \downarrow & & \downarrow \\ Y & \longrightarrow & [W/\mathbf{G}]. \end{array}$$

The geometry of $[W/\mathbf{G}]$ is encoded by the "atlas" $W \to [W/\mathbf{G}]$.

(iii) The *GIT quotient* $W/\!\!/\mathbf{G} := W/\!\!/_\theta\mathbf{G} := \mathrm{Proj}(\oplus_{n\geq 0}\Gamma(W, L_\theta^{\otimes n})^{\mathbf{G}})$. This is a quasi-projective scheme, equipped with a canonical *projective* morphism to $W/\!\!/_{\mathrm{aff}}\mathbf{G}$. It is called the *Proj quotient in direction* θ in [43, §6.13].

(iv) The *GIT stack quotient* $[W^{ss}/\mathbf{G}]$. This is an open substack of $[W/\mathbf{G}]$ since $W^{ss} := \{p \in W : s(p) \neq 0 \text{ for some } n > 0, s \in \Gamma(W, L_\theta^n)^{\mathbf{G}}\}$ is a $\mathbf{G}$-invariant open subset of W.

Assumption 2.1. $\mathbf{G}$ *acts on* W^{ss} *with at most finite stabilizers.*

Assumption 2.1 is equivalent to requiring that there are no strictly semi-stable points. Under this assumption, the GIT stack quotient $[W^{ss}/\mathbf{G}]$ is a Deligne-Mumford (DM) stack.

It follows that there is a natural commuting diagram of morphisms:

$$\begin{array}{ccc} [W^{ss}/\mathbf{G}] & \longrightarrow & [W/\mathbf{G}] \\ {\scriptstyle \text{proper}}\downarrow & & \downarrow \\ W/\!\!/\mathbf{G} & \xrightarrow[\text{projective}]{} & W/_{\text{aff}}\mathbf{G}. \end{array}$$

The left vertical morphism is proper, see e.g. [35].

2.2. Examples.

1. *Projective Spaces.* Let $\mathbf{G} = \mathbb{C}^*$ diagonally act on $V = \mathbb{C}^{n+1}$ and let $\theta = \mathrm{id}_{\mathbb{C}^*}$. Then
$$V/\!\!/\mathbf{G} = \mathbb{P}^n \subset [V/\mathbf{G}] = [\mathbb{C}^{n+1}/\mathbb{C}^*]$$
and L_θ restricted to $V/\!\!/\mathbf{G}$ is $\mathcal{O}(1)$.

   Note that the set of $\mathbb{C}$-points of $[V/G]$ contains one more element $[0, ..., 0]$ other than those in the projective space $\mathbb{P}^n$. This point has nontrivial automorphisms and is called a stacky point. Even when $n = 0$, the stack $[\mathbb{C}/\mathbb{C}^*]$ is interesting. This stack parameterizes pairs (L, s) with L a line bundle and s a section of L.
2. *Grassmannians.* Let $V = \mathrm{Hom}(\mathbb{C}^r, \mathbb{C}^n)$, $\mathbf{G} = GL(r, \mathbb{C})$ and $\theta = \det$. Then $V/\!\!/\mathbf{G} = Gr(r, n)$, the Grassmannian of r-planes in $\mathbb{C}^n$. A similar description works for a type A flag variety, see e.g. [5].
3. *Toric DM-stacks.* $V = \mathbb{C}^N$ and $\mathbf{G} = (\mathbb{C}^*)^r$; there are many choices of θ and the GIT quotient $[V^{ss}/\mathbf{G}]$ is a toric DM-stack.
4. *Complete Intersections.* Any projective variety $X \subset \mathbb{P}^{n-1}$ is a GIT quotient: $X = W/\!\!/\mathbb{C}^*$, with $W = C(X) \subset \mathbb{C}^n$, the affine cone over X, but only *complete intersections* lead to good theories (see Remark 3.3 below).
5. *Zero locus of regular sections of homogenous vector bundles.* Let $V, \mathbf{G}, \theta$ define a GIT quotient as in §2.1 and let E be a $\mathbf{G}$-representation with induced vector bundle $\mathcal{E} = V^{ss} \times_{\mathbf{G}} E$ on $V/\!\!/\mathbf{G}$. Let $s \in \Gamma(V, V \times E)^{\mathbf{G}}$ be regular with induced $\bar{s} \in \Gamma(V/\!\!/\mathbf{G}, \mathcal{E})$. If we set $W := Z(s) \subset V$ (note that W is lci), then $W/\!\!/\mathbf{G} = Z(\bar{s}) \subset V/\!\!/\mathbf{G}$. For example, complete intersections in toric varieties are obtained in this way, but there are many more non-abelian examples with indecomposable bundles $\mathcal{E}$ which are *not* complete intersection.

   According to Coates, Corti, Galkin, and Kasprzyk [17] who rework the Mori-Mukai classification of Fano 3-folds, every smooth Fano 3-fold can be realized as an example of this type. We remark that the Rødland's Pfaffian Calabi-Yau 3-fold and the determinantal Gulliksen-Negård Calabi-Yau 3-fold are also of this type (see [50, §2], [34, §5] respectively).
6. *Nakajima Quiver Varieties.* Nakajima quiver varieties ([47]) give a large class of typically quasi-projective only GIT quotients of the kind we are interested in, see [14, Example 6.3.2]. Particularly interesting such examples are certain Hilbert schemes of

points on non-compact surfaces. For example, let

$$V = \mathrm{Hom}(\mathbb{C}^n, \mathbb{C}^n)^{\oplus 2} \oplus \mathrm{Hom}(\mathbb{C}, \mathbb{C}^n) \oplus \mathrm{Hom}(\mathbb{C}^n, \mathbb{C}),$$
$$W := \{(A, B, i, j) \in V \mid [A, B] + ij = 0\},$$
$$\mathbf{G} = GL(n, \mathbb{C}), \text{ and } \theta = \det .$$

Then $W/\!\!/\mathbf{G} = \mathrm{Hilb}_n(\mathbb{C}^2)$ and $W/_{\mathrm{aff}}\mathbf{G} = \mathrm{Sym}^n(\mathbb{C}^2)$. This is the well-known ADHM presentation of the Hilbert scheme of points in the plane.

More generally, let $\Gamma \subset SL(2, \mathbb{C})$ be a finite subgroup. Let

$$X := \Gamma\text{-Hilb}(\mathbb{C}^2) := \{Z \subset \mathbb{C}^2 : \mathcal{O}_Z \cong \mathbb{C} \cdot \Gamma\}.$$

It is the crepant resolution of $\mathbb{C}^2/\Gamma$. Using an appropriate Fourier-Mukai functor $\Phi : D(X) \to D^\Gamma(\mathbb{C}^2)$, the Hilbert scheme $\mathrm{Hilb}_n(X)$ can be realized as the Nakajima quiver variety associated to the framed affine Dynkin diagram with a certain King's stability condition, see [37], [48].

7. *Local Targets.* Let $V, \mathbf{G}, \theta$ define a projective GIT quotient and let E be a $\mathbf{G}$-representation space, with an induced vector bundle $\mathcal{E} = V^{ss} \times_{\mathbf{G}} E$ on $V/\!\!/\mathbf{G}$. Assume E is a sum of $\mathbb{C}_{k_i\theta}$ for some negative integers $k_1, \ldots, k_r$. If $W := V \times E$, then θ gives a linearization and $W/\!\!/\mathbf{G}$ is the total space of $\mathcal{E}$ over $V/\!\!/\mathbf{G}$. Again, it is only quasi-projective. These are usually called *local targets* in Gromov-Witten theory.
8. $SU_C(2, L)$. Let C be a nonsingular projective curve. Then the moduli space of rank 2 stable vector bundles on C with an odd determinant L, $\deg L \geq 4g(C) - 1$ is realized as the GIT quotient of an affine variety by a general linear group (see [43, Theorem 10.1]).

2.3. Moduli of maps to the stack quotient. To keep the presentation simple, from now on we assume that *the* $\mathbf{G}$*-action on* W^{ss} *is free.* The general case is referred to [6].

Let $(C, p_1, \cdots, p_k)$ be a pointed, genus g prestable curve, i.e., C is a connected projective curve at worst with nodal singularities, p_i are ordered nonsingular points of C, and the arithmetic genus of C is g.

As explained, a map $C \xrightarrow{[u]} [W/\mathbf{G}]$ is described by the data

$$\big((C, \{p_i\}), P, u\big)$$

with P a principal $\mathbf{G}$-bundle on C and u a section of the induced W-bundle $P \times_{\mathbf{G}} W \xrightarrow{\rho} C$. Any such $[u] : C \to [W/\mathbf{G}]$ defines

$$\beta \in \mathrm{Pic}([W/\mathbf{G}])^\vee = \mathrm{Hom}_{\mathbb{Z}}(\mathrm{Pic}^{\mathbf{G}}(W), \mathbb{Z}), \quad \beta(L) = \deg_C \mathcal{L},$$

where $\mathcal{L} := u^*(P \times_{\mathbf{G}} L)$ (a line bundle on C). This β is called the *numerical class* of the triple $\big((C, \{p_i\}), P, u\big)$.

Consider the moduli stack $\mathfrak{M}_{g,k}([W/\mathbf{G}], \beta)$ parametrizing all $\big((C, \{p_i\}), P, u\big)$ as above. It is a non-separated Artin stack of infinite type. We describe here its obstruction theory. Consider the natural morphisms:

$$\begin{array}{ccc} \mathfrak{M}_{g,k}([W/\mathbf{G}], \beta) & \xrightarrow{\mu} & \mathfrak{B}un_{\mathbf{G}}^{g,k} \\ & \searrow^{\nu} & \downarrow \phi \\ & & \mathfrak{M}_{g,k} \end{array}$$

where

- $\mathfrak{M}_{g,k}$ is the moduli stack of prestable k-pointed curves of genus g;
- $\phi : \mathfrak{B}un_{\mathbf{G}}^{g,k} \longrightarrow \mathfrak{M}_{g,k}$ is the relative moduli stack of principal $\mathbf{G}$-bundles on the fibers of the universal curve $\mathfrak{C}_{g,k} \longrightarrow \mathfrak{M}_{g,k}$;
- μ and ν are the natural forgetful morphisms.

Both $\mathfrak{M}_{g,k}$ and $\mathfrak{B}un_{\mathbf{G}}^{g,k}$ are smooth Artin stacks and ϕ is a smooth morphism. It follows that the natural obstruction theory to consider is the μ-relative obstruction theory governing deformations of sections u. Over the open substack $M_{g,k}(W/\!\!/\mathbf{G}, \beta)$, this induces the usual *absolute* obstruction theory of maps to the GIT quotient. The stack $M_{g,k}(W/\!\!/\mathbf{G}, \beta)$ parameterizes the triples $\big((C, \{p_i\}), P, u\big)$ with C irreducible and the image of u contained in $P \times_{\mathbf{G}} W^{ss}$.

The above discussion suggests several natural questions to address:

1. The Kontsevich compactification $\overline{M}_{g,k}(W/\!\!/\mathbf{G}, \beta)$ is an open and closed substack of $\mathfrak{M}_{g,k}([W/\mathbf{G}], \beta)$. Using the linearization θ, can we impose *stability conditions* to single out other *Deligne-Mumford* open and closed substacks containing $M_{g,k}(W/\!\!/\mathbf{G}, \beta)$, and which are *proper* (over $W/\!\!/_{\mathrm{aff}}\mathbf{G}$)?
2. If in addition the restriction of obstruction theory is perfect, these substacks will have a virtual class, hence we get "numerical invariants" associated to the triple $(W, \mathbf{G}, \theta)$. When is the obstruction theory perfect?
3. Assuming the first two questions have been answered satisfactorily, how do the invariants change when varying the stability condition? Can one obtain explicit "wall-crossing" formulas?

In the rest of the paper we explain how quasimap theory provides some answers to the above questions. The first two questions are discussed in §3, while §4 and §5 deal with the wall-crossing phenomenon and its relation to Mirror Symmetry.

3. Quasimaps and ε-stability

3.1. Stable quasimaps.

Definition 3.1.

(i) $\big((C, \{p_i\}), P, u\big)$ is called a θ-**quasimap** (or simply quasimap) to $W/\!\!/\mathbf{G}$ if

$$\#\{u(C) \cap W^{us}\} < \infty,$$

where $W^{us} := W \setminus W^{ss}$. Hence, $C \overset{[u]}{\dashrightarrow} W/\!\!/\mathbf{G}$ is a rational map with finitely many base points.

(ii) A θ-quasimap is called **prestable**, if the base points are away from the nodes and markings of C.

For such a prestable quasimap and $x \in C$, define

$$\ell(x) := \mathrm{length}(\mathcal{O}_{x,C}/[u]^\sharp I_{[W^{us}/\mathbf{G}]}\mathcal{O}_{x,C}) \in \mathbb{Z}_{\geq 0}.$$

(iii) Fix $\varepsilon \in \mathbb{Q}_{>0}$. A prestable quasimap is called ε-**stable**, if

1. the line bundle $\omega_C(\sum p_i) \otimes \mathcal{L}_\theta^\varepsilon$ on C is ample, where $\mathcal{L}_\theta = u^*(P \times_{\mathbf{G}} L_\theta) = P \times_{\mathbf{G}} \mathbb{C}_\theta$.
2. $\varepsilon \ell(x) \leq 1$ for every nonsingular point $x \in C$.

There is also an "asymptotic" stability condition, obtained by requiring only the ampleness condition, but for *every* $\varepsilon \in \mathbb{Q}_{>0}$. We denote it by $\varepsilon = 0+$.

Denote by $\mathrm{Q}_{g,k}^\varepsilon(W/\!\!/\mathbf{G}, \beta)$ the moduli stack parameterizing ε-stable quasimaps of type (g, k, β).

Theorem 3.2 ([14]). *For every $\varepsilon \geq 0+$, $\mathrm{Q}_{g,k}^\varepsilon(W/\!\!/\mathbf{G}, \beta)$ is a DM stack with a natural proper morphism to the affine quotient. (In particular, if $W/\!\!/\mathbf{G}$ is projective, then $\mathrm{Q}_{g,k}^\varepsilon(W/\!\!/\mathbf{G}, \beta)$ is proper.)*

If W^{ss} is nonsingular and W has at worst lci singularities (necessarily in W^{us}), then the canonical obstruction theory on $\mathrm{Q}_{g,k}^\varepsilon(W/\!\!/\mathbf{G}, \beta)$ (relative to $\mathfrak{Bun}_{\mathbf{G}}^{g,k}$) is perfect.

From now on we assume the lci condition on W, so that $\mathrm{Q}_{g,k}^\varepsilon(W/\!\!/\mathbf{G}, \beta)$ carries a virtual fundamental class.

Remark 3.3.

1. The theory depends on the triple $(W, \mathbf{G}, \theta)$, not just on the geometric target $W/\!\!/\mathbf{G}$.
2. Assume $(g, k) \neq (0, 0)$.
   - If $\varepsilon > 1$ we get the Kontsevich stable maps to $W/\!\!/\mathbf{G}$; the obstruction theory is then perfect for *all* W (of course W^{ss} is assumed to be nonsingular). However, for $\varepsilon \leq 1$ the lci condition is necessary.
   - If $0 < \varepsilon \leq \frac{1}{\beta(L_\theta)}$, all lengths of base points are allowed and the domain curve has *no rational tails*. The asymptotic stability condition says that we are in this chamber for *all* β.
   - There are finitely many "chambers" $(\frac{1}{d+1}, \frac{1}{d}]$ such that the moduli spaces stay constant for $\varepsilon \in (\frac{1}{d+1}, \frac{1}{d}]$; intuitively, when crossing the wall we trade rational tails of degree d (with respect to $\mathcal{O}(\theta)$) with base points of length d.

3.2. Some history.

- For *fixed* curve with *no markings* and $\varepsilon = 0+$, many earlier compactifications are unified by this construction:
  - Drinfeld's quasimaps to $\mathbb{P}^n$, see [3]. However, note that the moduli of Drinfeld's quasimaps to flag varieties considered in [3] are defined using the Plücker embeddings and therefore fit into the situation described in Example 4 of §2.2. Since under the Plücker embedding the flag varieties are not complete intersections, the canonical obstruction theory of the moduli spaces is not perfect.
  - Gauged linear σ-models for toric targets (Witten [52], Morrison - Plesser [42], Givental [25, 26]).
  - Quot schemes for Grassmannians ((Strømme [49], Bertram [2]); their generalization to type A flag varieties due to Laumon [38, 39] (and rediscovered under the names hyperquot or flag-quot schemes in [9, 36]).

  - ADHM sheaves for $\mathrm{Hilb}_n(\mathbb{C}^2)$ (Diaconescu [21]).

- For the case when the complex structure of the domain curves varies and/or markings are allowed, the starting point was the work by Marian, Oprea, and Pandharipande [41] on moduli of stable quotients (in the terminology introduced above, this corresponds to target a Grassmannian and $\varepsilon = 0+$). Inspired by their paper, the authors developed the toric case and realized that the GIT point of view is the correct generalization of both ([10]). The ε-stability idea appeared first in work by Mustaţă and Mustaţă for target $\mathbb{P}^n$ ([46]). For Grassmannian targets, Toda introduced and studied ε-stable quotients in [51].
- There's a long (ongoing) related story in the symplectic category concerned with the study of (compactifications of) the moduli space of solutions to vortex equations, starting with work of Cieliebak - Gaio - Salamon and of Mundet i Riera, see [7, 8, 29, 30, 44, 45, 54]. An algebraic version of this theory is developed by Woodward in [53].
- Frenkel - Teleman - Tolland are developing a general formalism of a Gromov-Witten type theory of quotient stacks $[Y/G]$, see [24].

3.3. Quasimap Invariants. There are evaluation maps ev_i to $W/\!\!/\mathbf{G}$ (by the prestable condition) and tautological line bundles M_i on $\mathrm{Q}^{\varepsilon}_{g,k}(W/\!\!/\mathbf{G}, \beta)$ with fiber the cotangent line to C at the i^{th} marking:

$$ev_i : \mathrm{Q}^{\varepsilon}_{g,k}(W/\!\!/\mathbf{G}, \beta) \to W/\!\!/\mathbf{G}.$$

As usual, denote $\psi_i := c_1(M_i)$. Given

$$\delta_1, \dots \delta_k \in H^*(W/\!\!/\mathbf{G}, \mathbb{Q})$$

and integers $a_1, \dots, a_k \geq 0$, we define ε-quasimap invariants

$$\langle \delta_1 \psi_1^{a_1}, \dots, \delta_k \psi_k^{a_k} \rangle^{\varepsilon}_{g,k,\beta} := \int_{[\mathrm{Q}^{\varepsilon}_{g,k}(W/\!\!/\mathbf{G},\beta)]^{\mathrm{vir}}} \prod \psi_i^{a_i} \prod ev_i^*(\delta_i)$$

for all $\varepsilon \geq 0+$.

If $\varepsilon > 1$ (we write $\varepsilon = \infty$ for all such stability conditions), these are the descendant Gromov-Witten invariants of $W/\!\!/\mathbf{G}$.

The definition above requires $W/\!\!/\mathbf{G}$ projective; in the quasi-projective case there are equivariant versions available for all interesting targets, e.g., toric varieties, local targets, and Nakajima quiver varieties. Precisely, what is needed in order to have a good theory for non-compact targets $W/\!\!/\mathbf{G}$ is that there is an action on W by an algebraic torus $\mathbf{T} \cong (\mathbb{C}^*)^r$, commuting with the $\mathbf{G}$-action and such that the $\mathbf{T}$-fixed locus on the affine quotient $W/_{\mathrm{aff}}\mathbf{G}$ is proper (and therefore a finite set). To get a unified framework, we will make this assumption from now, allowing the case $r = 0$ of a trivial torus.

The invariants satisfy the "splitting axiom" and in fact they form the degree zero sector of a Cohomological Field Theory (CohFT) on $H^*(W/\!\!/\mathbf{G})$. However, for general targets $W/\!\!/\mathbf{G}$ and $\varepsilon \leq 1$, the *string equation* may fail so the CohFT will not have a flat identity. We refer the reader to [12, §2] for some more details on the quasimap CohFT.

4. Genus zero wall-crossing and mirror maps

It is natural to expect that different stability chambers carry the same information. This will be expressed via wall-crossing formulas for generating functions of the invariants. In this section we explain why the wall-crossing formulas for genus zero invariants are generalizations (in many directions) of Givental's Toric Mirror Theorems.

First we fix some notations:

- $H^*(W/\!\!/\mathbf{G})$ denotes the localized $\mathbf{T}$-equivariant cohomology with $\mathbb{Q}$-coefficients.
- $\langle\ ,\ \rangle$ is the intersection pairing on $H^*(W/\!\!/\mathbf{G})$.
- $\{\gamma_1 = \mathbb{1}, \dots, \gamma_s\}$ and $\{\gamma^1, \dots, \gamma^s\}$ are dual bases of $H^*(W/\!\!/\mathbf{G})$ with respect to $\langle\ ,\ \rangle$. Here $\mathbb{1}$ denotes the cohomology class dual to the fundamental cycle.
- $\mathrm{Eff}(W, \mathbf{G}, \theta)$ denotes the semigroup of numerical classes $\beta \in \mathrm{Pic}([W/\mathbf{G}])^\vee$ represented by θ-quasimaps with possibly disconnected domain. (Note that $\mathrm{Eff}(W, \mathbf{G}, \theta)$ is in general bigger than the cone of effective curves in $W/\!\!/\mathbf{G}$.)
- $\Lambda \cong \mathbb{Q}[[q]]$ denotes the Novikov ring of the theory, that is, the q-adic completion of the semigroup ring $\mathbb{C}[\mathrm{Eff}(W, \mathbf{G}, \theta)]$, $\beta \leftrightarrow q^\beta$.

4.1. *S*-operators. For $\delta_i \in H^*(W/\!\!/\mathbf{G})$ and integers $a_i \geq 0$, put

$$\langle\!\langle \delta_1\psi_1^{a_1}, \dots, \delta_k\psi_k^{a_k} \rangle\!\rangle^\varepsilon_{g,k} = \sum_{\beta \in \mathrm{Eff}(W,\mathbf{G},\theta)} \sum_{m \geq 0} \frac{q^\beta}{m!} \langle \delta_1\psi_1^{a_1}, \dots, \delta_k\psi_k^{a_k}, t, \dots, t) \rangle^\varepsilon_{g,k+m,\beta}.$$

It is a formal function of $t = \sum_{i=1}^s t_i\gamma_i \in H^*(W/\!\!/\mathbf{G})$.

Define, for $\gamma \in H^*(W/\!\!/\mathbf{G}, \Lambda)$ and a formal variable z,

$$S^\varepsilon_t(z)(\gamma) := \sum_{i=1}^s \gamma_i \langle\!\langle \frac{\gamma^i}{z - \psi}, \gamma \rangle\!\rangle^\varepsilon_{0,2}(t).$$

Here $\psi = \psi_1$ and the right-hand side is interpreted as usual by expanding $1/(z - \psi)$ as a geometric series in ψ/z. By convention, $\langle \frac{\gamma^i}{z-\psi}, \gamma \rangle^\varepsilon_{0,2,0} = \langle \gamma^i, \gamma \rangle$. We think of S^ε_t as a family (parametrized by t) of operators on $H^*(W/\!\!/\mathbf{G}, \Lambda)$. When the variable z is understood we drop it from the notation.

In Gromov-Witten theory, the operator S^∞_t is well-known. Its matrix is the (inverse of) a fundamental solution for the quantum differential equation. Furthermore, by the string equation for Gromov-Witten invariants, $S^\infty_t(\mathbb{1})$ coincides with Givental's (big) J-function of $W/\!\!/\mathbf{G}$ (we will come back to J-functions in the next subsection). The operator S^∞_t determines the entire genus zero sector of the Gromov-Witten theory of $W/\!\!/\mathbf{G}$ by a standard reconstruction procedure, essentially due to Dubrovin [23]. As shown in [12], the same reconstruction works for ε-quasimap invariants for all $\varepsilon \geq 0+$. The key point where a new idea is needed is the proof of the following result, which reconstructs invariants with *two* descendant insertions.

Theorem 4.1. *Let z, w be formal variables and define*

$$V^\varepsilon_t(z, w) := \sum_{i,j=1}^s \gamma_i \otimes \gamma_j \langle\!\langle \frac{\gamma^i}{z - \psi}, \frac{\gamma^j}{w - \psi} \rangle\!\rangle^\varepsilon_{0,2}(t),$$

where the convention

$$\sum_{i,j=1}^{s} \gamma_i \otimes \gamma_j \langle \frac{\gamma^i}{z-\psi}, \frac{\gamma^j}{w-\psi} \rangle_{0,2,0}^{\varepsilon} = \frac{[\Delta]}{z+w}$$

is made for the unstable term in the double bracket, with $[\Delta]$ *the diagonal class. Then*

$$V_t^{\varepsilon} = \frac{S_t^{\varepsilon}(z) \otimes S_t^{\varepsilon}(w)([\Delta])}{z+w}.$$

The usual - and very easy - argument that proves the above theorem in Gromov-Witten theory (see [27, item (4) on p.117]) requires the string equation and therefore does not extend to stability parameters $0+ \leq \varepsilon \leq 1$. The new proof from [12] is uniform for all values of ε.

4.2. Wall-crossing for S-operators. The most general wall-crossing formula in genus zero applies to the operators S_t^{ε}, see [11, Theorem 7.3.1]. We state here a slightly more special case.

Theorem 4.2. *Assume that there is an action by a torus* $\mathbf{T}$ *on* W*, commuting with the action of* $\mathbf{G}$*, and such that the induced* $\mathbf{T}$*-action on* $W/\!\!/\mathbf{G}$ *has isolated fixed points. For every* $\varepsilon \geq 0+$

$$S_t^{\varepsilon}(\mathbb{1}) = S^{\infty}_{\tau^{\varepsilon}(t)}(\mathbb{1}),$$

where the (invertible) transformation $\tau^{\varepsilon}(t)$ *is the series of primary* ε*-quasimap invariants*

$$\begin{aligned} \tau^{\varepsilon}(t) &= \sum_{i=1}^{s} \gamma_i \langle\!\langle \gamma^i, \mathbb{1} \rangle\!\rangle_{0,2}^{\varepsilon}(t) - \mathbb{1} \\ &= t + \sum_{i=1}^{s} \gamma_i \sum_{\beta \neq 0} \sum_{m \geq 0} \frac{q^{\beta}}{m!} \langle \gamma^i, \mathbb{1}, t, \dots, t \rangle_{0,2+m,\beta}^{\varepsilon}. \end{aligned}$$

Moreover, the same statement holds for E*-twisted theories, where* E *is any convex* $\mathbf{G}$*-representation.*

A $\mathbf{G}$-representation is called convex if the $\mathbf{G}$-equivariant bundle $W \times E$ on W is generated by $\mathbf{G}$-equivariant sections. By twisted theories in the last statement we mean that the twisting is by the top Chern class, in the sense of Coates - Givental [18], as extended for quasimap invariants in [14, §6.2]. The twisting vector bundle $\mathcal{E}$ on $W/\!\!/\mathbf{G}$ is descended from the representation E.

Note that no positivity assumptions are made in Theorem 4.2 on $(W, \mathbf{G}, \theta)$, or on $(W, E, \mathbf{G}, \theta)$ in the twisted case, and also that no assumption is made on the 1-dimensional orbits of the $\mathbf{T}$ action on $W/\!\!/\mathbf{G}$.

Theorem 4.2 applies to essentially every example listed earlier: toric manifolds, flag manifolds, some (but not all) Nakajima quiver varieties, and local targets over them all admit torus actions with the required property. Of course, the statement is conjectured to hold without the existence of a torus action with isolated fixed points, see [11, Conjecture 6.1.1]. In fact, the part of the Theorem involving twisted theories already covers such targets. This is because the E-twisted quasimap invariants give (almost all of) the genus zero quasimap invariants of the zero-locus of a regular section of the bundle $\mathcal{E} = W^{ss} \times_{\mathbf{G}} E$ and this zero-locus generally is not $\mathbf{T}$-invariant.

4.3. J^ε-functions and Birkhoff factorization. Recall first the big J-function of Gromov-Witten theory:

$$J^\infty(q,t,z) = \mathbb{1} + \frac{t}{z} + \sum_i \gamma_i \langle\!\langle \frac{\gamma^i}{z(z-\psi)} \rangle\!\rangle_{0,1}^\infty(t)$$
$$= \mathbb{1} + \frac{t}{z} + \sum_{\beta,k} \frac{q^\beta}{k!} (ev_1)_* \frac{[\overline{M}_{0,1+k}(W/\!\!/\mathbf{G},\beta)]^{\mathrm{vir}} \cap \prod_{j=2}^{1+k} ev_j^* t}{z(z-\psi)}$$

(the last sum is over $(\beta,k) \neq (0,0),(0,1)$). We want to extend it to all $\varepsilon \geq 0+$. The problem is that the spaces $\mathrm{Q}^\varepsilon_{0,1}(W/\!\!/\mathbf{G},\beta)$ do not exist for $\varepsilon \leq \frac{1}{\beta(L_\theta)}$. To resolve it we use the interpretation of the J-function as a sum of certain virtual localization residues for the natural $\mathbb{C}^*$-action on the Gromov-Witten *graph spaces* $\overline{M}_{0,k}(W/\!\!/\mathbf{G} \times \mathbb{P}^1, (\beta,1))$.

Specifically, for *all* $0+ \leq \varepsilon$, $k \geq 0$, we have the *quasimap graph space*

$$QG^\varepsilon_{0,k,\beta}(W/\!\!/\mathbf{G}) = \{\big((C,\{p_i\}),P,u,\varphi\big) \mid \varphi : C \to \mathbb{P}^1, \varphi_*[C] = [\mathbb{P}^1]\}.$$

This is the moduli space of (genus zero, k-pointed) ε-stable quasimaps whose domain curve contains a component C_0 which is a parametrized $\mathbb{P}^1$. The ampleness part of the ε-stability condition involves only $\overline{C \setminus C_0}$, while the length condition remains the same. These spaces are defined for all $k \geq 0$ and the analogue of Theorem 3.2 holds for them. For toric targets and $\varepsilon = 0+$ they were introduced in [10], the general case is in [14].

The $\mathbb{C}^*$-action on $\mathbb{P}^1$ induces an action on $QG^\varepsilon_{0,k,\beta}(W/\!\!/\mathbf{G})$. Let z denote the equivariant parameter.

Consider the fixed locus F_0 of quasimaps for which all markings and the entire degree β are over $0 \in \mathbb{P}^1 \cong C_0$. There are two cases:

- $k \geq 1$, or $\varepsilon > \frac{1}{\beta(L_\theta)}$. Then $F_0 \cong \mathrm{Q}^\varepsilon_{0,1+k}(W/\!\!/\mathbf{G},\beta)$ with its canonical virtual class and $\mathrm{e}_{\mathbb{C}^*}(N^{\mathrm{vir}}) := \mathrm{e}_{\mathbb{C}^*}(N^{\mathrm{vir}}_{F_0/QG^\varepsilon_{0,k,\beta}(W/\!\!/\mathbf{G})}) = z(z-\psi)$. We also have the evaluation map $ev = ev_1 : F_0 \to W/\!\!/\mathbf{G}$.
- $k = 0$ and $\varepsilon \leq \frac{1}{\beta(L_\theta)}$. Then $F_0 = \{(\mathbb{P}^1,P,u)\}$, with u having a base point of (maximal) length $\beta(L_\theta)$ at $0 \in \mathbb{P}^1$. We define $ev : F_0 \to W/\!\!/\mathbf{G}$ by taking evaluation at the generic point of $\mathbb{P}^1$. In this case $\mathrm{e}_{\mathbb{C}^*}(N^{\mathrm{vir}})$ changes with β.

Now for each $\varepsilon \geq 0+$ we define the big J^ε-function by

$$J^\varepsilon(q,t,z) := \sum_{\beta,k\geq 0} \frac{q^\beta}{k!} ev_* \mathrm{Res}_{F_0}\big([QG^\varepsilon_{0,k,\beta}(W/\!\!/\mathbf{G})]^{\mathrm{vir}} \cap \prod_{j=1}^k ev_j^* t\big)$$
$$= \mathbb{1} + \frac{t}{z} + \sum_{0<\beta(L_\theta)\leq 1/\varepsilon} q^\beta ev_* \frac{[F_0]}{\mathrm{e}_{\mathbb{C}^*}(N^{\mathrm{vir}})}$$
$$+ \sum_{\beta,k} \frac{q^\beta}{k!} (ev_1)_* \frac{[\mathrm{Q}^\varepsilon_{0,1+k}(W/\!\!/\mathbf{G},\beta)]^{\mathrm{vir}} \cap \prod_{j=2}^{1+k} ev_j^* t}{z(z-\psi)}.$$

The *small* J^ε-function is by definition the specialization at $t=0$,

$$J^\varepsilon_{sm}(q,z) := J^\varepsilon(q,0,z).$$

For the asymptotic stability $\varepsilon = 0+$ we have the *small I-function*

$$I_{sm}(q,z) = J^{0+}(q,0,z) = \mathbb{1} + \sum_{\beta\neq 0} q^\beta ev_* \frac{[F_0]}{\mathrm{e}_{\mathbb{C}^*}(N^{\mathrm{vir}})}.$$

When $W/\!\!/\mathbf{G}$ is a nonsingular toric variety, or a complete intersections in a toric variety, the small I-function is (essentially up to an exponential factor) the cohomology valued hypergeometric q-series introduced by Givental, see [26].

Closed expressions for I_{sm} are known also for many non-abelian GIT quotients: flag manifolds of classical type, zero loci of sections of homogeneous bundles in them, local targets over them, the Hilbert scheme of points in $\mathbb{C}^2$ ([4, 5, 15, 16]).

In general, the big J^ε-function and the operator S^ε_t are related by "Birkhoff factorization". This is the content of the following Theorem.

Theorem 4.3 ([11]). *For any GIT target and any $\varepsilon \geq 0+$*

$$J^\varepsilon(q,t,z) = S^\varepsilon_t(P^\varepsilon(q,t,z))$$

where $P^\varepsilon(q,t,z)$ is a power series *in z. (In fact, P^ε is naturally a generating function of $\mathbb{C}^*$-equivariant graph space integrals, see [11, §5.4].)*

4.4. The case of semi-positive targets. The triple $(W,\mathbf{G},\theta)$ is called *semi-positive* if

$$\beta(\det(T_W)) \geq 0$$

for every $\beta \in \mathrm{Eff}(W,\mathbf{G},\theta)$. Here T_W is the (virtual) tangent bundle of the lci $\mathbf{G}$-variety W, viewed as an element in the equivariant K-group $K^0_{\mathbf{G}}(W)$. We note that semi-positivity implies that the anti-canonical class of a projective $W/\!\!/\mathbf{G}$ is nef, but the converse need not be true.

The Birkhoff Factorization in Theorem 4.3 simplifies drastically for semi-positive targets. If $(W,\mathbf{G},\theta)$ is semi-positive, easy dimension counting arguments show that for every $\varepsilon \geq 0+$ the function J^ε contains no positive powers of z. Hence we have the asymptotic expansions

$$J^\varepsilon_{sm}(q,z) = J^\varepsilon_0(q)\mathbb{1} + \frac{J^\varepsilon_1(q)}{z} + O(1/z^2),$$

$$J^\varepsilon(q,t,z) = J^\varepsilon_0(q)\mathbb{1} + \frac{t + J^\varepsilon_1(q)}{z} + O(1/z^2).$$

In particular, we have

$$I_{sm}(q,z) = I_0(q)\mathbb{1} + I_1(q)\frac{1}{z} + O(1/z^2),$$

defining the q-series $I_0(q)$ and $I_1(q)$. They satisfy $I_0(q) = 1 + O(q) \in \Lambda$ and $I_1 \in qH^{\leq 2}(W/\!\!/\mathbf{G},\Lambda)$. For $\varepsilon > 0$, the coefficients $J^\varepsilon_0(q)$ and $J^\varepsilon_1(q)$ are polynomial truncations of the series I_0 and I_1. Note that since there are explicit closed formulas for I_{sm} in almost all examples, the series $I_0(q)$ and $I_1(q)$ are also explicit.

It follows that Theorem 4.3 specializes to the following Corollary (a very special case of this result is due to [19], by different methods).

Corollary 4.4 ([11]). *Let $(W, \mathbf{G}, \theta)$ be semi-positive and let $\varepsilon \geq 0+$ be arbitrary. Then the J-function and the S-operator are related by*

$$S_t^\varepsilon(\mathbb{1}) = \frac{J^\varepsilon(q,t,z)}{J_0^\varepsilon(q)}.$$

The transformation $\tau_\varepsilon(t) = \sum_{i=1}^s \gamma_i \langle\!\langle \gamma^i, \mathbb{1} \rangle\!\rangle_{0,2}^\varepsilon(t) - \mathbb{1}$ satisfies

$$\tau_\varepsilon(t) = \frac{t + J_1^\varepsilon(q)}{J_0^\varepsilon(q)},$$

and in particular

$$\sum_{i=1}^s \gamma_i \sum_{\beta \neq 0} q^\beta \langle \gamma^i, \mathbb{1} \rangle_{0,2,\beta}^\varepsilon = \frac{J_1^\varepsilon(q)}{J_0^\varepsilon(q)}.$$

Combining Theorem 4.2 with Corollary 4.4 gives the following Corollary.

Corollary 4.5 ([11]). *Assume $(W, \mathbf{G}, \theta)$ is semi-positive and there is a $\mathbf{T}$-action on $W/\!\!/\mathbf{G}$ with isolated fixed points. Then*

$$J^\infty\left(q, \frac{t + J_1^\varepsilon(q)}{J_0^\varepsilon(q)}, z\right) = \frac{J^\varepsilon(q,t,z)}{J_0^\varepsilon(q)}.$$

The same is true for E-twisted theories on $W/\!\!/\mathbf{G}$, where E is a convex $\mathbf{G}$-representation such that, for all θ-effective β,

$$\beta(\det(T_W)) - \beta(W \times \det(E)) \geq 0.$$

Let $\varepsilon = 0+$. After making $t = 0$ in the last Corollary and applying the string and divisor equations in the GW side, we obtain the usual formulation of the genus zero Mirror Theorem for the small J-function of Gromov-Witten theory

$$e^{\frac{1}{z}\frac{I_1(q)}{I_0(q)}} J_{sm}^\infty(Q, z) = I_{sm}(q, z)$$

after the change of variable $Q^\beta = q^\beta e^{\int_\beta \frac{I_1(q)}{I_0(q)}}$. For Calabi-Yau complete intersections in toric varieties, this change of variables is precisely the mirror map obtained from the solutions to the Picard-Fuchs equations associated to the mirror manifolds. Note that by the last equation in Corollary 4.4 the mirror map acquires a geometric interpretation in terms of two-point primary $(0+)$-quasimap invariants with a fundamental class insertion, as suggested by Jinzenji [33].

Hence the genus zero wall-crossing formula in Theorem 4.2 generalizes the mirror theorems as follows:

- from abelian to non-abelian quotients
- from the small to the big phase space
- from $\varepsilon = 0+$ to all ε
- from semi-positive GIT triples to all such triples.

4.5. Wall-crossing for J^ε-functions in the general case. Without the semi-positivity assumption the relation between $J^\varepsilon(q,t,z)$ and $J^\infty(q,t,z)$ is more complicated than the one given by Corollary 4.5. The most concise formulation is given by the following Conjecture [11, Conjecture 6.4.2].

Conjecture 4.6. *For all GIT triples $(W,\mathbf{G},\theta)$ and all stability parameters $\varepsilon \geq 0+$ the function $J^\varepsilon(q,t,z)$ is on the Lagrangian cone of the Gromov-Witten theory of $W/\!\!/\mathbf{G}$.*

Recall that for a general target X Givental introduced a formalism which encodes the genus zero sector of the Gromov-Witten theory of X via an overruled Lagrangian cone in an appropriate infinite-dimensional symplectic vector space, see [18, 28]. The Lagrangian cone is generated by the big J-function (this statement is another formulation of the Dubrovin reconstruction mentioned earlier). The conjecture then implies that $J^\infty(q,\tau_{\infty,\varepsilon}(q,t),z)$ is a linear combination of the derivatives $\partial_{t_i}J^\varepsilon(q,t,z)$ with uniquely determined coefficients (depending on q,t, and z) and unique change of variables $t\mapsto\tau_{\infty,\varepsilon}(q,t)$.

Theorem 4.7 ([11]). *Assume there is a $\mathbf{T}$-action on W such that the induced action on $W/\!\!/\mathbf{G}$ has isolated fixed points and isolated 1-dimensional orbits. Then Conjecture 4.6 holds true.*

4.6. Big $\mathbb{I}$-functions. The results described so far in this section elucidate the relationship between quasimap and GW invariants of $W/\!\!/\mathbf{G}$ in genus zero. However, if one is primarily interested in calculating GW invariants, the applicability of these results is restricted only to invariants with (descendant) insertions at one marking. This is because only for the small I-function one can write down explicit closed formulas. In general, quasimap invariants with two or more insertions are equally difficult to determine for all values of the stability parameter ε. To improve the situation the authors have introduced in [13] a new version of big $\mathbb{I}$-function of $(W,\mathbf{G},\theta)$ by considering a theory of $(0+)$-stable quasimaps with infinitesimally weighted markings. We conjectured that this function lies on the Lagrangian cone of the Gromov-Witten theory of $W/\!\!/\mathbf{G}$. Arguments parallel to the ones in the unweighted case are used to prove the following Theorem.

Theorem 4.8 ([13]). *Let $(W,\mathbf{G},\theta)$ be a GIT triple. Assume there is a $\mathbf{T}$-action on W such that the induced action on $W/\!\!/\mathbf{G}$ has isolated fixed points and isolated 1-dimensional orbits. Then the big $\mathbb{I}$-function associated to $(W,\mathbf{G},\theta)$ is on the Lagrangian cone of the Gromov-Witten theory of $W/\!\!/\mathbf{G}$. Furthermore, if E is a convex $\mathbf{G}$-representation, then the E-twisted $\mathbb{I}$ is on the E-twisted Lagrangian cone of $W/\!\!/\mathbf{G}$.*

As a consequence, the big J function of the (E-twisted) Gromov-Witten theory of $W/\!\!/\mathbf{G}$ is obtained from $\mathbb{I}$ via the Birkhoff factorization procedure of Coates and Givental [18]. The advantage is that one can calculate again explicit closed formulas for this new big $\mathbb{I}$-function in many cases. In [13] it is explained how to do so for toric varieties and for complete intersections in them. For example, if $\mathbb{C}^{n+1}/\!\!/_{\mathrm{id}}\mathbb{C}^* = \mathbb{P}^n$ is the standard GIT presentation of the projective space and $E=\mathbb{C}_{l(\mathrm{id})}$ is the 1-dimensional $\mathbb{C}^*$-representation with weight $l\in\mathbb{Z}_{>0}$, then one finds

$$\mathbb{I}^E_{\mathbb{C}^{n+1}/\!\!/\mathbb{C}^*}(t)=\sum_{d=0}^{\infty}q^d\frac{\exp(\sum_{i=0}^n t_i(H+dz)^i/z)}{\prod_{k=1}^d(H+kz)^{n+1}}\prod_{k=0}^{ld}(lH+kz),$$

where H is the hyperplane class and $t=\sum_{i=0}^n t_iH^i$ is the general element of $H^*(\mathbb{P}^n,\mathbb{Q})$.

Observe that if we denote by $t_{sm} = t_0 \mathbb{1} + t_1 H$ the restriction of t to the small parameter space $H^0(\mathbb{P}^n, \mathbb{Q}) \oplus H^2(\mathbb{P}^n, \mathbb{Q})$, then

$$\mathbb{I}^E_{\mathbb{C}^{n+1}/\!\!/\mathbb{C}^*}(t_{sm}) = \exp(\frac{t_0 \mathbb{1} + t_1 H}{z}) \sum_{d=0}^{\infty} q^d \exp(dt_1) \frac{\prod_{k=0}^{ld}(lH + kz)}{\prod_{k=1}^{d}(H + kz)^{n+1}},$$

which is precisely Givental's small I-function of a hypersurface of degree l in $\mathbb{P}^n$ (and differs from the function I_{sm} from §4.3 by the overall exponential factor $\exp(\frac{t_0 \mathbb{1} + t_1 H}{z})$ and the change $q \mapsto q \exp(t_1)$).

Remark 4.9. The results described in §4.2 - §4.6 above have been extended in [6] to the case of "orbifold GIT targets", that is, to the case when $[W^{ss}/\mathbf{G}]$ is a nonsingular Deligne-Mumford stack. A result related to Theorem 4.8 has been obtained earlier by Woodward, [53, Theorem 1.6].

5. Higher genus wall-crossing for semi-positive targets

In this section we discuss the wall-crossing formulas for higher genus ε-quasimap descendant invariants in the case of semi-positive triples $(W, \mathbf{G}, \theta)$.

Let

$$\mathbf{t}(\psi) := t_0 + t_1 \psi + t_2 \psi^2 + t_3 \psi^3 + \dots,$$

with $t_j = \sum_i t_{ji} \gamma_i \in H^*(W/\!\!/\mathbf{G}, \mathbb{Q})$ general cohomology classes.

By definition, the genus g, ε-descendant potential of $(W, \mathbf{G}, \theta)$ is

$$F^{\varepsilon}_g(\mathbf{t}) := \sum_{\beta \in \mathrm{Eff}(W,\mathbf{G},\theta)} \sum_{m \geq 0} \frac{q^\beta}{m!} \langle \mathbf{t}(\psi_1), \mathbf{t}(\psi_2), \dots \mathbf{t}(\psi_m) \rangle^{\varepsilon}_{g,m,\beta}.$$

As usual, we omit from the sum the unstable terms corresponding to $(g, m, \beta, \varepsilon)$ for which the moduli spaces are not defined.

Conjecture 5.1 ([12]). *For a semi-positive triple $(W, \mathbf{G}, \theta)$, and every $\varepsilon \geq 0+$*

$$(J^{\varepsilon}_0(q))^{2g-2} F^{\varepsilon}_g(\mathbf{t}(\psi)) = F^{\infty}_g \left(\frac{\mathbf{t}(\psi) + J^{\varepsilon}_1(q)}{J^{\varepsilon}_0(q)} \right). \tag{5.1}$$

Further, for every $\varepsilon_1 \neq \varepsilon_2$

$$(J^{\varepsilon_1}_0(q))^{2g-2} F^{\varepsilon_1}_g (J^{\varepsilon_1}_0(q) \mathbf{t}(\psi) - J^{\varepsilon_1}_1(q)) = (J^{\varepsilon_2}_0(q))^{2g-2} F^{\varepsilon_2}_g \left(J^{\varepsilon_2}_0(q) \mathbf{t}(\psi) - J^{\varepsilon_2}_1(q) \right). \tag{5.2}$$

To be precise, in the case $g = 0$ the equalities are conjectured to hold modulo terms of degree ≤ 1 in the coordinates t_{ji} (but see [12, Remark 3.1.3] for an explanation on how to extend the statement to an equality up to constants).

Note that the (a priori stronger) wall-crossing formula (5.2) follows from (5.1).

Considering the Taylor coefficients on both sides gives the following equivalent formulation of (5.1): If $2g - 2 + k \geq 0$, then for arbitrary $\delta_1, \dots \delta_k \in H^*(W/\!\!/\mathbf{G}, \mathbb{Q})$ and integers $a_1, \dots, a_k \geq 0$,

$$(J_0^\varepsilon(q))^{2g-2+k}\sum_\beta q^\beta\langle\delta_1\psi_1^{a_1},\dots,\delta_n\psi_k^{a_k}\rangle_{g,k,\beta}^\varepsilon=$$

$$\sum_\beta q^\beta\sum_{m=0}^\infty\frac{1}{m!}\left\langle\delta_1\psi_1^{a_1},\dots,\delta_k\psi_k^{a_k},\frac{J_1^\varepsilon(q)}{J_0^\varepsilon(q)},\dots,\frac{J_1^\varepsilon(q)}{J_0^\varepsilon(q)}\right\rangle_{g,k+m,\beta}^\infty.$$

Combining Corollary 4.5 with reconstruction for ε-quasimap invariants proves the Conjecture in genus zero.

Theorem 5.2 ([12]). *Let $(W,\mathbf{G},\theta)$ be semi-positive. Assume there is an action by a torus $\mathbf{T}$, such that the fixed points of the induced $\mathbf{T}$-action on $W/\!\!/\mathbf{G}$ are isolated. Then the $g=0$ case of Conjecture 5.1 holds. Moreover, if E is a convex $\mathbf{G}$-representation such that $\beta(\det(T_W))-\beta(W\times\det(E))\geq 0$ for all θ-effective β, then the conjecture also holds at $g=0$ for the E-twisted ε-quasimap theories of $W/\!\!/\mathbf{G}$.*

A more convincing piece of evidence for the validity of the Conjecture is provided by the following result:

Theorem 5.3 ([12]). *Let X be a nonsingular quasi-projective toric variety of dimension n, obtained as the GIT quotient of a semi-positive triple $(\mathbb{C}^{n+r},(\mathbb{C}^*)^r,\theta)$. Then Conjecture 5.1 holds for X.*

It is easy to see that toric varieties (in any semi-positive GIT presentation) have $I_0(q)=1$ (and hence $J_0^\varepsilon=1$ for all ε). When X is a nonsingular and projective toric Fano and we take its "standard" GIT presentation (as considered e.g. in [10]), then $I_1(q)=0$ as well. Hence we obtain the following

Corollary 5.4. *If X is a nonsingular projective Fano toric variety, then its quasimap invariants (for the standard GIT presentation) are independent on ε:*

$$F_g^\varepsilon(\mathbf{t}(\psi))=F_g^\infty(\mathbf{t}(\psi)),\ \ \forall\varepsilon\geq 0+.$$

The first statement of the kind in the Corollary was established by Marian - Oprea - Pandharipande [41] for $W/\!\!/\mathbf{G}$ a Grassmannian and for $\varepsilon=0+$. Their result was extended to all ε in [51] by Toda.

Remark 5.5.

1. The most interesting case covered by Theorem 5.3 is that of toric Calabi-Yau targets. For 3-folds, our theorem says that $F_g^{0+}|_{\mathbf{t}(\psi)=0}$ is *equal* to the B-model genus g prepotential, expanded near a large complex structure point for the mirror of X.
2. The arguments proving Theorem 5.3 also apply to show that the higher genus wall-crossing of Conjecture 5.1 holds for some non-abelian local Calabi-Yau targets, namely local Grassmannians, and in fact local type A flag manifolds, see [12, Theorem 1.3.4].
3. The remaining challenge is to prove Conjecture 5.1 for compact Calabi-Yau targets at $g\geq 1$.

Acknowledgements. The authors thank Daewoong Cheong, Duiliu-Emanuel Diaconescu, and Davesh Maulik for collaboration on parts of this quasimap project. The first named author was partially supported by NSF DMS-1305004 and the second named author was partially supported by KRF 2007-0093859. In addition, the second named author thanks University of Minnesota for hospitality during the writing of the paper.

Semiorthogonal decompositions in algebraic geometry

Alexander Kuznetsov

Abstract. In this review we discuss what is known about semiorthogonal decompositions of derived categories of algebraic varieties. We review existing constructions, especially the homological projective duality approach, and discuss some related issues such as categorical resolutions of singularities.

Mathematics Subject Classification (2010). Primary 18E30; Secondary 14F05.

Keywords. Semiorthogonal decompositions, exceptional collections, Lefschetz decompositions, homological projective duality, categorical resolutions of singularities, Fano varieties.

1. Introduction

In recent years an extensive investigation of semiorthogonal decompositions of derived categories of coherent sheaves on algebraic varieties has been done, and now we know quite a lot of examples and some general constructions. With time it is becoming more and more clear that semiorthogonal components of derived categories can be thought of as the main objects in noncommutative algebraic geometry. In this paper I will try to review what is known in this direction — how one can construct semiorthogonal decompositions and how one can use them.

In section 2 we will recall the basic notions, discuss the most frequently used semiorthogonal decompositions, and state the base change formula. In section 3 we review the theory of homological projective duality which up to now is the most powerful method to construct semiorthogonal decompositions. In section 4 we discuss categorical resolutions of singularities, a subject interesting by itself, and at the same time inseparable from homological projective duality. In section 5 examples of homologically projectively dual varieties are listed. Finally, in section 6 we discuss semiorthogonal decompositions of varieties of small dimension.

I should stress that in the area of algebraic geometry described in this paper there are more questions than answers, but it really looks very promising. Also, due to volume constraints I had to leave out many interesting topics closely related to the main subject, such as the categorical Griffiths component, Hochschild homology and cohomology, and many others.

Proceedings of the International Congress of Mathematicians, Seoul, 2014

2. Semiorthogonal decompositions

This paper can be considered as a continuation and a development of the ICM 2002 talk [7] of Alexei Bondal and Dmitri Orlov. So I will freely use results and definitions from [7] and restrict myself to a very short reminder of the most basic notion. In particular, the reader is referred to [7] for the definition of a Serre functor, Fourier–Mukai transform, etc.

2.1. A short reminder. Recall that a semiorthogonal decomposition of a triangulated category $\mathcal{T}$ is a collection $\mathcal{A}_1, \dots, \mathcal{A}_n$ of full triangulated subcategories such that:

(a) for all $1 \le j < i \le n$ and any objects $A_i \in \mathcal{A}_i$, $A_j \in \mathcal{A}_j$ one has $\mathsf{Hom}_{\mathcal{T}}(A_i, A_j) = 0$;

(b) the smallest triangulated subcategory of $\mathcal{T}$ containing $\mathcal{A}_1, \dots, \mathcal{A}_n$ coincides with $\mathcal{T}$.

We will use the notation $\mathcal{T} = \langle \mathcal{A}_1, \dots, \mathcal{A}_n \rangle$ for a semiorthogonal decomposition of $\mathcal{T}$ with components $\mathcal{A}_1, \dots, \mathcal{A}_n$.

We will be mostly interested in semiorthogonal decompositions of $\mathbf{D}^b(\mathsf{coh}(X))$, the *bounded derived category of coherent sheaves* on an algebraic variety X which in most cases will be assumed to be smooth and projective over a base field k.

Recall that a full triangulated subcategory $\mathcal{A} \subset \mathcal{T}$ is admissible if its embedding functor $i : \mathcal{A} \to \mathcal{T}$ has both left and right adjoint functors $i^*, i^! : \mathcal{T} \to \mathcal{A}$. An admissible subcategory $\mathcal{A} \subset \mathcal{T}$ gives rise to a pair of semiorthogonal decompositions

$$\mathcal{T} = \langle \mathcal{A}, {}^{\perp}\mathcal{A} \rangle \qquad \text{and} \qquad \mathcal{T} = \langle \mathcal{A}^{\perp}, \mathcal{A} \rangle, \tag{2.1}$$

where

$${}^{\perp}\mathcal{A} := \{T \in \mathcal{T} \mid \mathsf{Hom}(T, A[t]) = 0 \text{ for all } A \in \mathcal{A}, t \in \mathbb{Z}\}, \tag{2.2}$$

$$\mathcal{A}^{\perp} := \{T \in \mathcal{T} \mid \mathsf{Hom}(A[t], T) = 0 \text{ for all } A \in \mathcal{A}, t \in \mathbb{Z}\}, \tag{2.3}$$

are the left and the right orthogonals to $\mathcal{A}$ in $\mathcal{T}$. More generally, if $\mathcal{A}_1, \dots, \mathcal{A}_m$ is a semiorthogonal collection of admissible subcategories in $\mathcal{T}$, then for each $0 \le k \le m$ there is a semiorthogonal decomposition

$$\mathcal{T} = \langle \mathcal{A}_1, \dots, \mathcal{A}_k, {}^{\perp}\langle \mathcal{A}_1, \dots, \mathcal{A}_k \rangle \cap \langle \mathcal{A}_{k+1}, \dots, \mathcal{A}_m \rangle^{\perp}, \mathcal{A}_{k+1}, \dots, \mathcal{A}_m \rangle. \tag{2.4}$$

The simplest example of an admissible subcategory is the one generated by an exceptional object. Recall that an object E is exceptional if one has $\mathsf{Hom}(E, E) = \mathsf{k}$ and $\mathsf{Hom}(E, E[t]) = 0$ for $t \ne 0$. An exceptional collection is a collection of exceptional objects $E_1, E_2, \dots, E_m$ such that $\mathsf{Hom}(E_i, E_j[t]) = 0$ for all $i > j$ and all $t \in \mathbb{Z}$. An exceptional collection in $\mathcal{T}$ gives rise to a semiorthogonal decomposition

$$\mathcal{T} = \langle \mathcal{A}, E_1, \dots, E_m \rangle \quad \text{with} \quad \mathcal{A} = \langle E_1, \dots, E_m \rangle^{\perp}. \tag{2.5}$$

Here E_i denotes the subcategory generated by the same named exceptional object. If the category $\mathcal{A}$ in (2.5) is zero the exceptional collection is called full.

2.2. Full exceptional collections. There are several well-known and quite useful semiorthogonal decompositions. The simplest example is the following

Theorem 2.1 (Beilinson's collection). *There is a full exceptional collection*

$$\mathbf{D}^b(\mathsf{coh}(\mathbb{P}^n)) = \langle \mathcal{O}_{\mathbb{P}^n}, \mathcal{O}_{\mathbb{P}^n}(1), \dots, \mathcal{O}_{\mathbb{P}^n}(n) \rangle. \tag{2.6}$$

Of course, twisting by $\mathcal{O}_{\mathbb{P}^n}(t)$ we get $\langle \mathcal{O}_{\mathbb{P}^n}(t), \mathcal{O}_{\mathbb{P}^n}(t+1), \dots, \mathcal{O}_{\mathbb{P}^n}(t+n)\rangle$ which is also a full exceptional collection for each $t \in \mathbb{Z}$.

A bit more general is the Grassmannian variety:

Theorem 2.2 (Kapranov's collection, [19]). *Let $\mathsf{Gr}(k,n)$ be the Grassmannian of k-dimensional subspaces in a vector space of dimension n. Let $\mathcal{U}$ be the tautological subbundle of rank k. If $\mathsf{char}\,\mathsf{k} = 0$ then there is a semiorthogonal decomposition*

$$\mathbf{D}^b(\mathsf{coh}(\mathsf{Gr}(k,n))) = \langle\, \Sigma^\alpha \mathcal{U}^\vee \,\rangle_{\alpha \subset R(k,n-k)}, \tag{2.7}$$

where $R(k,n-k)$ is the $k\times(n-k)$ rectangle, α is a Young diagram, and Σ^α is the associated Schur functor.

When $\mathsf{char}\,\mathsf{k} > 0$ there is an exceptional collection as well, but it is a bit more complicated, see [9].

Another interesting case is the case of a smooth quadric $Q^n \subset \mathbb{P}^{n+1}$.

Theorem 2.3 (Kapranov's collection, [19]). *When $\mathsf{char}\,\mathsf{k} \neq 2$ and k is algebraically closed, there is a full exceptional collection*

$$\mathbf{D}^b(\mathsf{coh}(Q^n)) = \begin{cases} \langle \mathsf{S}, \mathcal{O}_{Q^n}, \mathcal{O}_{Q^n}(1), \dots, \mathcal{O}_{Q^n}(n-1)\rangle, & \text{if } n \text{ is odd} \\ \langle \mathsf{S}^-, \mathsf{S}^+, \mathcal{O}_{Q^n}, \mathcal{O}_{Q^n}(1), \dots, \mathcal{O}_{Q^n}(n-1)\rangle, & \text{if } n \text{ is even} \end{cases} \tag{2.8}$$

where S and $\mathsf{S}^\pm$ are the spinor bundles.

Many exceptional collections have been constructed on other rational homogeneous spaces, see e.g. [48], [32], [47], [42], [11], and [41]. Full exceptional collections on smooth toric varieties (and stacks) were constructed by Kawamata [20]. Also exceptional collections were constructed on del Pezzo surfaces [46], some Fano threefolds [24, 45] and many other varieties.

2.3. Relative versions. Let S be a scheme and E a vector bundle of rank r on it. Let $\mathbb{P}_S(E)$ be its projectivization, $f : \mathbb{P}_S(E) \to S$ the projection, and $\mathcal{O}_{\mathbb{P}_S(E)/S}(1)$ the Grothendieck line bundle on $\mathbb{P}_S(E)$.

Theorem 2.4 ([46]). *For each $i \in \mathbb{Z}$ the functor*

$$\Phi_i : \mathbf{D}^b(\mathsf{coh}(S)) \to \mathbf{D}^b(\mathsf{coh}(\mathbb{P}_S(E))), \qquad F \mapsto Lf^*(F) \overset{\mathbb{L}}{\otimes} \mathcal{O}_{\mathbb{P}_S(E)/S}(i) \tag{2.9}$$

is fully faithful, and there is a semiorthogonal decomposition

$$\mathbf{D}^b(\mathsf{coh}(\mathbb{P}_S(E))) = \langle \Phi_0(\mathbf{D}^b(\mathsf{coh}(S))), \dots, \Phi_{r-1}(\mathbf{D}^b(\mathsf{coh}(S)))\rangle. \tag{2.10}$$

Of course, analogously to the case of a projective space, one can replace the sequence of functors $\Phi_0, \dots, \Phi_{r-1}$ by $\Phi_t, \dots, \Phi_{t+r-1}$ for any $t \in \mathbb{Z}$.

An interesting new feature appears for Severi–Brauer varieties. Recall that a Severi–Brauer variety over S is a morphism $f : X \to S$ which étale locally is isomorphic to a projectivization of a vector bundle. A Severi–Brauer variety X can be constructed from a torsion element in the Brauer group $\mathsf{Br}(S)$ of S.

Theorem 2.5 (Bernardara's decomposition, [3]). *Let $f : X \to S$ be a Severi–Brauer variety of relative dimension n and $\beta \in \mathsf{Br}(S)$ its Brauer class. Then for each $i \in \mathbb{Z}$ there is a fully faithful functor $\Phi_i : \mathbf{D}^b(\mathsf{coh}(S, \beta^i)) \to \mathbf{D}^b(\mathsf{coh}(X))$ and a semiorthogonal decomposition*

$$\mathbf{D}^b(\mathsf{coh}(X)) = \langle \Phi_0(\mathbf{D}^b(\mathsf{coh}(S))), \Phi_1(\mathbf{D}^b(\mathsf{coh}(S, \beta))), \dots, \Phi_n(\mathbf{D}^b(\mathsf{coh}(S, \beta^n)))\rangle. \quad (2.11)$$

Here $\mathsf{coh}(S, \beta^i)$ is the category of β^i-twisted coherent sheaves on S and the functor Φ_i is given by $F \mapsto Lf^*(F) \overset{\mathbb{L}}{\otimes} \mathcal{O}_{X/S}(i)$, where the sheaf $\mathcal{O}_{X/S}(i)$ is well defined as a $f^*\beta^{-i}$-twisted sheaf.

Another important semiorthogonal decomposition can be constructed for a smooth blowup. Let $Y \subset X$ be a locally complete intersection subscheme of codimension c and let $\tilde{X}$ be the blowup of X with center in Y. Let $f : \tilde{X} \to X$ be the blowup morphism and $D \subset \tilde{X}$ the exceptional divisor of the blowup. Let $i : D \to \tilde{X}$ be the embedding and $p : D \to Y$ the natural projection (the restriction of f to D). Note that $D \cong \mathbb{P}_Y(\mathcal{N}_{Y/X})$ is the projectivization of the normal bundle.

Theorem 2.6 (Blowup formula, [46]). *The functor $Lf^* : \mathbf{D}^b(\mathsf{coh}(X)) \to \mathbf{D}^b(\mathsf{coh}(\tilde{X}))$ as well as the functors*

$$\Psi_k : \mathbf{D}^b(\mathsf{coh}(Y)) \to \mathbf{D}^b(\mathsf{coh}(\tilde{X})), \qquad F \mapsto Ri_*(Lp^*(F) \overset{\mathbb{L}}{\otimes} \mathcal{O}_{D/Y}(k)),$$

are fully faithful for all $k \in \mathbb{Z}$, and there is a semiorthogonal decomposition

$$\mathbf{D}^b(\mathsf{coh}(\tilde{X})) = \langle Lf^*(\mathbf{D}^b(\mathsf{coh}(X))), \Psi_0(\mathbf{D}^b(\mathsf{coh}(Y))), \dots, \Psi_{c-2}(\mathbf{D}^b(\mathsf{coh}(Y)))\rangle. \quad (2.12)$$

Finally, consider a flat fibration in quadrics $f : X \to S$. In other words, assume that $X \subset \mathbb{P}_S(E)$ is a divisor of relative degree 2 in a projectivization of a vector bundle E of rank $n + 2$ on a scheme S corresponding to a line subbundle $\mathscr{L} \subset S^2E^\vee$.

Theorem 2.7 (Quadratic fibration formula, [31]). *For each $i \in \mathbb{Z}$ there is a fully faithful functor*

$$\Phi_i : \mathbf{D}^b(\mathsf{coh}(S)) \to \mathbf{D}^b(\mathsf{coh}(X)), \qquad F \mapsto Lf^*(F) \overset{\mathbb{L}}{\otimes} \mathcal{O}_{X/S}(i)$$

and a semiorthogonal decomposition

$$\mathbf{D}^b(\mathsf{coh}(X)) = \langle \mathbf{D}^b(\mathsf{coh}(S, \mathcal{C}\ell_0)), \Phi_0(\mathbf{D}^b(\mathsf{coh}(S))), \dots, \Phi_{n-1}(\mathbf{D}^b(\mathsf{coh}(S)))\rangle, \quad (2.13)$$

where $\mathcal{C}\ell_0$ is the sheaf of even parts of Clifford algebras on S associated with the quadric fibration $X \to S$.

The sheaf $\mathcal{C}\ell_0$ is a sheaf of $\mathcal{O}_S$-algebras which as an $\mathcal{O}_S$-module is isomorphic to

$$\mathcal{C}\ell_0 \cong \mathcal{O}_S \oplus (\Lambda^2 E \otimes \mathscr{L}) \oplus (\Lambda^4 E \otimes \mathscr{L}^2) \oplus \dots$$

and equipped with an algebra structure via the Clifford multiplication. If the dimension n of fibers of $X \to S$ is odd, then $\mathcal{C}\ell_0$ is a sheaf of Azumaya algebras on the open subset of S corresponding to nondegenerate quadrics (which of course may be empty). On the other hand, if n is even then $\mathcal{O}_S \oplus \Lambda^n E \otimes \mathscr{L}^{n/2}$ is a central subalgebra in $\mathcal{C}\ell_0$, so the latter gives a sheaf $\tilde{\mathcal{C}\ell}_0$ of algebras on the twofold covering

$$\tilde{S} := \mathsf{Spec}_S(\mathcal{O}_S \oplus \Lambda^n E \otimes \mathscr{L}^{n/2}) \quad (2.14)$$

of S, and $\tilde{\mathcal{C}\ell}_0$ is a sheaf of Azumaya algebras on the preimage of the open subset of S corresponding to nondegenerate quadrics.

2.4. Base change. A triangulated category $\mathcal{T}$ is S-linear if it is equipped with a module structure over the tensor triangulated category $\mathbf{D}^b(\mathsf{coh}(S))$. In particular, if X is a scheme over S and $f : X \to S$ is the structure morphism then a semiorthogonal decomposition

$$\mathbf{D}^b(\mathsf{coh}(X)) = \langle \mathscr{A}_1, \dots, \mathscr{A}_m \rangle \tag{2.15}$$

is S-linear if each of subcategories $\mathscr{A}_k$ is closed under tensoring with an object of $\mathbf{D}^b(\mathsf{coh}(S))$, i.e. for $A \in \mathscr{A}_k$ and $F \in \mathbf{D}^b(\mathsf{coh}(S))$ one has $A \overset{\mathbb{L}}{\otimes} Lf^*(F) \in \mathscr{A}_k$.

The semiorthogonal decompositions of Theorems 2.4, 2.5 and 2.7 are S-linear, and the blowup formula of Theorem 2.6 is X-linear. The advantage of linear semiorthogonal decompositions lies in the fact that they obey a base change result. For a base change $T \to S$ denote by $\pi : X \times_S T \to X$ the induced projection.

Theorem 2.8 ([37]). *If X is an algebraic variety over S and* (2.15) *is an S-linear semiorthogonal decomposition then for a change of base morphism $T \to S$ there is, under a certain technical condition, a T-linear semiorthogonal decomposition*

$$\mathbf{D}^b(\mathsf{coh}(X \times_S T)) = \langle \mathscr{A}_{1T}, \dots, \mathscr{A}_{mT} \rangle$$

such that $\pi^*(A) \subset \mathscr{A}_{iT}$ for any $A \in \mathscr{A}_i$ and $\pi_*(A') \subset \mathscr{A}_i$ for any $A' \in \mathscr{A}_{iT}$ which has proper support over X.

2.5. Important questions. There are several questions which might be crucial for further investigations.

Question 2.9. *Find a good condition for an exceptional collection to be full.*

One might hope that if the collection generates the Grothendieck group (or the Hochschild homology) of the category then it is full. However, recent examples of quasiphantom and phantom categories (see section 6.2) show that this is not the case. Still we may hope that in the categories generated by exceptional collections there are no phantoms. In other words one could hope that the following is true.

Conjecture 2.10. *Let $\mathcal{T} = \langle E_1, \dots, E_n \rangle$ be a triangulated category generated by an exceptional collection. Then any exceptional collection of length n in $\mathcal{T}$ is full.*

If there is an action of a group G on an algebraic variety X, one can consider the equivariant derived category $\mathbf{D}^b(\mathsf{coh}^G(X))$ along with the usual derived category. In many interesting cases (flag varieties, toric varieties, GIT quotients) it is quite easy to construct a full exceptional collection in the equivariant category. It would be extremely useful to find a way to transform it into a full exceptional collection in the usual category. In some sense the results of [41] can be considered as an example of such an approach.

Another very important question is to find possible restrictions for existence of semiorthogonal decompositions. Up to now there are only several cases when we can *prove* indecomposability of a category. The first is the derived category of a curve of positive genus. The proof (see e.g. [44]) is based on special properties of categories of homological dimension 1. Another is the derived category of a Calabi–Yau variety (smooth connected variety with trivial canonical class). Its indecomposability is proved by a surprisingly simple argument due to Bridgeland [8]. This was further generalized in [21] to varieties with globally generated canonical class. On the other hand, the original argument of Bridgeland generalizes to any connected Calabi–Yau category (i.e. with the Serre functor isomorphic to a shift and Hochschild cohomology in degree zero isomorphic to k).

3. Homological projective duality

The starting point of a homological projective duality (HP duality for short) is a smooth projective variety X with a morphism into a projective space and a semiorthogonal decomposition of $\mathbf{D}^b(\mathsf{coh}(X))$ of a very special type.

3.1. Lefschetz decompositions. Let X be an algebraic variety and $\mathscr{L}$ a line bundle on X.

Definition 3.1. A right Lefschetz decomposition of $\mathbf{D}^b(\mathsf{coh}(X))$ with respect to $\mathscr{L}$ is a semiorthogonal decomposition of form

$$\mathbf{D}^b(\mathsf{coh}(X)) = \langle \mathscr{A}_0, \mathscr{A}_1 \otimes \mathscr{L}, \dots, \mathscr{A}_{m-1} \otimes \mathscr{L}^{m-1} \rangle \tag{3.1}$$

with $0 \subset \mathscr{A}_{m-1} \subset \cdots \subset \mathscr{A}_1 \subset \mathscr{A}_0$. In other words, each component of the decomposition is a subcategory of the previous component twisted by $\mathscr{L}$.

Analogously, a left Lefschetz decomposition of $\mathbf{D}^b(\mathsf{coh}(X))$ with respect to $\mathscr{L}$ is a semiorthogonal decomposition of form

$$\mathbf{D}^b(\mathsf{coh}(X)) = \langle \mathscr{B}_{m-1} \otimes \mathscr{L}^{1-m}, \dots, \mathscr{B}_1 \otimes \mathscr{L}^{-1}, \mathscr{B}_0 \rangle \tag{3.2}$$

with $0 \subset \mathscr{B}_{m-1} \subset \cdots \subset \mathscr{B}_1 \subset \mathscr{B}_0$.

The subcategories $\mathscr{A}_i$ (resp. $\mathscr{B}_i$) forming a Lefschetz decomposition will be called blocks, the largest will be called the first block. Usually we will consider right Lefschetz decompositions. So, we will call them simply Lefschetz decompositions.

Beilinson's collection on $\mathbb{P}^n$ is an example of a Lefschetz decomposition with $\mathscr{A}_0 = \mathscr{A}_1 = \cdots = \mathscr{A}_n = \langle \mathcal{O}_{\mathbb{P}^n} \rangle$. Kapranov's collection on the Grassmannian $\mathsf{Gr}(k, n)$ also has a Lefschetz structure with the category $\mathscr{A}_i$ generated by $\Sigma^\alpha \mathcal{U}^\vee$ for $\alpha \subset R(k-1, n-k-i)$.

Note that in Definition 3.1 one can replace the twist by a line bundle with any other autoequivalence of $\mathbf{D}^b(\mathsf{coh}(X))$ and get the notion of a Lefschetz decomposition with respect to an autoequivalence. This may be especially useful when dealing with arbitrary triangulated categories.

It is also useful to know that for a given line bundle $\mathscr{L}$ a Lefschetz decomposition is completely determined by its first block. Moreover, an admissible subcategory extends to a right Lefschetz decomposition if and only if it extends to a left Lefschetz decomposition. The simplest example of an admissible subcategory which does not extend to a Lefschetz decomposition is the subcategory $\langle \mathcal{O}_{\mathbb{P}^2}, \mathcal{O}_{\mathbb{P}^2}(2) \rangle \subset \mathbf{D}^b(\mathsf{coh}(\mathbb{P}^2))$.

Question 3.2. *Find a good sufficient condition for a Lefschetz extendability of an admissible subcategory $\mathscr{A}_0 \subset \mathbf{D}^b(\mathsf{coh}(X))$.*

One can define a partial ordering on the set of all Lefschetz decompositions of $\mathbf{D}^b(\mathsf{coh}(X))$ by inclusions of their first blocks. As we will see soon, the most interesting and strong results are obtained by using minimal Lefschetz decompositions.

3.2. Hyperplane sections. Let X be a smooth projective variety with a morphism into a projective space $f : X \to \mathbb{P}(V)$ (not necessarily an embedding). Put $\mathcal{O}_X(1) := f^*\mathcal{O}_{\mathbb{P}(V)}(1)$ and assume that a right Lefschetz decomposition with respect to $\mathcal{O}_X(1)$

$$\mathbf{D}^b(\mathsf{coh}(X)) = \langle \mathscr{A}_0, \mathscr{A}_1(1), \dots, \mathscr{A}_{m-1}(m-1) \rangle \tag{3.3}$$

is given (we abbreviate $\mathscr{A}_i(i) := \mathscr{A}_i \otimes \mathcal{O}_X(i)$). Consider the dual projective space $\mathbb{P}(V^\vee)$. By the base change (Theorem 2.8) the product $X \times \mathbb{P}(V^\vee)$ inherits a $\mathbb{P}(V^\vee)$-linear semiorthogonal decomposition

$$\mathbf{D}^b(\mathsf{coh}(X \times \mathbb{P}(V^\vee))) = \langle \mathscr{A}_{0\mathbb{P}(V^\vee)}, \mathscr{A}_1(1)_{\mathbb{P}(V^\vee)}, \dots, \mathscr{A}_{m-1}(m-1)_{\mathbb{P}(V^\vee)} \rangle$$

Consider the universal hyperplane section of X, $\mathscr{X} := X \times_{\mathbb{P}(V)} Q \subset X \times \mathbb{P}(V^\vee)$, where $Q \subset \mathbb{P}(V) \times \mathbb{P}(V^\vee)$ is the incidence quadric and denote by $\alpha : \mathscr{X} \to X \times \mathbb{P}(V^\vee)$ the natural embedding.

Lemma 3.3. *The functor $L\alpha^* : \mathbf{D}^b(\mathsf{coh}(X \times \mathbb{P}(V^\vee))) \to \mathbf{D}^b(\mathsf{coh}(\mathscr{X}))$ is fully faithful on each of the subcategories $\mathscr{A}_1(1)_{\mathbb{P}(V^\vee)}, \dots, \mathscr{A}_{m-1}(m-1)_{\mathbb{P}(V^\vee)}$ and induces a $\mathbb{P}(V^\vee)$-linear semiorthogonal decomposition*

$$\mathbf{D}^b(\mathsf{coh}(\mathscr{X})) = \langle \mathscr{C}, \mathscr{A}_1(1)_{\mathbb{P}(V^\vee)}, \dots, \mathscr{A}_{m-1}(m-1)_{\mathbb{P}(V^\vee)} \rangle. \tag{3.4}$$

The first component $\mathscr{C}$ of this decomposition is called the HP dual category of X. It is a very interesting category, especially if it can be identified with the derived category of some algebraic variety Y. In this case this variety is called the HP dual variety of X.

Definition 3.4. An algebraic variety Y equipped with a morphism $g : Y \to \mathbb{P}(V^\vee)$ is called homologically projectively dual to $f : X \to \mathbb{P}(V)$ with respect to a given Lefschetz decomposition (3.3) if there is given an object $\mathcal{E} \in \mathbf{D}^b(\mathsf{coh}(Q(X,Y)))$ such that the Fourier–Mukai functor $\Phi_{\mathcal{E}} : \mathbf{D}^b(\mathsf{coh}(Y)) \to \mathbf{D}^b(\mathsf{coh}(\mathscr{X}))$ is an equivalence onto the HP dual subcategory $\mathscr{C} \subset \mathbf{D}^b(\mathsf{coh}(\mathscr{X}))$ of (3.4).

Here $Q(X,Y) = (X \times Y) \times_{\mathbb{P}(V)\times\mathbb{P}(V^\vee)} Q = \mathscr{X} \times_{\mathbb{P}(V^\vee)} Y$. If a homological projective duality between varieties X and Y is established then there is an interesting relation between derived categories of their linear sections.

3.3. Homologically projectively duality statement. For each linear subspace $L \subset V^\vee$ denote its orthogonal complement in V by $L^\perp := \mathsf{Ker}(V \to L^\vee)$. Further denote

$$X_L := X \times_{\mathbb{P}(V)} \mathbb{P}(L^\perp), \qquad Y_L := Y \times_{\mathbb{P}(V^\vee)} \mathbb{P}(L). \tag{3.5}$$

Varieties defined in this way are called mutually orthogonal linear sections of X and Y. We will say that X_L and Y_L have expected dimensions if

$$\dim X_L = \dim X - r \qquad \text{and} \qquad \dim Y_L = \dim Y - (N - r),$$

where $N = \dim V$ and $r = \dim L$ (so that $N - r = \dim L^\perp$).

Theorem 3.5 (Homological projective duality, [29]). *Let (Y, g) be an HP dual variety for (X, f) with respect to* (3.3)*. Then*

(1) *Y is smooth and $\mathbf{D}^b(\mathsf{coh}(Y))$ has an admissible subcategory $\mathscr{B}_0$ equivalent to $\mathscr{A}_0$ and extending to a left Lefschetz decomposition*

$$\mathbf{D}^b(\mathsf{coh}(Y)) = \langle \mathscr{B}_{n-1}(1-n), \dots, \mathscr{B}_1(-1), \mathscr{B}_0 \rangle, \quad \mathscr{B}_{n-1} \subset \dots \subset \mathscr{B}_1 \subset \mathscr{B}_0. \tag{3.6}$$

(2) *(X, f) is HP dual to (Y, g) with respect to* (3.6)*.*

(3) *The set of critical values of g is the classical projective dual of X.*

(4) *For any subspace $L \subset V^\vee$ if X_L and Y_L have expected dimensions then there are semiorthogonal decompositions*

$$\mathbf{D}^b(\mathsf{coh}(X_L)) = \langle \mathscr{C}_L, \mathscr{A}_r(r), \dots, \mathscr{A}_{m-1}(m-1) \rangle, \tag{3.7}$$

$$\mathbf{D}^b(\mathsf{coh}(Y_L)) = \langle \mathscr{B}_{n-1}(1-n), \dots, \mathscr{B}_{N-r}(r-N), \mathscr{C}_L \rangle \tag{3.8}$$

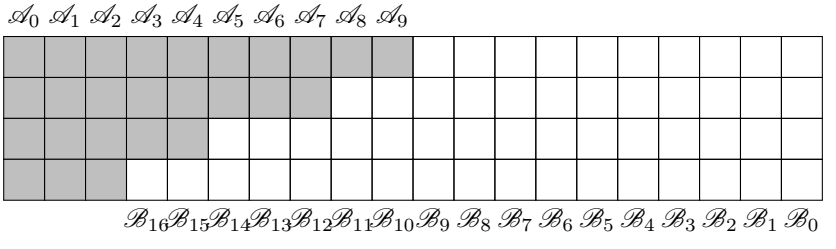
with the same triangulated category $\mathscr{C}_L$ appearing in the RHS.

The decomposition (3.6) of $\mathbf{D}^b(\mathsf{coh}(Y))$ will be referred to as the HP dual Lefschetz decomposition. The common component $\mathscr{C}_L$ of decompositions (3.7) and (3.8) will be referred to as the nontrivial part of the derived categories of X_L and Y_L, while the subcategories $\mathscr{A}_i(i)$ and $\mathscr{B}_j(-j)$ (one checks that the pullback functors for the embeddings $X_L \to X$ and $Y_L \to Y$ are fully faithful on the subcategories $\mathscr{A}_i$ and $\mathscr{B}_j$ for $i \geq r$ and $j \geq N - r$) are considered as trivial (in the sense that they come from the ambient varieties).

The first two statements of this Theorem show that the relation we are dealing with is indeed a duality, the third statement shows the relation to the classical projective duality (and so justifies the word "projective" in the name), and the last statement is the real result. We will soon see how powerful it is.

Note also that in the statement of the Theorem the linear sections X_L and Y_L need not be smooth. In fact, one can show that for HP dual varieties X and Y a section X_L is smooth if and only if its orthogonal section Y_L is smooth, but no matter whether this is the case or not, the decompositions (3.7) and (3.8) hold true.

Now let us say some words about the relations of the Lefschetz decompositions (3.3) and (3.6) for HP dual varieties. As it was already mentioned, the largest components of those are just equivalent $\mathscr{B}_0 \cong \mathscr{A}_0$. Further, the component $\mathscr{B}_i$ is very close to the orthogonal complement of $\mathscr{A}_{N-1-i}$ in $\mathscr{A}_0$. More precisely, these two categories have semiorthogonal decompositions with the same components but with in general different gluing functors. This can be visualized by a picture.



The gray part of the picture corresponds to the initial Lefschetz decomposition, the columns correspond to its blocks, while the white part corresponds to the dual decomposition, the complementary columns correspond to the complementary subcategories of the dual Lefschetz decomposition. The number of rows is equal to the number of different components in the initial (and the dual) Lefschetz decomposition. In this example picture $\mathscr{A}_0 = \mathscr{A}_1 = \mathscr{A}_2 \neq \mathscr{A}_3 = \mathscr{A}_4 \neq \mathscr{A}_5 = \mathscr{A}_6 = \mathscr{A}_7 \neq \mathscr{A}_8 = \mathscr{A}_9$, and so one can say that the rows correspond to the "primitive parts" $(\mathscr{A}_3)^\perp_{\mathscr{A}_0}$, $(\mathscr{A}_5)^\perp_{\mathscr{A}_3}$, $(\mathscr{A}_8)^\perp_{\mathscr{A}_5}$, and $\mathscr{A}_8$ of all the categories in the picture, the length of the initial decomposition is $m = 10$, the length of the dual decomposition is $n = 17$, while the dimension of the ambient space is $N = 20$.

Note that $\mathscr{B}_i = 0$ if and only if $\mathscr{A}_{N-1-i} = \mathscr{A}_0$, so the number n of components in (3.6) equals N minus the number of components in (3.3) equal to $\mathscr{A}_0$.

In fact, the best (in many aspects) situation is when in the original Lefschetz decomposition (3.3) all components coincide $\mathscr{A}_0 = \mathscr{A}_1 = \cdots = \mathscr{A}_{m-1}$ (such Lefschetz decompositions are called rectangular). Then the HP dual Lefschetz decomposition is also rectangular, has the same components $\mathscr{B}_0 = \mathscr{B}_1 = \cdots = \mathscr{B}_{n-1} \cong \mathscr{A}_0$ and

$$n = N - m$$

(in particular in a picture analogous to the above the gray and the white parts are rectangles, which explains the name "rectangular"). Moreover, in this case for any $0 < r < N$ one has either $r \geq m$ or $N - r \geq n$, hence in decompositions (3.7) and (3.8) either the first or the second category has only one component $\mathscr{C}_L$ and nothing else. Then the other decomposition shows that the nontrivial component of the derived category of a linear section is equivalent to the derived category of the orthogonal linear section of the dual variety.

3.4. HP duality and noncommutative varieties. In general, the homologically projectively dual category $\mathscr{C} \subset \mathbf{D}^b(\mathsf{coh}(\mathscr{X}))$ defined by (3.4) need not be equivalent to $\mathbf{D}^b(\mathsf{coh}(Y))$ for an algebraic variety Y. In fact, only a few such cases are known — the linear duality, the duality for quadrics, the duality for Grassmannians $\mathsf{Gr}(2,4)$ and $\mathsf{Gr}(2,5)$, and the spinor variety $\mathbb{S}_5$ (see section 5).

One can get many additional interesting examples by allowing Y to be a noncommutative variety. Here a noncommutative variety can be understood in different ways. If one uses the most general sense — as a semiorthogonal component of the derived category of an algebraic variety — then tautologically the HP dual category $\mathscr{C}$ itself will provide a noncommutative HP dual variety. In fact, one can develop a theory of HP duality for noncommutative varieties in this sense and prove the same results (see [30]). However, in this most general form the semiorthogonal decompositions provided by the HP duality Theorem will not have an apparent geometric interpretation.

In fact, an interesting geometry arises in HP duality if the dual variety Y is close to a commutative variety. For example, it often happens that there is a (commutative) algebraic variety Y_0 with a map $g_0 : Y_0 \to \mathbb{P}(V^\vee)$, a sheaf of finite $\mathcal{O}_{Y_0}$-algebras $\mathcal{R}$ on Y_0 whose bounded derived category $\mathbf{D}^b(\mathsf{coh}(Y_0, \mathcal{R}))$ of coherent $\mathcal{R}$-modules on Y_0 is equivalent to the HP dual category $\mathscr{C}$ of X and such that the equivalence $\mathscr{C} \cong \mathbf{D}^b(\mathsf{coh}(Y_0, \mathcal{R}))$ is given by an appropriate object $\mathcal{E} \in \mathbf{D}^b(\mathsf{coh}(Q(X, Y_0), \mathcal{R}))$. Of course, one can easily allow here the variety X also to be noncommutative in the same sense. It is easy to modify all the definitions accordingly.

In section 5 we discuss examples showing that this generalization is meaningful. Among such examples are the Veronese–Clifford duality, the Grassmannian–Pfaffian duality, and their generalizations.

In fact, in some of these examples, the HP duality Theorem 3.5 still gives semiorthogonal decompositions for usual commutative varieties (even though the dual variety is noncommutative). Indeed, the sheaf of algebras $\mathcal{R}$ on Y_0 is frequently isomorphic to a matrix algebra on an open subset of Y_0, typically, on its smooth locus — in fact, in these cases the noncommutative variety $(Y_0, \mathcal{R})$ can be thought of as a categorical resolution of singularities of Y. In this situation, taking a subspace $L \subset V^\vee$ such that Y_{0L} is contained in that open subset, one gets $\mathbf{D}^b(\mathsf{coh}(Y_L)) = \mathbf{D}^b(\mathsf{coh}(Y_{0L}, \mathcal{R})) \cong \mathbf{D}^b(\mathsf{coh}(Y_{0L}))$.

4. Categorical resolutions of singularities

As it was explained above (and we will see in some of the examples below) in many cases the HP dual variety looks as a noncommutative (or categorical) resolution of singularities of a singular variety. So, a good notion of a categorical resolution is necessary for the theory.

4.1. The definition. If $\pi : \tilde{Y} \to Y$ is a resolution of singularities (in the usual sense), we have an adjoint pair of triangulated functors

$$R\pi_* : \mathbf{D}^b(\mathsf{coh}(\tilde{Y})) \to \mathbf{D}^b(\mathsf{coh}(Y))$$

and

$$L\pi^* : \mathbf{D}^{\mathsf{perf}}(Y) \to \mathbf{D}^b(\mathsf{coh}(\tilde{Y}))$$

(here $\mathbf{D}^{\mathsf{perf}}(Y)$ stands for the category of perfect complexes on Y). We axiomatize this situation in the following

Definition 4.1 (cf. [33, 39]). A categorical resolution of singularities of a scheme Y is a smooth triangulated category $\mathcal{T}$ and an adjoint pair of triangulated functors

$$\pi_* : \mathcal{T} \to \mathbf{D}^b(\mathsf{coh}(Y))$$

and

$$\pi^* : \mathbf{D}^{\mathsf{perf}}(Y) \to \mathcal{T}$$

such that $\pi_* \circ \pi^* \cong \mathsf{id}_{\mathbf{D}^{\mathsf{perf}}(Y)}$. In particular, the functor π^* is fully faithful.

We will not discuss the notion of smoothness for a triangulated category. In fact, for our purposes it is always enough to assume that $\mathcal{T}$ is an admissible Y-linear subcategory of $\mathbf{D}^b(\mathsf{coh}(\tilde{Y}))$ for a geometric resolution $\tilde{Y} \to Y$.

Let $(\mathcal{T}, \pi_*, \pi^*)$ and $(\mathcal{T}', \pi'_*, \pi'^*)$ be two categorical resolutions of Y. We will say that $\mathcal{T}$ dominates $\mathcal{T}'$ if there is a fully faithful functor $\epsilon : \mathcal{T}' \to \mathcal{T}$ such that $\pi'_* = \pi_* \circ \epsilon$. Clearly, this is compatible with the usual dominance relation between geometric resolutions — if a resolution $\pi : \tilde{Y} \to Y$ factors as $\tilde{Y} \xrightarrow{f} \tilde{Y}' \xrightarrow{\pi'} Y$ then the pullback functor $\epsilon := Lf^* : \mathbf{D}^b(\mathsf{coh}(\tilde{Y}')) \to \mathbf{D}^b(\mathsf{coh}(\tilde{Y}))$ is fully faithful and

$$R\pi_* \circ Lf^* = R\pi'_* \circ Rf_* \circ Lf^* \cong R\pi'_*.$$

Categorical resolutions have two advantages in comparison with geometric ones. First, if Y has irrational singularities the pullback functor for a geometric resolution is never fully faithful and so its derived category is not a categorical resolution in sense of Definition 4.1. However, it was shown in [39] that any separated scheme of finite type (even nonreduced) over a field of zero characteristic admits a categorical resolution.

The second advantage is that the dominance order for categorical resolutions is more flexible. For example, in many examples one can find a categorical resolution which is much smaller than any geometric resolution. There are strong indications that the Minimal Model Program on the categorical level may be much simpler than the classical one. In particular, we expect the following.

Conjecture 4.2 (cf. [7]). *For any quasiprojective scheme Y there exists a categorical resolution which is minimal with respect to the dominance order.*

4.2. Examples of categorical resolutions. As an evidence for the conjecture we will construct categorical resolutions which are presumably minimal.

Theorem 4.3 ([33]). *Let $f : \tilde{Y} \to Y$ be a resolution of singularities and let E be the exceptional divisor with $i : E \to \tilde{Y}$ being the embedding. Assume that the derived category $\mathbf{D}^b(\mathsf{coh}(E))$ has a left Lefschetz decomposition with respect to the conormal bundle $\mathcal{O}_E(-E)$:*

$$\mathbf{D}^b(\mathsf{coh}(E)) = \langle \mathscr{C}_{m-1}((m-1)E), \dots, \mathscr{C}_1(E), \mathscr{C}_0 \rangle, \tag{4.1}$$

which is Y-linear and has $Li^*(Lf^*(\mathbf{D}^{\mathsf{perf}}(Y))) \subset \mathscr{C}_0$. Then the functor Ri_* is fully faithful on subcategories $\mathscr{C}_k \subset \mathbf{D}^b(\mathsf{coh}(E))$ for $k > 0$, the subcategory

$$\tilde{\mathscr{C}} := \{F \in \mathbf{D}^b(\mathsf{coh}(\tilde{Y})) \mid Li^*(F) \in \mathscr{C}_0\} \tag{4.2}$$

is admissible in $\mathbf{D}^b(\mathsf{coh}(\tilde{Y}))$, and there is a semiorthogonal decomposition

$$\mathbf{D}^b(\mathsf{coh}(\tilde{Y})) = \langle Ri_*(\mathscr{C}_{m-1}((m-1)E)), \dots, Ri_*(\mathscr{C}_1(E)), \tilde{\mathscr{C}} \rangle. \tag{4.3}$$

Moreover, the functor $Lf^* : \mathbf{D}^{\mathsf{perf}}(Y) \to \mathbf{D}^b(\mathsf{coh}(\tilde{Y}))$ factors as a composition of a fully faithful functor $\pi^* : \mathbf{D}^{\mathsf{perf}}(Y) \to \tilde{\mathscr{C}}$ with the embedding $\gamma : \tilde{\mathscr{C}} \to \mathbf{D}^b(\mathsf{coh}(\tilde{Y}))$, and the functors $\pi_* := Rf_* \circ \gamma$ and π^* give $\tilde{\mathscr{C}}$ a structure of a categorical resolution of singularities of Y.

If $\mathscr{C}'_0 \subset \mathscr{C}_0 \subset \mathbf{D}^b(\mathsf{coh}(E))$ are two admissible Lefschetz extendable subcategories (with respect to the conormal bundle) then clearly by (4.2) the categorical resolution $\tilde{\mathscr{C}}'$ constructed from $\mathscr{C}'_0$ is a subcategory in the categorical resolution $\tilde{\mathscr{C}}$ constructed from $\mathscr{C}_0$. Moreover, if $\epsilon : \tilde{\mathscr{C}}' \to \tilde{\mathscr{C}}$ is the embedding functor then $\pi'_* = \pi_* \circ \epsilon$, so $\tilde{\mathscr{C}}$ dominates $\tilde{\mathscr{C}}'$. This shows that minimal categorical resolutions are related to minimal Lefschetz decompositions.

As an example of the application of the above Theorem consider the cone Y over a smooth projective variety $X \subset \mathbb{P}(V)$. Then $\tilde{Y} = \mathsf{Tot}_X(\mathcal{O}_X(-1))$, the total space of the line bundle $\mathcal{O}_X(-1) = \mathcal{O}_{\mathbb{P}(V)}(-1)_{|X}$, is a geometric resolution of Y. The exceptional divisor of the natural morphism $f : \tilde{Y} \to Y$ then identifies with the zero section of the total space, $E = X$, and the conormal bundle identifies with $\mathcal{O}_X(1)$. So, a left Lefschetz decomposition of $\mathbf{D}^b(\mathsf{coh}(X))$ with respect to $\mathcal{O}_X(1)$ gives a categorical resolution of the cone Y over X.

Example 4.4. Take $X = \mathbb{P}^3$ with the double Veronese embedding $f : \mathbb{P}^3 \to \mathbb{P}^9$, so that $f^*\mathcal{O}_{\mathbb{P}^9}(1) = \mathcal{O}_{\mathbb{P}^3}(2)$, and a left Lefschetz decomposition

$$\mathbf{D}^b(\mathsf{coh}(\mathbb{P}^3)) = \langle \mathscr{C}_1(-2), \mathscr{C}_0 \rangle \quad \text{with } \mathscr{C}_0 = \mathscr{C}_1 = \langle \mathcal{O}_{\mathbb{P}^3}(-1), \mathcal{O}_{\mathbb{P}^3} \rangle.$$

Then the category $\tilde{\mathscr{C}} := \{F \in \mathbf{D}^b(\mathsf{coh}(\mathsf{Tot}_{\mathbb{P}^3}(\mathcal{O}_{\mathbb{P}^3}(-2)))) \mid Li^*F \in \langle \mathcal{O}_{\mathbb{P}^3}(-1), \mathcal{O}_{\mathbb{P}^3} \rangle\}$ is a categorical resolution of the Veronese cone, which is significantly smaller than the usual geometric resolution. It is expected to be minimal.

4.3. Crepancy of categorical resolutions. Crepancy is an important property of a resolution which in the geometric situation ensures its minimality. A resolution $f : \tilde{Y} \to Y$ is crepant if the relative canonical class $K_{\tilde{Y}/Y}$ is trivial. There is an analogue of crepancy for categorical resolutions. In fact, there are two such analogues.

Definition 4.5 ([33]). A categorical resolution $(\mathcal{T}, \pi_*, \pi^*)$ of a scheme Y is weakly crepant if the functor $\pi^* : \mathbf{D}^{\mathsf{perf}}(Y) \to \mathcal{T}$ is simultaneously left and right adjoint to the functor $\pi_* : \mathcal{T} \to \mathbf{D}^b(\mathsf{coh}(Y))$.

By Grothendieck duality, the right adjoint of the derived pushforward functor Rf_* : $\mathbf{D}^b(\mathsf{coh}(\tilde{Y})) \to \mathbf{D}^b(\mathsf{coh}(Y))$ is given by $f^!(F) = Lf^*(F) \otimes \mathcal{O}_{\tilde{Y}}(K_{\tilde{Y}/Y})$, so for a geometric resolution crepancy and weak crepancy are equivalent.

Definition 4.6 ([33]). A categorical resolution $(\mathcal{T}, \pi_*, \pi^*)$ of a scheme Y is strongly crepant if the relative Serre functor of $\mathcal{T}$ over $\mathbf{D}^b(\mathsf{coh}(Y))$ is isomorphic to the identity.

Again, Grothendieck duality implies that for a geometric resolution crepancy and strong crepancy are equivalent. Moreover, it is not so difficult to show that strong crepancy of a categorical resolution implies its weak crepancy, but the converse is not true in general. To see this one can analyze the weak and strong crepancy of categorical resolutions provided by Theorem 4.3.

Proposition 4.7. *In the setup of Theorem* 4.3 *assume that the scheme Y is Gorenstein and $K_{\tilde{Y}/Y} = (m-1)E$, where m is the length of the left Lefschetz decomposition* (4.1)*. The corresponding categorical resolution $\tilde{\mathscr{C}}$ of Y is weakly crepant if and only if*

$$Li^*(Lf^*(\mathbf{D}^{\mathsf{perf}}(Y))) \subset \mathscr{C}_{m-1}. \tag{4.4}$$

Furthermore, $\tilde{\mathscr{C}}$ is strongly crepant if and only if (4.1) *is rectangular, i.e.*

$$\mathscr{C}_{m-1} = \cdots = \mathscr{C}_1 = \mathscr{C}_0. \tag{4.5}$$

So, starting from a nonrectangular Lefschetz decomposition it is easy to produce an example of a weakly crepant categorical resolution which is not strongly crepant.

Example 4.8. Take $X = Q^3 \subset \mathbb{P}^4$ and let Y be the cone over X (i.e. a 4-dimensional quadratic cone). Then the left Lefschetz collection

$$\mathbf{D}^b(\mathsf{coh}(X)) = \langle \mathscr{C}_2(-2), \mathscr{C}_1(-1), \mathscr{C}_0 \rangle \qquad \text{with } \mathscr{C}_0 = \langle \mathsf{S}, \mathcal{O}_X \rangle, \mathscr{C}_1 = \mathscr{C}_2 = \langle \mathcal{O}_X \rangle$$

(S is the spinor bundle) gives a weakly crepant categorical resolution $\tilde{\mathscr{C}}$ of Y which is not strongly crepant. In fact, if $q : \mathsf{Tot}_X(\mathcal{O}_X(-1)) \to X$ is the canonical projection, the vector bundle $q^*\mathsf{S}$ is a spherical object in $\tilde{\mathscr{C}}$ and the relative Serre functor is isomorphic to the corresponding spherical twist.

4.4. Further questions. Of course, the central question is Conjecture 4.2. Theorem 4.3 shows that it is closely related to the question of existence of minimal Lefschetz decompositions.

Another interesting question is to find new methods of construction of minimal categorical resolutions. An interesting development in this direction is the work [1] in which a notion of a wonderful resolution of singularities (an analogue of wonderful compactifications) is introduced and it is shown that a wonderful resolution gives rise to a weakly crepant categorical resolution. This can be viewed as an advance on the first part of Proposition 4.7. It would be very interesting to find a generalization of the second part of this Proposition in the context of wonderful resolutions.

Another aspect is to find explicit constructions of minimal resolutions for interesting varieties, such as Pfaffian varieties for example. Some of these arise naturally in the context of HP duality as we will see later.

5. Examples of homological projective duality

If an HP duality for two varieties X and Y is proved, one gets as a consequence an identification of the nontrivial components of the derived categories of linear sections of X and Y. Because of that it is clear that such a result is a very strong statement and is usually not so easy to prove. In this section we list several examples of HP duality. We assume that $\mathsf{char}\,\mathsf{k} = 0$ in this section.

5.1. Linear duality. Let $X = \mathbb{P}_S(E)$ be a projectivization of a vector bundle E on a scheme S and assume that the map $f : X \to \mathbb{P}(V)$ is *linear on fibers* of X over S. In other words, we assume that f is induced by an embedding of vector bundles $E \to V \otimes \mathcal{O}_S$ on S. In this case the line bundle $\mathcal{O}_X(1) = f^*\mathcal{O}_{\mathbb{P}(V)}(1)$ is a Grothendieck line bundle for X over S. By Theorem 2.4 we have a rectangular Lefschetz decomposition of $\mathbf{D}^b(\mathsf{coh}(X))$ of length $m = \mathsf{rk}(E)$ with blocks

$$\mathscr{A}_0 = \mathscr{A}_1 = \cdots = \mathscr{A}_{m-1} = p^*(\mathbf{D}^b(\mathsf{coh}(S))),$$

where $p : X \to S$ is the projection. So, we are in the setup of HP duality and one can ask what the dual variety is?

The answer turns out to be given by a projectivization of another vector bundle over S. Define $E^\perp$ as the kernel of the dual morphism

$$E^\perp := \mathsf{Ker}(V^\vee \otimes \mathcal{O}_S \to E^\vee).$$

The projectivization $\mathbb{P}_S(E^\perp)$ comes with a natural morphism $g : \mathbb{P}_S(E^\perp) \to \mathbb{P}(V^\vee)$ and Theorem 2.4 provides $\mathbb{P}_S(E^\perp)$ with a rectangular Lefschetz decomposition of length $N-m$ with blocks $\mathscr{B}_0 = \mathscr{B}_1 = \cdots = \mathscr{B}_{N-m-1} = q^*(\mathbf{D}^b(\mathsf{coh}(S)))$, where $q : \mathbb{P}_S(E^\perp) \to S$ is the projection.

Theorem 5.1 ([29]). *The projectivizations $X = \mathbb{P}_S(E)$ and $Y = \mathbb{P}_S(E^\perp)$ with their canonical morphisms to $\mathbb{P}(V)$ and $\mathbb{P}(V^\vee)$ and the above Lefschetz decompositions are homologically projectively dual to each other.*

The picture visualizing this duality is very simple:

with m gray boxes and $N - m$ white boxes.

In the very special case of $S = \mathsf{Spec}\,\mathsf{k}$ the bundle E is just a vector space and the variety X is a (linearly embedded) projective subspace $\mathbb{P}(E) \subset \mathbb{P}(V)$. Then the HP-dual variety is the orthogonal subspace $\mathbb{P}(E^\perp) \subset \mathbb{P}(V^\vee)$. In particular, the dual of the space $\mathbb{P}(V)$ itself with respect to its identity map is the empty set.

5.2. Quadrics. There are two ways to construct a smooth quadric: one — as a smooth hypersurface of degree 2 in a projective space, and the other — as a double covering of a projective space ramified in a smooth quadric hypersurface. These representations interchange in a funny way in HP duality.

Denote by S the spinor bundle on an odd dimensional quadric or one of the spinor bundles on the even dimensional quadric.

Theorem 5.2.

(1) *If $X = Q^{2m} \subset \mathbb{P}^{2m+1}$ with Lefschetz decomposition given by*

$$\mathscr{A}_0 = \mathscr{A}_1 = \langle \mathsf{S}_X, \mathcal{O}_X \rangle, \qquad \mathscr{A}_2 = \mathscr{A}_3 = \cdots = \mathscr{A}_{2m-1} = \langle \mathcal{O}_X \rangle \tag{5.1}$$

then the HP dual variety is the dual quadric $Y = Q^\vee \subset \check{\mathbb{P}}^{2m+1}$ with the same Lefschetz decomposition.

(2) *If $X = Q^{2m-1} \subset \mathbb{P}^{2m}$ with Lefschetz decomposition given by*

$$\mathscr{A}_0 = \langle \mathsf{S}_X, \mathcal{O}_X \rangle, \qquad \mathscr{A}_1 = \mathscr{A}_2 = \cdots = \mathscr{A}_{2m-2} = \langle \mathcal{O}_X \rangle \tag{5.2}$$

then the HP dual variety is the double covering $Y \to \check{\mathbb{P}}^{2m}$ ramified in the dual quadric $Q^\vee \subset \check{\mathbb{P}}^{2m}$ with Lefschetz decomposition (5.1)

(3) *If $X = Q^{2m-1} \to \mathbb{P}^{2m-1}$ is the double covering ramified in a quadric $\bar{Q} \subset \mathbb{P}^{2m-1}$ with Lefschetz decomposition* (5.2) *then the HP dual variety is the double covering $Y \to \check{\mathbb{P}}^{2m-1}$ ramified in the dual quadric $\bar{Q}^\vee \subset \check{\mathbb{P}}^{2m-1}$ with the same Lefschetz decomposition.*

5.3. Veronese–Clifford duality. Let W be a vector space of dimension n and $V = S^2W$ its symmetric square. We take $X = \mathbb{P}(W)$ and consider its double Veronese embedding $f : \mathbb{P}(W) \to \mathbb{P}(V)$. Then $f^*\mathcal{O}_{\mathbb{P}(V)}(1) = \mathcal{O}_{\mathbb{P}(W)}(2)$. Beilinson's collection (2.6) on $\mathbb{P}(W)$ can be considered as a Lefschetz decomposition (with respect to $\mathcal{O}_{\mathbb{P}(W)}(2)$) of $\mathbf{D}^b(\mathsf{coh}(\mathbb{P}(W)))$ with $\lfloor n/2 \rfloor$ blocks equal to

$$\mathscr{A}_0 = \mathscr{A}_1 = \cdots = \mathscr{A}_{\lfloor n/2 \rfloor - 1} := \langle \mathcal{O}_{\mathbb{P}(W)}, \mathcal{O}_{\mathbb{P}(W)}(1) \rangle,$$

and if n is odd one more block

$$\mathscr{A}_{\lfloor n/2 \rfloor} := \langle \mathcal{O}_{\mathbb{P}(W)} \rangle.$$

The universal hyperplane section $\mathscr{X}$ of X is nothing but the universal quadric in $\mathbb{P}(W)$ over the space $\mathbb{P}(V^\vee) = \mathbb{P}(S^2W^\vee)$ of all quadrics. Then the quadratic fibration formula of Theorem 2.7 gives an equivalence of the HP dual category $\mathscr{C}$ with the derived category $\mathbf{D}^b(\mathsf{coh}(\mathbb{P}(V^\vee), \mathcal{C}\ell_0))$ of coherent sheaves of modules over the even part of the universal Clifford algebra

$$\mathcal{C}\ell_0 = \mathcal{O}_{\mathbb{P}(S^2W^\vee)} \oplus \Lambda^2 W \otimes \mathcal{O}_{\mathbb{P}(S^2W^\vee)}(-1) \oplus \ldots,$$

on the space $\mathbb{P}(S^2W^\vee)$ of quadrics. We will consider the pair $(\mathbb{P}(S^2W^\vee), \mathcal{C}\ell_0)$ as a noncommutative variety and call it the Clifford space.

Theorem 5.3 (Veronese–Clifford duality, [31]). *The homological projective dual of the projective space $X = \mathbb{P}(W)$ in the double Veronese embedding $\mathbb{P}(W) \to \mathbb{P}(S^2W)$ is the Clifford space $Y = (\mathbb{P}(S^2W^\vee), \mathscr{C}\ell_0)$.*

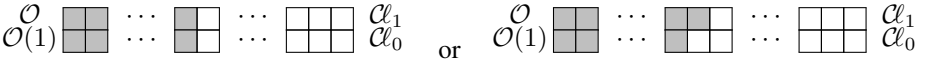
The HP dual Lefschetz decomposition of the Clifford space is given by the full exceptional collection

$$\mathbf{D}^b(\mathsf{coh}(\mathbb{P}(S^2W^\vee, \mathscr{C}\ell_0))) = \langle \mathscr{C}\ell_{1-n^2}, \mathscr{C}\ell_{2-n^2}, \dots, \mathscr{C}\ell_{-1}, \mathscr{C}\ell_0 \rangle,$$

where

$$\mathscr{C}\ell_1 = W \otimes \mathcal{O}_{\mathbb{P}(S^2W^\vee)} \oplus \Lambda^3 W \otimes \mathcal{O}_{\mathbb{P}(S^2W^\vee)}(-1) \oplus \dots$$

is the odd part of the Clifford algebra and $\mathscr{C}\ell_{k-2} = \mathscr{C}\ell_k \otimes \mathcal{O}_{\mathbb{P}(S^2W^\vee)}(-1)$ for each $k \in \mathbb{Z}$. The picture visualizing this duality is:



n even $\qquad$ n odd

For even n it has $n/2$ gray columns and $n^2/2$ white columns, and for odd n it has $(n-1)/2$ gray columns, one mixed column, and $(n^2-1)/2$ white columns.

5.4. Grassmannian–Pfaffian duality. The most interesting series of examples is provided by Grassmannians $\mathsf{Gr}(2, m)$ of two-dimensional subspaces in an m-dimensional vector space.

Let W be a vector space of dimension m and let $V = \Lambda^2 W$, the space of bivectors. The group $\mathsf{GL}(W)$ acts on the projective space $\mathbb{P}(\Lambda^2 W)$ with orbits indexed by the rank of a bivector which is always even and ranges from 2 to $2\lfloor m/2 \rfloor$. We denote by $\mathsf{Pf}(2k, W)$ the closure of the orbit consisting of bivectors of rank $2k$ and call it the k-th Pfaffian variety. Clearly, the smallest orbit $\mathsf{Pf}(2, W)$ is smooth and coincides with the Grassmannian $\mathsf{Gr}(2, W)$ in its Plücker embedding. Another smooth Pfaffian variety is the maximal one — $\mathsf{Pf}(2\lfloor m/2 \rfloor, W) = \mathbb{P}(\Lambda^2 W)$. All the intermediate Pfaffians are singular with $\mathsf{sing}(\mathsf{Pf}(2k, W)) = \mathsf{Pf}(2k-2, W)$. The submaximal Pfaffian variety $\mathsf{Pf}(2\lfloor m/2 \rfloor - 2, W^\vee)$ of the dual space is classically projectively dual to the Grassmannian $\mathsf{Gr}(2, W)$. This suggests a possible HP duality between them.

To make a precise statement we should choose a Lefschetz decomposition of $\mathbf{D}^b(\mathsf{coh}(\mathsf{Gr}(2, W)))$. A naive choice is to take Kapranov's collection (2.7). It can be considered as a Lefschetz decomposition on $X := \mathsf{Gr}(2, m)$ with $m-1$ blocks

$$\mathscr{A}_0 = \langle \mathcal{O}_X, \mathcal{U}_X^\vee, \dots, S^{m-2}\mathcal{U}_X^\vee \rangle,\ \mathscr{A}_1 = \langle \mathcal{O}_X, \mathcal{U}_X^\vee, \dots, S^{m-3}\mathcal{U}_X^\vee \rangle,\ \dots,\ \mathscr{A}_{m-2} = \langle \mathcal{O}_X \rangle.$$

However, it is very far from being minimal. It turns out that a reasonable result can be obtained for another Lefschetz decomposition

$$\mathbf{D}^b(\mathsf{coh}(\mathsf{Gr}(2, m)) = \langle \mathscr{A}_0, \mathscr{A}_1(1), \dots, \mathscr{A}_{m-1}(m-1) \rangle$$

with

$$\mathscr{A}_0 = \dots = \mathscr{A}_{m-1} = \langle \mathcal{O}_X, \mathcal{U}_X^\vee, \dots, S^{(m-1)/2}\mathcal{U}_X^\vee \rangle. \tag{5.3}$$

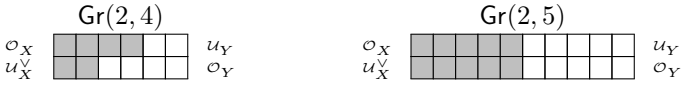
if m is odd, and with

$$\begin{aligned} \mathscr{A}_0 = \dots = \mathscr{A}_{m/2-1} &= \langle \mathcal{O}_X, \mathcal{U}_X^\vee, \dots, S^{m/2-1}\mathcal{U}_X^\vee \rangle, \\ \mathscr{A}_{m/2} = \dots = \mathscr{A}_{m-1} &= \langle \mathcal{O}_X, \mathcal{U}_X^\vee, \dots, S^{m/2-2}\mathcal{U}_X^\vee \rangle, \end{aligned} \tag{5.4}$$

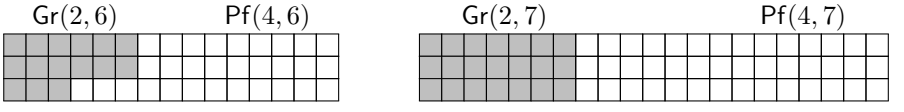
if m is even.

Conjecture 5.4. *The HP dual of the Grassmannian* $\mathsf{Gr}(2, W)$ *with Lefschetz decomposition* (5.4) (*or* (5.3) *depending on the parity of* $m = \dim W$) *is given by a minimal categorical resolution of the submaximal Pfaffian* $\mathsf{Pf}(2\lfloor m/2 \rfloor - 2, W^\vee)$. *When* m *is odd, this resolution is strongly crepant.*

This conjecture is proved for $m \le 7$ in [28]. In fact, for $m = 2$ and $m = 3$ one has $\mathsf{Gr}(2, W) = \mathbb{P}(\Lambda^2 W)$ and linear duality applies. For $m = 4$ and $m = 5$ the submaximal Pfaffian $\mathsf{Pf}(2, W^\vee)$ coincides with the Grassmannian, and the above duality is the duality for Grassmannians:



For $m = 6$ and $m = 7$ the submaximal Pfaffian $Y = \mathsf{Pf}(4, W^\vee)$ is singular, but its appropriate categorical resolutions can be constructed by Theorem 4.3. It turns out that these resolutions indeed are HP dual to the corresponding Grassmannians:



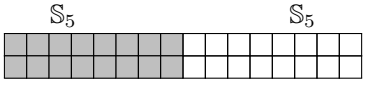
For $m \ge 8$ this construction of a categorical resolution does not work. However it is plausible that the Pfaffians have wonderful resolutions of singularities, so a development of [1] may solve the question.

5.5. The spinor duality. Let W be a vector space of even dimension $2m$ and $q \in S^2 W^\vee$ a nondegenerate quadratic form. The isotropic Grassmannian of m-dimensional subspaces in W has two connected components, abstractly isomorphic to each other and called spinor varieties $\mathbb{S}_m$. These are homogeneous spaces of the spin group $\mathsf{Spin}(W)$ with the embedding into $\mathbb{P}(\Lambda^m W)$ given by the square of the generator of the Picard group, while the generator itself gives an embedding into the projectivization $\mathbb{P}(V)$ of a half-spinor representation V (of dimension 2^{m-1}) of $\mathsf{Spin}(W)$. For small m the spinor varieties are very simple (because the spin-group simplifies): in fact, $\mathbb{S}_1$ is a point, $\mathbb{S}_2 = \mathbb{P}^1$, $\mathbb{S}_3 = \mathbb{P}^3$, and $\mathbb{S}_4 = Q^6$. The first interesting example is $\mathbb{S}_5$.

Theorem 5.5 ([27]). *The spinor variety* $X = \mathbb{S}_5$ *has a Lefschetz decomposition*

$$\mathbf{D}^b(\mathsf{coh}(X)) = \langle \mathscr{A}_0, \mathscr{A}_1(1), \dots, \mathscr{A}_7(7) \rangle \quad \textit{with} \quad \mathscr{A}_0 = \dots = \mathscr{A}_7 = \langle \mathcal{O}_X, \mathcal{U}_5^\vee \rangle. \tag{5.5}$$

The HP dual variety is the same spinor variety $Y = \mathbb{S}_5$.



5.6. Incomplete dualities. It is often quite hard to give a full description of the HP dual variety. On the other hand, there is sometimes an open dense subset $U \subset \mathbb{P}(V^\vee)$ for which there is a description of the category $\mathscr{C}_U$ obtained by a base change $U \to \mathbb{P}(V^\vee)$ from the HP dual category $\mathscr{C}$. If $\mathbf{D}^b(\mathsf{coh}(Y_U))$ is a (noncommutative) variety such that $Y_U \cong \mathscr{C}_U$ (a U-linear equivalence), we will say that Y_U is the HP dual of X over U, or an incomplete HP dual variety.

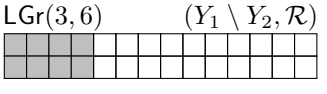
Proposition 5.6. *If Y_U is an HP dual of X over an open subset $U \subset \mathbb{P}(V^\vee)$ then the semiorthogonal decompositions* (3.7) *and* (3.8) *hold for any subspace $L \subset V^\vee$ such that $\mathbb{P}(L) \subset U$ and the varieties X_L and Y_L have expected dimensions.*

There are several examples of HP duality when only an incomplete dual variety is known. Below we discuss two of them. Let W be a vector space of dimension 6 with a symplectic form ω, and $X = \mathsf{LGr}(3, W) \subset \mathbb{P}^{13}$ the corresponding Lagrangian Grassmannian. The classical projectively dual variety $Y_1 := X^\vee \subset \check{\mathbb{P}}^{13}$ is a quartic hypersurface which is singular along a 9-dimensional variety $Y_2 \subset Y_1$. One can check that X has a rectangular Lefschetz decomposition (see [48])

$$\begin{aligned} &\mathbf{D}^b(\mathsf{coh}(X)) = \langle \mathscr{A}_0, \mathscr{A}_1(1), \mathscr{A}_2(2), \mathscr{A}_3(3)\rangle \quad \text{with} \\ &\mathscr{A}_0 = \mathscr{A}_1 = \mathscr{A}_2 = \mathscr{A}_3 = \langle \mathcal{O}_X, \mathcal{U}_X^\vee\rangle. \end{aligned} \tag{5.6}$$

The HP dual variety in this case is described only over the open set $U = \check{\mathbb{P}}^{13} \setminus Y_2$, see [27]. For this a morphism $\pi : \tilde{Y} \to Y_1$ which is a nondegenerate conic bundle over $Y_1 \setminus Y_2$ is constructed in *loc. cit.* Let $\mathcal{R}$ be the associated quaternion algebra on $Y_1 \setminus Y_2$.

Theorem 5.7 ([27]). *If $X = \mathsf{LGr}(3, 6) \subset \mathbb{P}^{13}$ with Lefschetz decomposition* (5.6) *then the noncommutative variety $(Y_1 \setminus Y_2, \mathcal{R})$ is the HP dual of X over $\check{\mathbb{P}}^{13} \setminus Y_2$.*



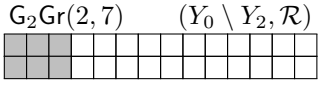
Another example is related to the simple algebraic group G_2. Let X be the orbit of the highest weight vector in the projectivization $\mathbb{P}^{13} = \mathbb{P}(V)$ of the adjoint representation V of G_2. Then X can also be realized as the zero locus of a global section of the vector bundle $\Lambda^4(W/\mathcal{U})$ on the Grassmannian $\mathsf{Gr}(2, W)$ for a 7-dimensional fundamental representation W of G_2 corresponding to a generic 3-form $\lambda \in \Lambda^3 W^\vee$. By that reason we use the notation $\mathsf{G}_2\mathsf{Gr}(2, W)$ for X.

The classical projectively dual variety $Y_1 := X^\vee \subset \check{\mathbb{P}}^{13}$ is a sextic hypersurface which is singular along a 10-dimensional variety $Y_2 \subset Y_1$. One can check that X has a rectangular Lefschetz decomposition

$$\mathbf{D}^b(\mathsf{coh}(X)) = \langle \mathscr{A}_0, \mathscr{A}_1(1), \mathscr{A}_2(2)\rangle \quad \text{with} \quad \mathscr{A}_0 = \mathscr{A}_1 = \mathscr{A}_2 = \langle \mathcal{O}_X, \mathcal{U}_X^\vee\rangle. \tag{5.7}$$

As in the previous case, the HP dual variety is described only over the open set $U = \check{\mathbb{P}}^{13} \setminus Y_2$, see [27]. A morphism $\pi : \tilde{Y} \to Y_0$ to the double covering $Y_0 \to \check{\mathbb{P}}^{13}$ ramified in Y_1 which is a Severi–Brauer variety with fiber $\mathbb{P}^2$ over $Y_0 \setminus Y_2$ is constructed in *loc. cit.* Let $\mathcal{R}$ be the associated Azumaya algebra on $Y_0 \setminus Y_2$.

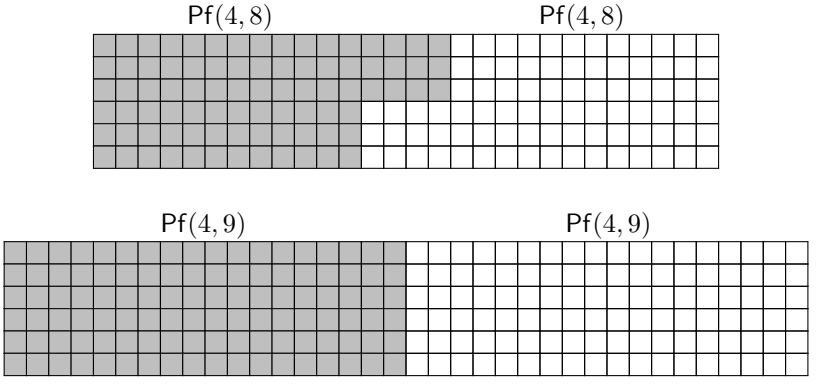
Theorem 5.8 ([27]). *If $X = \mathsf{G}_2\mathsf{Gr}(2, 7)$ with Lefschetz decomposition* (5.7) *then the noncommutative variety $(Y_0 \setminus Y_2, \mathcal{R})$ is the HP dual of X over $\check{\mathbb{P}}^{13} \setminus Y_2$.*



5.7. Conjectures. Note that $\mathsf{Gr}(2, W) = \mathsf{Pf}(2, W)$. This suggests a generalization of the Grassmannian–Pfaffian duality to higher Pfaffians.

Conjecture 5.9. *For any k there is an HP duality between appropriate minimal categorical resolutions of the Pfaffians $\mathsf{Pf}(2k, W)$ and $\mathsf{Pf}(2(\lfloor m/2 \rfloor - k), W^\vee)$. When $m = \dim W$ is odd these resolutions are strongly crepant.*

Below are the expected pictures for the HP duality for $\mathsf{Pf}(4, 8)$ and for $\mathsf{Pf}(4, 9)$:



It is also expected that there is a generalization of the Veronese–Clifford duality. Consider a vector space W of dimension n and its symmetric square $V = S^2W$. The group $\mathsf{GL}(W)$ acts on the projective space $\mathbb{P}(V) = \mathbb{P}(S^2W)$ with orbits indexed by the rank of a tensor. We denote by $\Sigma(k, W) \subset \mathbb{P}(S^2W)$ the closure of the orbit consisting of symmetric tensors of rank k. The smallest orbit $\Sigma(1, W)$ is smooth and coincides with the double Veronese embedding of $\mathbb{P}(W)$. On the other hand, $\Sigma(n, W) = \mathbb{P}(S^2W)$ is also smooth. All the intermediate varieties $\Sigma(k, W)$ are singular with $\mathsf{sing}(\Sigma(k, W)) = \Sigma(k-1, W)$. The classical projective duality acts on these varieties by $\Sigma(k, W)^\vee = \Sigma(n-k, W^\vee)$. However, the HP duality is organized in a much more complicated way.

Besides $\Sigma(k, W)$ itself one can consider its modifications:

- the Clifford modification $(\Sigma(k, W), \mathcal{C}\ell_0)$ for the natural sheaf of even parts of Clifford algebras on it, and
- (for even k) the double covering $\tilde{\Sigma}(k, W)$ of $\Sigma(k, W)$ corresponding to the central subalgebra in $\mathcal{C}\ell_0$ as in (2.14),

and their minimal categorical resolutions. It seems that HP duality interchanges in a complicated way modifications of different type. For example, besides the original Veronese–Clifford duality between $\Sigma(1, n)$ and $(\Sigma(n, n), \mathcal{C}\ell_0)$ there are strong indications that (the minimal resolution of) $\Sigma(2, 4)$ is HP dual to (the minimal resolution of) the double covering $\tilde{\Sigma}(4, 4)$ of $\Sigma(4, 4) = \mathbb{P}^9$ (see [15]), (the minimal resolution of) $\Sigma(2, 5)$ is HP dual to (the minimal resolution of) the double covering $\tilde{\Sigma}(4, 5)$ of $\Sigma(4, 5)$ (see [14]), while (the minimal resolution of) the double covering $\tilde{\Sigma}(2, n)$ of $\Sigma(2, n)$ is HP dual to (the minimal resolution of) $\Sigma(n-1, n)$ for all n (this can be easily deduced from the linear duality).

6. Varieties of small dimension

Let us list what is known about semiorthogonal decompositions of smooth projective varieties by dimension. In this section we assume that $\mathsf{k} = \mathbb{C}$.

6.1. Curves. Curves are known to have no nontrivial semiorthogonal decompositions with the only exception of $\mathbb{P}^1$ (for which every semiorthogonal decomposition coincides with the Beilinson decomposition up to a twist), see [44].

6.2. Surfaces. For surfaces the situation is more complicated. Of course, by the blowup formula any surface has a semiorthogonal decomposition with several exceptional objects and the derived category of a minimal surface as components. In particular, any rational surface has a full exceptional collection. Moreover, for $\mathbb{P}^2$ it is known that any full exceptional collection can be obtained from Beilinson's collection by mutations (which are related to Markov numbers and toric degenerations of $\mathbb{P}^2$). For other del Pezzo surfaces all exceptional objects have been classified [23], and moreover, three-blocks exceptional collections were constructed [18], but the complete picture is not known.

For minimal ruled surfaces, of course there is a semiorthogonal decomposition into two copies of the derived category of the curve which is the base of the ruling.

For surfaces of Kodaira dimension 0 it is well known that there are no nontrivial semiorthogonal decompositions for K3 and abelian surfaces. The same was proved for bielliptic surfaces in [21]. For Enriques surfaces there may be an exceptional collection of line bundles of length up to 10 (see [49]), and for so-called nodal Enriques surfaces the complementary component is related to the Artin–Mumford quartic double solid [15].

For surfaces of Kodaira dimension 1 with $p_q > 0$ there are no semiorthogonal decompositions by [21].

Finally, for surfaces of general type there is an unexpectedly rich theory of semiorthogonal decompositions. In fact, for many surfaces of general type with $p_g = q = 0$ (the classical Godeaux surface, the Beauville surface, the Burniat surfaces, the determinantal Barlow surface, some fake projective planes) exceptional collections of length equal to the rank of the Grothendieck group have been constructed in [2, 4, 5, 10, 12, 13]. The collections, however, are not full. The complementary components have finite (or even zero) Grothendieck group and trivial Hochschild homology and by that reason they are called quasiphantom or phantom categories. The phantoms cannot be detected by additive invariants, but one can use Hochschild cohomology instead, see [38].

An interesting feature here is that the structure of the constructed exceptional collections resembles very much the structure of exceptional collections of del Pezzo surfaces with the same K^2. The only (but a very important) difference is that whenever there is a Hom-space between exceptional bundles on del Pezzo, the corresponding exceptional bundles on the surface of general type have Ext^2-space. This seemingly small difference, however, has a very strong effect on the properties of the category. See more details in *loc. cit.*

6.3. Fano 3-folds. For derived categories of threefolds (and higher dimensional varieties) there are no classification results (as there is no classification of threefolds). Of course, as it already was mentioned for varieties with trivial (or globally generated) canonical class there are no nontrivial decompositions. So, from now on we will discuss Fano varieties.

In dimension 3 all Fano varieties were classified in the works of Fano, Iskovskikh and Mukai. All Fano 3-folds with Picard number greater than 1 are either the blowups of other Fano varieties with centers in points and smooth curves (and then their derived category reduces to the derived category of a Fano 3-fold with smaller Picard number), or conic bundles over rational surfaces (see Tables 12.3–12.6 of [17]). For conic bundles one can use the quadratic bundle formula (Theorem 2.7). It gives a semiorthogonal decomposition with several exceptional objects and the derived category of sheaves of modules over the even part of the Clifford algebra on the base of the bundle.

If the Picard number is 1, the next discrete invariant of a Fano 3-fold to look at is the index, i.e. the maximal integer dividing the canonical class. By Fujita's Theorem the only Fano 3-folds of index greater than 2 are $\mathbb{P}^3$ and Q^3. Their derived categories are well understood, so let us turn to 3-folds of index 2 and 1.

For a Fano 3-fold Y of index 2 the pair of line bundles $(\mathcal{O}_Y, \mathcal{O}_Y(1))$ is exceptional and gives rise to a semiorthogonal decomposition

$$\mathbf{D}^b(\mathsf{coh}(Y)) = \langle \mathscr{B}_Y, \mathcal{O}_Y, \mathcal{O}_Y(1) \rangle. \tag{6.1}$$

The component $\mathscr{B}_Y$ is called the nontrivial component of $\mathbf{D}^b(\mathsf{coh}(Y))$.

A similar decomposition can be found for a Fano 3-fold X of index 1 if its degree $d_X := (-K_X)^3$ is not divisible by 4 (the degree of a 3-fold of index 1 is always even). By a result of Mukai [43] if $d_X > 2$ on such X there is an exceptional vector bundle $\mathcal{E}_X$ of rank 2 with $c_1(\mathcal{E}_X) = K_X$, which is moreover orthogonal to the structure sheaf of X. In other words, $(\mathcal{E}_X, \mathcal{O}_X)$ is an exceptional pair and there is a semiorthogonal decomposition

$$\mathbf{D}^b(\mathsf{coh}(X)) = \langle \mathscr{A}_X, \mathcal{E}_X, \mathcal{O}_X \rangle. \tag{6.2}$$

The component $\mathscr{A}_X$ is called the nontrivial component of $\mathbf{D}^b(\mathsf{coh}(X))$.

It is rather unexpected that the nontrivial parts $\mathscr{B}_Y$ and $\mathscr{A}_X$ for a Fano 3-fold Y of index 2 and degree $d_Y := (-K_Y/2)^3$ and for a Fano 3-fold X of index 1 and degree $d_X = 4d_Y + 2$ have the same numerical characteristics, and are, moreover, expected to belong to the same deformation family of categories. In fact, this expectation is supported by the following result. Recall that the degree of a Fano 3-fold of index 2 with Picard number 1 satisfies $1 \le d \le 5$, while the degree of a Fano 3-fold of index 1 with Picard number 1 is even and satisfies $2 \le d \le 22$, $d \ne 20$. So there are actually 5 cases to consider.

Theorem 6.1 ([34]). *For $3 \le d \le 5$ each category $\mathscr{B}_{Y_d}$ is equivalent to some category $\mathscr{A}_{X_{4d+2}}$ and vice versa.*

See *loc. cit.* for a precise statement. In fact, for $d = 5$ the category is rigid and is equivalent to the derived category of representations of the quiver with 2 vertices and 3 arrows from the first vertex to the second (this follows from the construction of explicit exceptional collections in the derived categories of Y_5 and X_{22}, see [45] and [24]). Further, for $d = 4$ each of the categories $\mathscr{B}_{Y_4}$ and $\mathscr{A}_{X_{18}}$ is equivalent to the derived category of a curve of genus 2, and moreover, each smooth curve appears in both pictures. This follows from HP duality for the double Veronese embedding of $\mathbb{P}^5$ and from HP duality for G_2 Grassmannian respectively (Theorem 5.8). Finally, for $d = 3$ no independent description of the category in question is known, but the HP duality for the Grassmannian $\mathsf{Gr}(2, 6)$ gives the desired equivalence (see [25, 28]).

It turns out, however, that already for $d = 2$ the situation is more subtle. It seems that in that case the categories $\mathscr{B}_{Y_2}$ lie at the boundary of the family of categories $\mathscr{A}_{X_{10}}$. And for $d = 1$ the situation is completely unclear.

The situation with Fano 3-folds of index 1 and degree divisible by 4 is somewhat different. For such threefolds it is, in general, not clear how one can construct an exceptional pair. However, for $d_X = 12$ and $d_X = 16$ this is possible. For $d_X = 12$ Mukai has proved [43] that there is an exceptional pair $(\mathcal{E}_5, \mathcal{O}_X)$ where $\mathcal{E}_5$ is a rank 5 exceptional bundle with $c_1(\mathcal{E}_5) = 2K_X$. Using HP duality for the spinor variety $\mathbb{S}_5$ (Theorem 5.5) one can check that this pair extends to a semiorthogonal decomposition

$$\mathbf{D}^b(\mathsf{coh}(X_{12})) = \langle \mathbf{D}^b(\mathsf{coh}(C_7)), \mathcal{E}_5, \mathcal{O}_{X_{12}} \rangle,$$

where C_7 is a smooth curve of genus 7 (see [26, 27]). Analogously, for $d_X = 16$ Mukai has constructed [43] an exceptional bundle $\mathcal{E}_3$ of rank 3 with $c_1(\mathcal{E}_3) = K_X$. Using HP duality for $\mathsf{LGr}(3, 6)$ (Theorem 5.7) one can check that there is a semiorthogonal decomposition

$$\mathbf{D}^b(\mathsf{coh}(X_{16})) = \langle \mathbf{D}^b(\mathsf{coh}(C_3)), \mathcal{E}_3, \mathcal{O}_{X_{16}} \rangle,$$

where C_3 is a smooth curve of genus 3 [27].

6.4. Fourfolds. Of course, for Fano 4-folds we know much less than for 3-folds. So, we will not even try to pursue a classification, but will restrict attention to some very special cases of interest.

Maybe one of the most interesting 4-folds is the cubic 4-fold. One of its salient features is the hyperkähler structure on the Fano scheme of lines, which turns out to be a deformation of the second Hilbert scheme of a K3 surface. This phenomenon has a nice explanation from the derived categories point of view.

Theorem 6.2 ([36]). *Let $Y \subset \mathbb{P}^5$ be a cubic 4-fold. Then there is a semiorthogonal decomposition*

$$\mathbf{D}^b(\mathsf{coh}(Y)) = \langle \mathscr{A}_Y, \mathcal{O}_Y, \mathcal{O}_Y(1), \mathcal{O}_Y(2) \rangle,$$

and its nontrivial component $\mathscr{A}_Y$ is a Calabi–Yau category of dimension 2. Moreover, the category $\mathscr{A}_Y$ is equivalent to the derived category of coherent sheaves on a K3 surface, at least if Y is a Pfaffian cubic 4-fold, or if Y contains a plane Π and a 2-cycle Z such that $\deg Z + Z \cdot \Pi \equiv 1 \bmod 2$.

To establish this result for Pfaffian cubics one can use HP duality for $\mathsf{Gr}(2, 6)$. The associated K3 is then a linear section of this Grassmannian. For cubics with a plane a quadratic bundle formula for the projection of Y from the plane Π gives the result. The K3 surface then is the double covering of $\mathbb{P}^2$ ramified in a sextic curve, and the cycle Z gives a splitting of the requisite Azumaya algebra on this K3.

For generic Y the category $\mathscr{A}_Y$ can be thought of as the derived category of coherent sheaves on a noncommutative K3 surface. Therefore, any smooth moduli space of objects in $\mathscr{A}_Y$ should be hyperkähler, and the Fano scheme of lines can be realized in this way, see [40].

The fact that a cubic 4-fold has something in common with a K3 surface can be easily seen from its Hodge diamond. In fact, the Hodge diamond of Y is

$$\begin{array}{ccccccccccc}
 & & & & 1 & & & & & & \\
 & & & 0 & & 0 & & & & & \\
 & & 0 & & 1 & & 0 & & & & \\
 & 0 & & 0 & & 0 & & 0 & & & \\
0 & & 1 & & 21 & & 1 & & 0 & & \\
 & 0 & & 0 & & 0 & & 0 & & & \\
 & & 0 & & 1 & & 0 & & & & \\
 & & & 0 & & 0 & & & & & \\
 & & & & 1 & & & & & &
\end{array}$$

and one sees immediately the Hodge diamond of a K3 surface in the primitive part of the cohomology of Y. There are some other 4-dimensional Fano varieties with a similar Hodge diamond. The simplest example is the 4-fold of degree 10 in $\mathsf{Gr}(2,5)$ (an intersection of $\mathsf{Gr}(2,5)$ with a hyperplane and a quadric in $\mathbb{P}^9$). Its Hodge diamond is

$$\begin{array}{ccccccccccc}
 & & & & 1 & & & & & & \\
 & & & 0 & & 0 & & & & & \\
 & & 0 & & 1 & & 0 & & & & \\
 & 0 & & 0 & & 0 & & 0 & & & \\
0 & & 1 & & 22 & & 1 & & 0 & & \\
 & 0 & & 0 & & 0 & & 0 & & & \\
 & & 0 & & 1 & & 0 & & & & \\
 & & & 0 & & 0 & & & & & \\
 & & & & 1 & & & & & &
\end{array}$$

and again its primitive part has K3 type. On a categorical level this follows from the following result

Theorem 6.3 ([35]). *Let X be a smooth projective variety of index m with a rectangular Lefschetz decomposition*

$$\mathbf{D}^b(\mathsf{coh}(X)) = \langle \mathscr{B}, \mathscr{B}(1), \dots, \mathscr{B}(m-1) \rangle$$

of length m. Let Y_d be the smooth zero locus of a global section of the line bundle $\mathcal{O}_X(d)$ for $1 \le d \le m$. Then there is a semiorthogonal decomposition

$$\mathbf{D}^b(\mathsf{coh}(Y_d)) = \langle \mathscr{A}_{Y_d}, \mathscr{B}, \mathscr{B}(1), \dots, \mathscr{B}(m-d-1) \rangle$$

and moreover, a power of the Serre functor $\mathbf{S}_{\mathscr{A}_{Y_d}}$ is isomorphic to a shift

$$(\mathbf{S}_{\mathscr{A}_{Y_d}})^{d/c} = \left[\frac{d \cdot (\dim X + 1) - 2m}{c} \right], \qquad \text{where } c = \gcd(d, m). \tag{6.3}$$

In particular, if d divides m then the component $\mathscr{A}_{Y_d}$ is a Calabi–Yau category of dimension $\dim X + 1 - 2m/d$.

Remark 6.4. Analogously, one can consider a double covering $Y'_d \to X$ ramified in a zero locus of a global section of the line bundle $\mathcal{O}_X(2d)$ instead. Then there is an analogous semiorthogonal decomposition and the Serre functor has the property
